***Abstract*—Digital Microfluidic Biochip (DMFB) is a ground-breaking invention in many areas of Microelectronics, Biochemistry, and Biomedical sciences. It is also known as 'Lab-on-a-Chip' for its performance as an alternative for laboratory experiments. Various types of diagnosis procedures are performed on it through a sequence of modular operations like sample preparation, mixing, and detection. Mixing is the most important operation of DMFB as the outcome of the experiment is almost dominated by mixing. A good mixing of corresponding sample and reagent gives proper result while an improper mixing leads to erroneous result, which may be the reason to discard the assay. So, our objective is the betterment of mixing operation. In this paper, we have proposed a design using equilateral triangular electrodes instead of square electrodes, maintaining all the constraints required to ensure safe droplet movement and other modular operations, while improvement of the mixing operation is the key design issue.**

Keywords: ***Digital microfluidics; Electrowetting on dielectric; Square electrodes; Triangular electrodes; Mixing; Detection; Assay; Principal diagonal.***

I. Introduction

Microfluidics based biochips combine Electronics with Biology, which open new application areas. These are used for different clinical diagnosis, massive parallel DNA sequencing, automated drug discovery, and real time bio-molecular recognition. Digital microfluidic biochip, which is a popular biomedical analytic instrument now-a-days, is based on Electro-Wetting-on-Dielectric (EWOD) theory [3]. Here discrete droplet of nanoliter volume can be moved on over the patterned array of electrodes. Due to dynamic reconfigurability, different types of operations like mixing, storing, etc. can be done in the same set of microfluidic cells in different time span. Discrete droplets can move through the electrodes under clock pulse in *digital manner*; hence the term *digital microfluidics* comes into picture. This approach exhibits dynamic reconfigurability, by which without affecting the functionality, the droplets can be relocated on other places of the array, consists of square electrodes [1,2].

In this paper we have proposed a design using equilateral triangular electrodes instead of square electrodes, maintaining all the constraints required to ensure safe droplet movement and other modular operations. This may be regarded as a technological shift where mixing operation is better performed than a set of square electrodes due to more zigzag path that enhances the scope and quality of mixing. As mixing is the most prior operation in case of diagnostic use of biochip, this is undoubtedly an improvised design procedure.

II. Preliminaries and Inherent Constraints

In this section, we briefly discuss on the working principle of DMFB, microfluidic architectural choice, droplet type, and the modular operations in the context of square electrodes. Electrowetting on dielectric is the phenomenon where electric field modifies the wetting characteristic of a polarizable and/or conductive liquid droplet in contact with a hydrophobic, insulated electrode [1,2,3]. According to the Lippmann-Young equation, the electric field generated due to the voltage gradient reduces the interfacial tension between the liquid and the surface, hence can manipulate the droplets [3]. Again droplets are sandwiched between two parallel plates, where the bottom is the chip surface holding the electrode array and the top is the continuous ground plate. The upper plate contains the continuous ground electrode of transparent, conductive indium tin oxide (ITO). Intermediate gap is filled with silicon fluid preventing droplet evaporation as well as reducing the contamination on the surface due to the use of various types of biological samples. The top and bottom surfaces are covered by a thin hydrophobic film, made by Teflon AF. This reduces the wet ability of a surface and improves the capacitance between the droplets and the solid electrodes [1,2,3].

Some basic definitions have been stated in the existing articles that comprise droplet formation, routing, mixing, and detection in the context of DMFB.

Droplet formation is a process of making droplet of a desired size from a source (of larger volume) of the material (sample or reagent or wash droplet) we like to dispose into the array perpendicularly by activation and deactivation of adjacent electrodes [1,2].

A *routing path* is the passageway that a droplet uses for its movement following adjacent cells of an array through a synchronized activation and deactivation of the electrodes [1,2,5].

A *mixer* is a module in an array where the most important task of mixing happens. Here different

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

sample(s) and reagent(s) come from their respective sources and mix for detection. This operation takes a maximum amount of time needed for an assay. A mixer can also be used for splitting of a droplet or dilute a sample droplet. A typical mixer takes 1000-2000 clock cycles [1,3,4].

Detection site is a small module usually formed by a single cell in the array that helps to detect the parameters present in a sample from its mixed droplet. Usually, the number of detection sites is not many (as it is a costly module) and their locations are also tentatively fixed [1,3].

An *assay* is a whole operation that includes creation of droplets, their routing, mixing, and detection (of a sample's state). We usually deploy an array of electrodes that are activated and deactivated in a preferred synchronized fashion, and all subsequent steps of an assay are tracked to meet the objective(s) affirmed by the assay [1].

Though we are supposed to satisfy all the constraints in isolation, maintaining all the constraints for some bioassay may introduce the problem of *cross contamination* [4]. This problem tells that an overlapping region may occur for two routing paths of two different droplets that are not supposed to mix.

Constraints in Performing Bioassay Operations:

A bioassay operation involves routing, mixing, detecting some parameters present in a sample, and many others. Naturally, some problem related constraints are there; some of which are fluidic constraint, electrode constraint, time constraint, and area constraint, as follows.

Fluidic constraint: During droplet routing, in static condition, at least one cell is supposed to be kept in between two electrodes containing two droplets to prevent unintended mixing. During movement of droplets following a particular direction, we may observe that at least a gap to two electrodes is must to avoid unwanted mixing. Hence static and dynamic fluidic constraints are introduced, as these are necessary for a pair of droplets for their minimum separation on a bioassay [4,6].

Electrode constraint: In case of pin constrained design, more than one electrode is controlled by a single pin. This may introduce unwanted effect of voltage on some electrodes, this imposes several constraints during routing. If we can make proper voltage assignment over the pins, correct movement of droplets can be guaranteed [1,2,5].

Timing constraint: Timing constraint in droplet routing is given by an upper bound on droplet transportation time. It is defined to have the proper synchronization among all the bioassay operations held in different modules [1,5].

Area constraint: In order to perform all the bioassays in a minimum chip area in view of all the abovementioned constraints, area constraints are introduced. A mixing region is supposed to be located in a proper position for utilization of total array area. So a design must support how capably a chip of some fixed area can be utilized [1].

III. Problem Formulation and Proposed Design

In this section we propose the design of equilateral triangular electrodes as well as we demonstrate droplet position, movement, and modification of fluidic constraint due to this replacement.

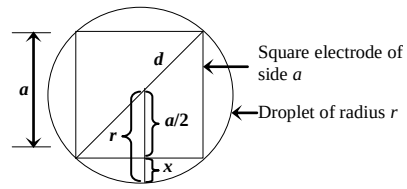

Fig. 1: Top view of a droplet placed on a charged square electrode.

A droplet moves from one electrode to the next due to the gradient of electrostatic force when the electrodes are deactivated and activated serially. To maintain the voltage level constant while shifting from square to triangular electrode, we consider the overlapped region of a droplet over its immediate neighbours where the droplet may move in one clock pulse, is fixed. Hence we achieve a relation between the sides of a triangular electrode with that of a square electrode, while keeping the side of the square electrode as the reference. Fig. 1 depicts the top view of a droplet of radius r placed on a charged square electrode. The portion (here we consider the part of the radius which is out of the electrode) of droplet outside the square is denoted by x, as shown in Fig. 1.

A. Calculation of the value of x:

Let the diagonal of the square = d and the side of the square = a. Hence, $d = \sqrt{2}a$, and the radius of the droplet (r) = $d/2 = a/\sqrt{2}$. Now, $a/2 + x = r = a/\sqrt{2}$; so, $x = 0.207a$. Here we consider the following two assumptions:

i) The volume of the droplet which we keep on a square electrode is same for a triangular electrode.
ii) The portion of the droplet beyond the side of a square electrode is same for the equilateral triangular electrode as well.

Satisfying the above assumptions, we next calculate the side of an equilateral triangular electrode which is most fitted for holding a droplet of radius r while the electrode is charged.

B. The side of the equilateral triangular electrode:

Let, the radius of the droplet which is kept on the equilateral triangle be r_1. From Fig. 2, $r_1 = (1/3)h + x$, where h is the height of the triangle. Now, $h = (\sqrt{3}/2)y$, where y is the side of the equilateral triangle. Therefore, $r_1 = (1/3)\times(\sqrt{3}/2)\times y + 0.207a = y/(2\sqrt{3}) + 0.207a$.

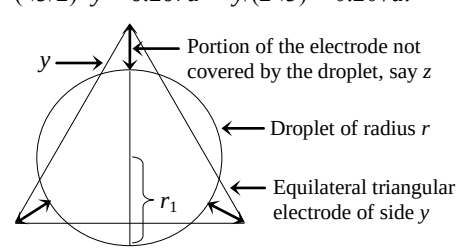

Fig. 2: Top view of a droplet placed on a charged equilateral triangular electrode.

As the volume of the droplet is same, keeping on both square and equilateral triangular electrode, the radii must be same for the above two cases. So, radius of the droplet on the equilateral triangular electrode (r_1) = radius of the

droplet on the square electrode (r). So, $a/\sqrt{2} = y/(2\sqrt{3}) + 0.207a$, and $y = 1.73a = \sqrt{3}a$. Hence, $y > a$, i.e., the length of one side of an equilateral triangular electrode is greater than the side of a square electrode. From Fig. 2, we can say that, $(2/3)h$ = radius of the droplet + length beyond the droplet up to a vertex of the triangular electrode (say z).

Hence, $(2/3)\times(\sqrt{3}/2)\times(\sqrt{3}a) = (a/\sqrt{2}) + z$ (putting the value of h), and $z = 0.3a$, where a is the length of a side of the square electrode.

The path of movement of the droplet through the triangular electrodes is *zigzag*, because the center of masses of two horizontally consecutive equilateral triangles are not at the same horizontal line, whereas this path is straight for the square electrodes, for the location of their center of masses at the same horizontal and vertical lines. Again the gap between two square electrodes is kept $a/2$ [1]. If the gap is greater than $a/2$, then two droplets can stay on two adjacent square electrodes (obviously in absence of voltage). This violates the fluidic constraints of droplet transportation on microfluidic biochip. If the gap is less than $a/2$, then there is a chance of unintentional mixing of two droplets on two adjacent square electrodes. We are to keep this value constant for triangular electrodes as well, as our objective is to provide the same voltage source as for the square electrodes, i.e., we consider the least gap between two triangular electrodes same as $a/2$.

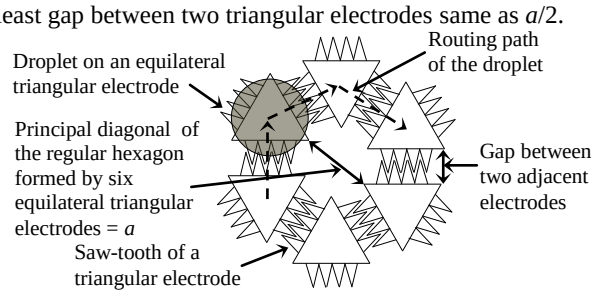

Fig. 3: Top view of a droplet on an equilateral triangular electrode. Here saw-teeth of adjacent electrodes are not short circuited.

The junction of four square electrodes forms a square of side $a/2$. Hence, the length of principal diagonal of the square formed by four adjacent square electrodes is therefore $a/\sqrt{2}$, whereas the junction of six equilateral triangular electrodes forms a regular hexagon of side $a/2$. So, the length of the principal diagonal = 2×(length of a side of the regular hexagon) = $2\times(a/2) = a$.

C. Fluidic constraints for triangular electrodes:

Throughout the droplet routing, a minimum spacing between droplets must be maintained to prevent the unintentional mixing, except the requirement of merging of droplets. Fig. 3 sows the top view of equilateral triangular electrodes with saw-teeth, holding one droplet, and the movement of droplet from one electrode to another electrode. For multiple droplet routes, droplet may intersect or overlap with each other. Hence, fluidic constraint rules are to be introduced to avoid the unintentional behaviour. At first we consider two droplets D_i and D_j. To avoid unintentional mixing, it is assumed that their initial locations at time t should not directly or diagonally adjacent to each other.

Let us represent the microfluidic array by 2D co-ordinate (X, Y). At time t, location of D_i is represented by $X_i(t)$ and $Y_i(t)$. We discuss the fluidic constraints for triangular electrodes in two phases, one for X-coordinate, and other for Y-coordinate.

Fluidic Constraints along *X*-Coordinate: This can be categorized into two parts: (a) Static fluidic constraints and (b) Dynamic fluidic constraints.

(a) Static Fluidic Constraints:

Rule 1: $|X_i(t) - X_j(t)| \geq 2$. So, the minimum spacing between two droplets at time t, on same horizontal row is at least two (i.e., two electrodes). Here in Fig. 4(a), $D_i(t)$ and $D_j(t)$ are on electrodes 1 and 3, respectively. To avoid unintentional mixing, the minimum spacing between them must be of two electrodes.

Rule 2: $|X_i(t+1) - X_j(t+1)| \geq 2$. At time t+1, the minimum difference between the X-coordinate of D_i and D_j must be two, such that D_i and D_j are not adjacent to each other. Here in Fig. 4(b), at time t+1, D_i goes from electrode 1 to electrode 2, and at the same time D_j moves from electrode 5 to electrode 4. So, the gap between the new locations of the two droplets at time t+1 is of two electrodes.

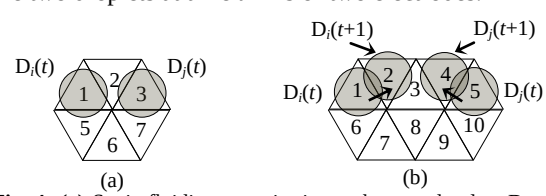

Fig. 4: (a) Static fluidic constraint is met by two droplets D_i and D_j along X-axis at time t. **(b)** Static fluidic constraint is met by two droplets D_i and D_j along X-axis at time t+1.

(b) Dynamic Fluidic Constraints:

Rule 3: $|X_i(t+1) - X_j(t)| \geq 2$. The least distance along X-coordinate for D_i at time t+1 and D_j at time t must be two, to avoid unwanted mixing. Similarly, $|X_i(t) - X_j(t+1)| \geq 2$ is also true. So, finally we can conclude that the minimum separation between two droplets situated in the same horizontal row is of two electrodes in both static and dynamic cases.

Fluidic Constraints along *Y*-Coordinate: Now we are concerned about the Y-coordinate of the droplets D_i and D_j. In the array of the equilateral triangular electrodes we notice that there are two types of triangular electrode as shown in Fig. 5.

If a droplet is placed on a *Type 1* electrode, then for this type of electrode the movement of droplet to the upward direction is restricted as movement of a droplet is only possible to the electrodes that are adjacent through an edge of the triangle. Similarly, if a droplet is placed on a *Type 2* electrode, then the movement of the droplet is restricted to the downward direction for the same reason. Again, according to the calculation of principal diagonal of the inter-electrode gap, which is hexagonal in shape, we know that there is a safe distance between a *Type 1* (*2*) electrode and the electrode just above (below) it. Hence, we may conclude that these two droplets may safely be kept in these two electrodes as they are not adjacent to each other with respect to fluidic constraints.

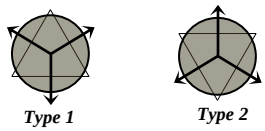

Fig. 5: Two types of electrode with droplet movement directions.

(a) Static Fluidic Constraints:

Rule 1: $Y_i(t)-Y_j(t) \geq 2$, if D_i is on a *Type 1* electrode, else $Y_i(t)-Y_j(t) \geq 1$, if D_i is on a *Type 2* electrode, where D_i is the droplet that has been considered to have higher *Y*-coordinate than the other. So, the least distance between the *Y*-coordinates of D_i and D_j depends on the position of the droplets. Here, in Fig. 6(a), D_i and D_j are on electrodes 7 and 11, respectively, keeping their safe separation.

Rule 2: At time t+1, Rule 1 must be maintained again depending on the relative positions of the droplets. In Fig. 6(b), at time t+1, D_i may go from electrode 7 to 6, and at the same time D_j may move from electrode 11 to 10. So the difference between the new locations of these two droplets at time t+1 is one electrode, disobeying the fluidic constraint; this often may lead to unintentional mixing.

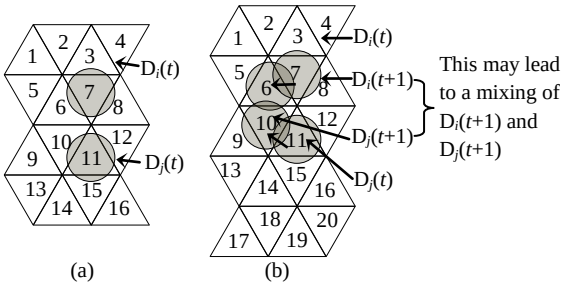

Fig. 6: (a) Static fluidic constraint is met by two droplets D_i and D_j along *Y*-axis at time *t*. **(b)** Static fluidic constraint is met by two droplets D_i and D_j along *Y*-axis at time t+1.

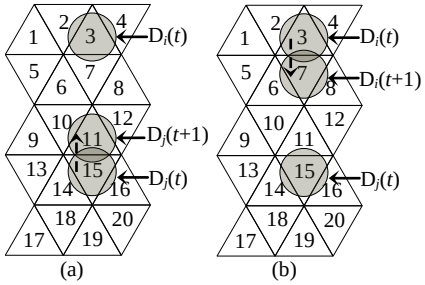

Fig. 7: (a) and **(b)** Dynamic fluidic constraints along *Y*-axis is met by two droplets D_i and D_j.

Table I: Table of comparison between square and triangular electrodes.

Type of electrode	Square electrode	Triangular electrode
Length of one side	a	$1.732a$
Overlapping length	$0.207a$	$0.207a$
Length of the principal diagonal	$a/\sqrt{2}$	a
Gap between two consecutive electrodes	$a/2$	$a/2$
Number of direct neighbours	4	3
Path measured between two electrodes	Manhattan distance	Number of electrodes passed by a droplet
Area of electrode	a^2	$1/2\times(3/2)a\times(\sqrt{3}a)=3\sqrt{3}a^2/4$

(b) Dynamic Fluidic Constraints:

Rule 3: Throughout the movement of one or more droplets, the static fluidic constraints at time t and t+1 are to be considered simultaneously that also satisfy the dynamic fluidic constraints as well, as shown in Fig. 7.

Table I shows a comparative study between a square and a triangular electrode citing some variables that are the most important issues to be considered in designing a chip.

VI. Applications and Importance

Digital microfluidic biochip is a revolutionary invention in modern science due to its versatile utilizations as well as reduced cost. It can perform enzymatic analysis (e.g., glucose and lactate assays), DNA analysis (e.g., PCR and nucleic acid sequence analysis), toxicity monitoring, and several biomedical and biochemical testing efficiently, which are of ultimate importance now-a-days. Droplet speed is high (up to 25 cm/sec for square electrodes) that makes the time of routing negligible. DMFB is of utmost importance as most of the electrolyte solutions work as biological samples or reagents that are utilized without any loss. DMFB is extremely energy efficient as it needs nanowatts or microwatts amount of power per movement of droplets. Among all the modular operations, the importance of mixing procedure is dominating, as it is the key of proper result of an assay performed on a biochip. A good mixing of sample and reagent offers desired result while an improper mixing leads to discard the whole assay. Triangular electrodes offer betterment in mixing as the accumulated droplets of samples and reagents are moved through a zigzag path and the scope of diffusion between the droplets is higher than moving through a straight path as happens in the case of square electrodes.

VI. Conclusion

In this paper, we have introduced a new design of digital microfluidic biochip which is a better alternative over square electrodes. In case of triangular electrodes, as the centers of the electrodes follow a zigzag path, hence the mixing operation becomes better, and as result we may consider it as a successful shift to a new design concept. The pin constrained design may be planned in a better way such that the number of pins is reduced than that of a chip containing square electrodes, which may decrease the required voltage making the chip more power efficient.

*Email: fkchwdhr@memphis.edu

Abstract— **Tractography is a non-invasive process for reconstruction, modelling and visualization of neural fibers in the white matter (WM) of the human brain. It has emerged as a major breakthrough for neuroscience research due to its usefulness in clinical applications. In this research, we have investigated deterministic and probabilistic tractography approaches. We have evaluated the performance of different approaches on fiber bundle tracking using diffusion tensor imaging (DTI) data having multiple gradient directions. Experimental results show that global tractography is best for reconstruction of kissing and crossing fibers compared to deterministic tractography. We have also shown that DTI acquisition with a higher number of gradient directions provides better tracking results given limitations of acquisition and computation time.**

Index Terms— **Tractography, diffusion tensor imaging, white matter, gradient directions.**

I. INTRODUCTION

Diffusion tensor imaging (DTI) based tractography has been given much attention in recently due to its applications in several medical fields such as patients with acute stroke or brain tumors, neurodegenerative disorders including multiple sclerosis (hardening or thickening of tissue), epilepsy, Alzheimer disease, autism, and movement disorders [3]. DTI enables visualization and characterization of white matter fascicles in two and three dimensions. In general, it measures the displacement of water molecules on the micron scale and yields information about white matter (WM) fibers that pass within a voxel. Water molecules contain hydrogen nuclei (protons), which become aligned in a magnetic field. Motion or diffusion of water molecules is found to be much faster along the WM fibers than perpendicular to them [2]. The difference between the two motions (parallel and perpendicular to fibers, also termed diffusion anisotropy) is the basis of DTI.

DTI gradient directions are the list of vectors that describe the diffusion weighting directions for DTI acquisition on a MRI scanner. To observe the diffusion in all direction, many diffusion weighted images with diffusion weighting gradients are acquired in different directions. From these diffusion-weighted images, a 3D description of the direction for the diffusion of water within a voxel is inferred. Diffusion is anisotropic in nature and an ellipsoid is used to represent diffusion directions. These directions of water diffusion are tracked in DTI based tractography. Two different approaches to tractography [1] are considered in this research: deterministic and probabilistic. In deterministic tractography, the reconstruction of long neuronal pathways occurs in small successive steps by following the local direction of the fiber in a given voxel. This method is computationally efficient but minor errors in the determination of a local step may significantly affect the final path, making the method unstable. More recently, probabilistic approaches are predominant among tractography methods. Global tractography is a probabilistic approach. The global methods [8] try to reconstruct the fiber paths simultaneously while finding the configuration that minimizes the difference between the measured data and the reconstruction. This tracking is more stable in the presence of noise and imaging artifacts in the data.

In this research, we have compared the performances of deterministic and global tractography based on the simulation using various gradient directions data. We investigate the reconstruction performance considering crossing and kissing fibers and the effects of multi-gradient direction data. The background is discussed in section 2. Section 3 presents the description of the data sets. Methodology, experimental results, and the conclusion are discussed in sections 4, 5 and 6 respectively.

II. BACKGROUND

The development of magnetic resonance imaging (MRI) has led to the design of numerous imaging techniques. Among them DTI assesses white matter changes in the patients that are not normally seen on conventional MRI.

The relationship between the signal intensity of the diffusion weighted images S, diffusion sensitizing field gradient based on Stejeskal Tanner spin echo scheme and the signal value S_0 without the gradient is given in (1):

$$S = S_0 e^{-\gamma^2 G^2 \delta^2 (\Delta - \frac{\delta}{3}) D_{app}} \tag{1}$$

where γ is the gyromagnetic ratio of proton, δ and G represent the duration and the magnitude of the motion probing (or diffusion sensitizing field) gradient, Δ is the time between the centers of the pair of gradient pulses, and D_{app} is a scalar value called the apparent diffusion coefficient (ADC) which reflects molecular diffusivity under motion restriction such as fluid viscosity.

In DTI, the diffusion coefficient is a 3 ×3 symmetric positive semi-definite matrix as shown in (2).

$$\mathbf{D} = \begin{matrix} D_{xx} & D_{xy} & D_{xz} \\ D_{xy} & D_{yy} & D_{yz} \\ D_{xz} & D_{yz} & D_{zz} \end{matrix} \tag{2}$$

The largest eigenvector of the diffusion tensor as shown in Fig. 1 is assumed to be oriented parallel to the local fiber

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

tracts, which can be reconstructed in a brain dataset by following paths in the estimated eigenvector field.

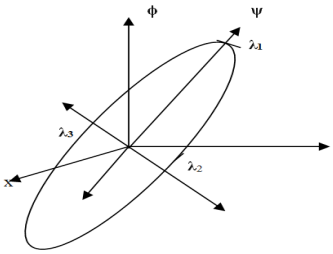

Fig. 1 Diffusion tensor represented by an ellipsoid ($\lambda_1 \geq \lambda_2 \geq \lambda_3$)

One of the most important factors in DTI acquisition is gradient direction. At least 6 gradient directions are required to calculate the diffusion tensor [4]. If gradient directions are increased, more diffusion weighted images are used to calculate the diffusion tensor, resulting in more accurate tensor estimation but much longer imaging time [7].

A long thin ellipsoid means very good diffusion for water along the long axis of that ellipsoid. The mean diffusivity (MD) and fractional anisotropy (FA) as shown in (3) and (4) respectively are the most widely used indices of DTI for representing the motional anisotropy of water molecules, being sensitive to the presence and integrity of WM fibers [11][12]. Color coded FA maps are the way to show the directional information embedded in DTI.

$$\mathrm{MD} = \frac{\lambda_1+\lambda_2+\lambda_3}{3} \tag{3}$$

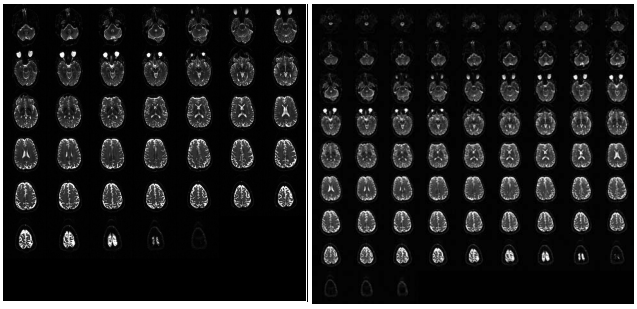
$$\mathrm{FA} = \sqrt{\frac{3}{2}} * \sqrt{\frac{(\lambda_1-D)^2+(\lambda_2-D)^2+(\lambda_3-D)^2}{\lambda_1^2+\lambda_2^2+\lambda_3^2}} \tag{4}$$

These indices help to detect brain diseases. For example, in case of pediatric multiple sclerosis, the value D increases and FA decreases compare to their normal value [9] [10].

Deterministic tractography methods are primarily based upon streamline algorithms where the local tract direction is defined by the major eigenvector of the diffusion tensor [1]. Crossing and kissing white matter tracts create a significant challenge for reconstruction. These limitations can be solved using global tractography.

III. DATA SETS

Data provided by St Jude children's research hospital was used for this research. They have diffusion MRI scanners of 1.5 and 3 Teslas. Samples of the DTI data sets provided are shown in Fig. 2.



(a) (b)
Fig. 2 Example data (a) 12 directions (b) 20 directions

We have conducted research on four data sets: (1) 12 gradient directions, 4 averages (40 slices and each 3 mm thick) (2) 20 gradient directions, 3 averages (75 slices and each 2 mm thick) (3) 30 gradient directions, 2 averages (70 slices and each 2 mm thick), and (4) 64 gradient directions, 2 averages (96 slices and each 1.7 mm thick).

IV. METHODOLOGY OF TRACTOGRAPHY

We have done the simulation for both deterministic and probabilistic tractography. There are various deterministic and probabilistic tracking techniques such as connect the voxel [13], Fiber Assignment by Continuous Tracking (FACT) [11], path- integral method [14], Gibbs tracking [5], spin glass model [15]. FACT and Gibbs tracking techniques have been considered for our simulation. Camino [16] and DTI & fiber tools [16] are used for simulation. The simulation procedure is discussed step by step in the following sections.

A. Pre-processing

For both of the tractography techniques, the first step in processing the data is ordering and sorting. In this step artifacts and the quality of data [6] are controlled. At first, we have to change the raw image format because medical imaging supports some specific image format. After that the data was pre-processed using several tools. Pre-processing involved artifact removal, skull stripping and reformatting.

B. Diffusion Tensor Calculation

Voxel based single and multi diffusion tensor models for the orientation distribution function (ODF) were fit to the data by Camino. After calculating FA and MD, we obtained the orientation distribution function (ODF) as shown in Fig. 3. It is used to describe the directionality of multimodal diffusion in regions with complex fiber architecture present in the brain. The maximum diffusivity is normalized to voxel size. The color indicates the direction of maximum diffusivity i.e. red means left to right, green indicates anterior-posterior and blue for superior-inferior. This step is also performed in Gibbs tracking tensor calculation but is done only for those pixels having signal intensity above the threshold value 40 in the average image.

C. Deterministic Tractography

The tractography process was done in three steps: region of interest (ROI) selection, track, and visualization [6]. ROI was selected using the ITK snap tool [16]. Corpus callosum (CC) is the largest white matter structure in brain that connects the left and right cerebral hemispheres. So selecting CC as a ROI will give the maximum number of fiber connections. Using the ROI, Camino tracked the fiber connections and the visualization is done by the Paraview tool.

D. Global Tractography

Gibbs tracking is a powerful global tractography method. This method includes three main steps [5]: (1) Creation of a trial fiber configuration, (2) Calculation of the corresponding DW signal (simulated signal), and (3) Adjustment of the trial configuration with the experimentally measured signal to minimize the difference.

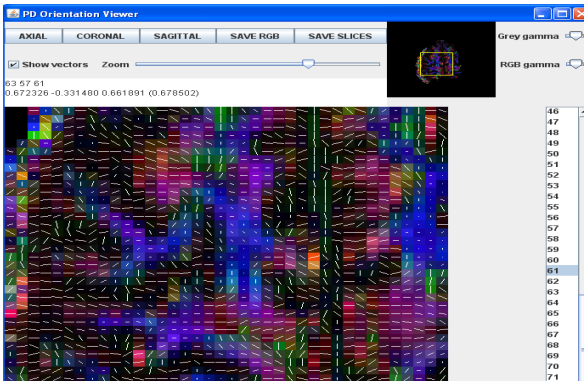


Fig. 3 Orientation distribution function of deterministic tractography.

The building elements of reconstructed fibers are small straight cylinders whose length, position and orientation can vary continuously. These cylinders are re-oriented through a process similar the distribution of states in the cooling of an ideal gas. The reconstruction begins at very high "temperature" where the cylinders are randomly distributed in the space occupied by the white matter as shown in Fig 4. The interaction between them results in building long fiber chains with decreasing temperatures. The neuronal fibers start and end on predefined surfaces, for example at the boundary with the grey matter. Each cylinder contributes a signal typical for parallel fibers to all voxels it crosses [5].

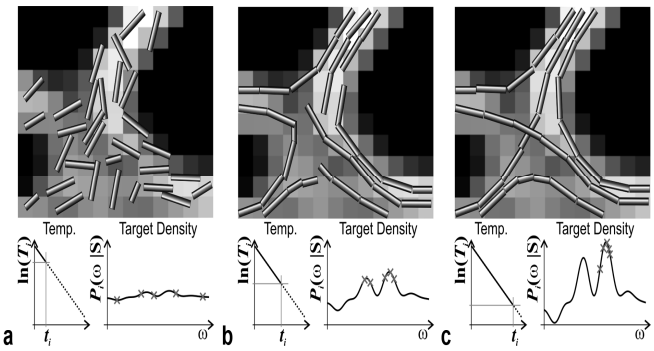

Fig. 4 Principle of Gibbs tracking method; (a) at high temperature (b) at lower temperature (c) temperatures close to zero. [5]

The sum of such contributions is the anisotropic part of the signal. This described method is known as the Gibbs Tracking [5], keeping in mind its close analogy to statistical physics. On the other hand, the described simulation can be considered as a Bayesian approach based on a spatial point processes. The interactions between the cylinders represent the a priori probability and the likelihood function represents the similarity of the measured signal and simulated signal.

Before the visualization step, the diffusion tensor images are provided with the tracking parameters. The tracking can be started by dense reconstruction that counts many fibers and takes in the range of 12-24 hours of computation or sparse reconstruction that shows fewer fibers and has reconstruction times around 1 hour.

After tracking completion, fibers are sent to a fiber viewer to show the fiber distribution of the whole brain, the spatial diffusion distribution, and the fiber distribution in a single slice.

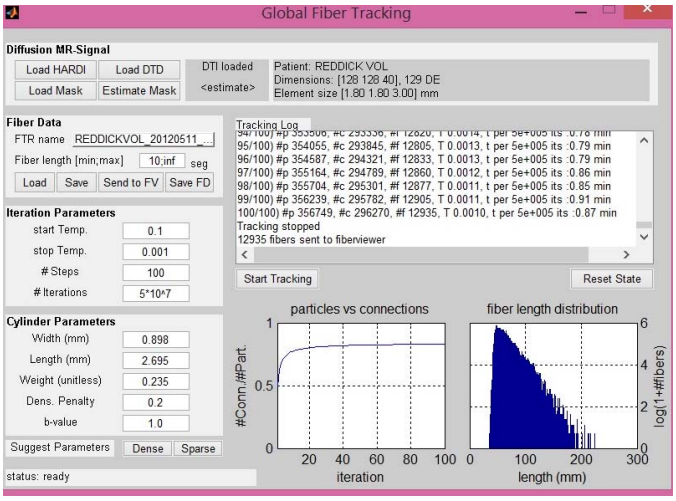

Fig. 5 Gibbs tracking of 12 D gradient directions using DTI & Fiber tools

V. EXPERIMENTAL RESULTS

We obtained the fiber trajectories after completing the deterministic and global tractography simulations. All the prepocessing and tensor calculation steps of simulation are run on an intel PC core i5, 1.8 GHz and 8 GB RAM with Windows 8™ as an operating system. Complete simulation of 12 directions data is possible on a laptop with the configuration as mentioned for prepocessing steps. Simulation of 20, 30 and 64 directions data sets are run on a high performance computing platform with 512 GB RAM.

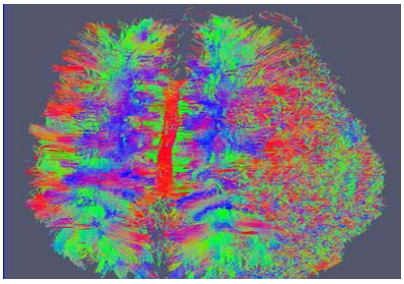

Fig. 6 Deterministic tractography

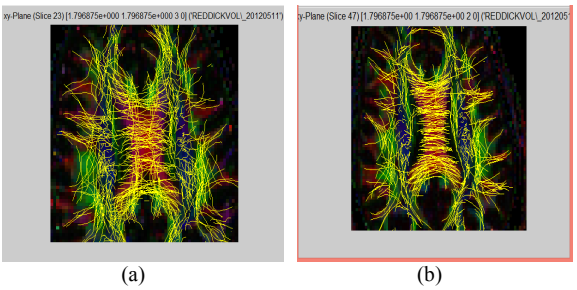
Visualization of fibers by deterministic tractography is shown in Fig. 6. A microscopic observation by an expert points out the limitation of this technique. The reconstruction does not work well where fiber crossing and kissing occur, though it takes only couple of hours for the simulation to execute. The tractography results for the Gibbs tracking method are shown in Fig. 7 and 8.

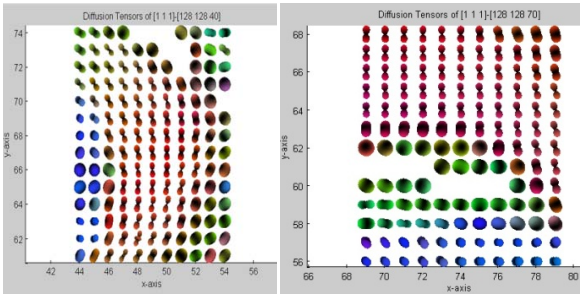
Fig. 7 Fiber tract for 20 D



(a) (b)

Fig. 8 Fiber cut (a) 12 D (b) 20 D

Fiber tract shows a projection of the complete actual fiber subset and fiber cut indicates the curve segments inside the actual slice of the current fiber structure subset. Spatial diffusion distribution represents diffusivity of the tensor in a particular position or region of interest as an ellipsoid as shown in Fig. 9. The maximal diffusivity is normalized to the voxel size. The color indicates the direction of diffusivity of the spatial distribution inside the current voxel.



(a) (b)

Fig. 9 Spatial distribution Red: left to right; Green: Anterior- posterior; Blue: Superior to inferior (a) 12 D (b) 30 D

For different positions or slices, we get different FA and MD values. The value of FA is normalized from 0 to 1. FA close to 0 indicates isotropic diffusion and anisotropic nature increases as FA values tend to 1. Here we have taken positions near to corpus callosum for different gradient directions and their corresponding FA and MD values are shown in Table 1.

TABLE I
COMPARISON OF FA AND MD VALUES FOR DIFFERENT GRADIENT DIRECTIONS

Gradient directions	Position	FA	MD
12 D	[67 68 23]	8.376×10^{-1}	6.730×10^{-4}
20 D	[66 70 47]	8.269×10^{-1}	6.686×10^{-4}
30 D	[67 69 43]	8.184×10^{-1}	6.604×10^{-4}
64 D	[67 64 47]	8.456×10^{-1}	6.292×10^{-4}

TABLE II
NUMBER OF FIBERS VS GRADIENT DIRECTIONS.

Gradient directions	Reconstruction process	Number of fibers	Time (Hours)
12 D	Sparse	12935	0:26
	Dense	80165	10:25
20 D	Sparse	13527	0.30
	Dense	83454	11:35
30 D	Sparse	13457	0:35
	Dense	88835	12:45
64 D	Sparse	14597	0:42
	Dense	99491	14:18

Tracking is started by selecting the required parameters like cylinder parameters, starting and ending temperature etc. An example of parameter sets for sparse reconstruction is provided in Fig. 5. In dense reconstruction, the weight of the cylinder was set to a low value e.g. 0.059. It can produce more fibers compared to the sparse process though it takes long computation time. Table 2 shows how the number fibers found are increased with an increase in gradient directions.

VI. CONCLUSION

Diffusion tensor imaging is a powerful tool for the visualization of white matter structures. Although deterministic approaches are computationally efficient, they have some limitations which can be overcome by global tractography. The characteristic features of the traced neural fiber networks, such as structure, topology, and connectivity, can serve as biomarkers for various dementias and brain diseases, and can be used in various clinical applications. It is shown that gradient directions have positive effect on tracking though the time requirement introduces artifacts in the data due to patient motion which limits the clinical application. There should be a trade off between the number of gradient directions and the specific clinical application. Developing a tractography algorithm to overcome difficulties associated with the current techniques is a topic of our future research.

ACKNOWLEDGMENT

We are grateful to Dr. Gene Reddick from St. Jude Children's reasearch hospital for the dataset, continuous support and comments on results.

Abstract— **The focus of this work was to develop a 3D mapping of brain tumor (glioma) growth based on cell proliferation and diffusion. In this mathematical model, we incorporated high resolution brain tissue maps (white and gray matter) from an anonymized pediatric patient and initialized the model with a single voxel seed point of tumor with a Gaussian distribution. We used this model to investigate the ratio of growth rate to the diffusion coefficient (ρ/D) which determines the proportion of tumor that is detectable. After expansion of the tumor growth model to three dimensions and solving the differential equations for our specific starting conditions, we performed several simulations to assess tumor growth patterns. After observing the performance of the model at varying time points across a one year time frame with different values for ρ/D, we ascertained that the tumor diffused more rapidly than the cell proliferated for a short period of time followed by an exponential growth in detectable tumor size.**

Index Terms—**Proliferation, Diffusion, Tumor.**

I. Introduction

Glioma are major intracranial tumors that constitute more than 50% of all primary brain tumors and are one of the major causes of morbidity and mortality in the world [1]. They are thought to arise from the supporting glial cells of brain that have lost or ceased to respond to normal growth regulatory mechanism, presumably through mutations and/or altered gene expression. One of the fundamental problems in treating glioma is their highly diffusive and infiltrative nature that makes it difficult to differentiate between healthy brain tissue and the tumor boundary as seen in various conventional imaging modalities [2]. In the tumor mass model [3], it is shown that tumor growth follows the 'universal' growth law curve which is exponential in nature. The basic rate of tumor growth can be calculated by deducting the tumor cell death from the rate of tumor cell birth [4]. A tumor growth model is proposed based on diffusion and cell proliferation [5].

Our hypothesis is that 3D diffusion mapping will provide a more sensitive method to better delineate tumor growth patterns by focusing on the extent of tumor invasiveness. The focus of our work is to develop a 3D mapping of brain tumor (glioma) growth based on cell proliferation and diffusion. The universal growth curve [3] gives us the idea for using exponential growth in our 3D model. The 3D growth model of PK Burgess et al. [6] incorporates tumor radius. A radius is defined there at which the glioma is usually fatal and then ρ and D are investigated as indicators of how long it may take the tumor to reach this critical radius. But actual tissue segmentation has not been used here for the image sets. Uniform diffusion properties have been assumed. The situation after the tumor has destroyed the underlying neuroanatomical structure has been observed but it has not been defined if it is in gray or white matter. However, in our 3D model, we have defined human brain as inhomogeneous considering two types of diffusion coefficients in gray and white matter. Also, we have considered a specific tumor cell density as a threshold of detection for MR images.

II. Method

We propose a 3D brain tumor growth model based on cell proliferation and diffusion that incorporates actual tissue mapping of white and gray matter from a pediatric subject. The tumor seed is assumed to be a Gaussian distribution with a mean of zero and a standard deviation of one (measured in millimetres). We begin by checking the performance of the model in 1D.

A. The Mathematical Model

Original works from Burgess et al. [6] Cruywagen et al. [7], Tracqui et al. [8] and Woodward et al. [9] develop a mathematical model of glioma growth based solely on cell proliferation and diffusion.

$$\frac{dc}{dt} = \nabla.(D\nabla c) + \rho c \qquad (1)$$

where $c(x,t)$ is the number of cells, ρ (1/day) represents the net rate of growth of cells including proliferation and death (or loss), D (mm^2/day) is the diffusion coefficient of cells in brain tissue and ∇ represents the spatial gradient.

The diffusion term describes the active migration of the glioma cells using a simple Fickian diffusion where cells move from regions of higher to lower densities.

We propose to solve equation (1) through equations (2) and (3).

$$\frac{dc}{dt} = D\nabla^2 c + \rho c \qquad (2)$$

$$c = T(t)R(x,y,z) \qquad (3)$$

First, we assume that diffusion D is homogeneous in each region and c is the number of cells which is a function of time $T(t)$ and position $R(x,y,z)$.

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

The 3D model is developed as follows.

$$c(x,y,z,t) = c_0 \frac{1}{\Pi^{3/2} G^3} . e^{-\frac{x^2+y^2+z^2}{G^2}} . e^{\rho t} \quad (4)$$

where c_0 is the initial number of cells and

$$G^2 = a^2 \left(1 + \frac{4Dt}{a^2} \right) \quad (5)$$

where a is the standard deviation for the seed point.

We have assumed here that tumor growth occurs in two phases ([7]-[9]). In the first phase, the tumor cells only proliferate to form a small dense lesion and only at some later time the tumor cells begin to diffuse. The growth model is applied only in the second phase. Without this assumption, the model simulates the case of gliomatosis cerebri that is tumor cells can be found throughout the brain but no single bulk tumor is identifiable [5]. One special characteristic of the analysis is the use of a zero diffusion coefficient in all voxels not segmented as gray or white matter. This constrains the tumor from growing outside the head or into the ventricles.

B. Parameter Estimation

Parameter estimates in any realistic mathematical model are crucial. Doubling times for glioma have been estimated at 1 week to 12 months covering the range of high to low grade glioma [10]. To relate linear velocity of the detectable tumor margin, v, with the proliferation rate , ρ, and a random walk diffusion coefficient D, we used Fisher's approximation $D \approx \frac{v^2}{4\rho}$ ([6],[11]). This approximation comes from the observation that a population governed by growth and diffusion alone expands at a rate of $2\sqrt{\rho D}$ for a large period of time. The diffusion coefficients $D_w = \frac{v_w^2}{4\rho}$ and $D_g = \frac{v_g^2}{4\rho}$ are assigned the experimentally observed linear velocities v_g and v_w in gray and white matter, respectively ([7]-[9]). From the CT scans, the speed of advance of the tumor margin across the corpus callosum (white matter) is two to three times as fast as that in (predominately) gray matter. We therefore, estimate $v_w > 2.2 v_g$ at 0.18 mm/day and $D_w > 5 D_g$ at 0.22 mm^2/day. Parameter values are shown in Table I.

In our model, we have used empirically estimated parameters. We get the idea as to what the parameter values usually can be in case of high and low grade glioma from Swanson et al.'s model [5]. We also get the idea of the ratio between the diffusion coefficients of gray and white matter, but we considered two more empirical ideas for our estimation. First, we have used a pediatric brain which is structurally different than the adult one. So the diffusion coefficient will be smaller and the growth rate for the pediatric glioma should be faster than the adult glioma. Second, Swanson et al. [5] derived their parameters using contrast enhanced CT images, but our model is based on MR images. Therefore, detection threshold should be different in our case.

TABLE I
ESTIMATED PARAMETER VALUES

	Swanson et al. [5]	**High grade glioma**	**Low grade glioma**
Doubling Time (days)	56	28	56
Growth rate, ρ(/day), corresponding to doubling time	0.012	0.036	0.018
Linear velocity of the detectable tumor margin in gray matter, v_g (mm/day)	0.08	0.046	0.018
Diffusion coefficient in gray matter, D_g (mm^2/day)	0.13	0.015	0.005
Linear velocity in white matter, v_w (mm/day)	0.176	0.08	0.03
Diffusion coefficient in white matter, D_w (mm^2/day)	0.65	0.045	0.015

III. RESULTS

We investigated the performance of this model under several experimental conditions and reported those observed results. These investigations began with a simple 1D implementation to gain more experience with the affect and interaction of the variable parameters. Next, we implemented the full 3D version of the model in Matlab using an actual tissue map obtained from a pediatric patient treated for acute lymphoblastic leukaemia at St. Jude Children's Research Hospital, Memphis, Tennessee, USA. Diffusion and proliferation rates were chosen to model both high grade and low grade glioma and tested for seed points arising from both white matter and gray matter.

The first study conducted began with a 1D investigation of tumor cell density changes with time. In an early phase of growth, diffusion is the dominant factor for a period of time. After that time, the situation is reversed, with cell proliferation becoming the more dominant factor. Figures 1 and 2 demonstrate the results for 1D model experiment.

We initialized a 1 mm^3 Gaussian seed voxel in white matter of a segmented image and observed the growth of tumor (both high and low grade) in serial time steps from three orthogonal views. Figures 3 and 4 demonstrate the results.

Later we initialized a 1 mm^3 Gaussian seed voxel in gray matter of a segmented image and observed the growth of tumor (both high and low grade) in serial time steps from

three orthogonal views. Figures 5 and 6 demonstrate the results.

IV. Discussions

The general observations from figures 3, 4, 5 and 6 are as follows. First, in the high-grade case, ρ / D results in a larger portion of the tumor remaining detectable relative to the low grade case. Second, high-grade glioma take less time to diffuse than low-grade. Third, detectable tumor was found to spread faster and to become larger when arising in white matter than gray matter

V. Conclusions

In the initial preliminary simulations conducted in this study using the tumor growth model, the three key observations as discussed in section IV were consistent with clinical experiences.

We have implemented a tumor growth model in 3D which used real patient 3D tissue maps from an MR imaging set. This use of real imaging from the patient will be important for future testing in actual brain tumor patients since their distribution of white and gray matter (D_w, D_g) will be different for each patient and needs to be based on actual imaging. Since our model is truly 3D, the results can be overlaid on patient imaging and viewed in orthogonal planes. The model we have implemented is a necessary and essential first step in any investigation of more elaborate tumor models.

Abstract— **Heart rate and oxygen saturation level measurement device needs to flash two LEDs alternatively at working mode. These flashing LEDs dominate the power requirement of the whole system. To save power dissipation in the LEDs, the LED drive signals are chopped with a small duty cycle along with high switching frequency. But this small duty cycle lowers the signal SNR and leads to an inaccurate result. So we need to find out an optimum duty cycle which can satisfy both criterions while the device works. This paper made an investigation to find out an optimum duty cycle of LED drive signals which can fulfil not only the low power consumption criterion but also ensures the data accuracy of the device. At first, theoretical design has been given. Then a prototype has been constructed and implemented by which the data accuracy variation at different duty cycle has been checked out. Finally we got the promising result at 5% duty cycle.**

Index Terms— **Duty cycle, low power consumption, data accuracy.**

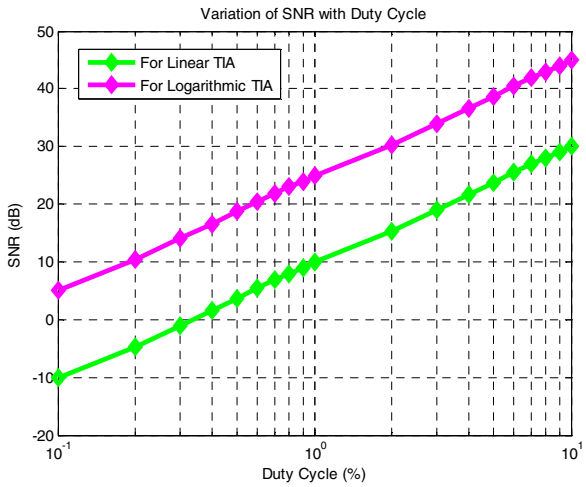

Fig. 1 Variation of SNR with Duty Cycle

I. Introduction

Low power consumable device which can measure the heart rate and oxygen saturation level (SpO2) combinedly is still a major challenge to design in health care system[1]-[2]. To measure the heart rate and oxygen saturation level, circuit needs to flash two LEDs (Red and Infrared) alternatively [2]-[5]. These LEDs are one of the dominant sources of power consumption. To save power dissipation in LEDs, it is necessary to chop the LED drive signals with small duty cycle. Different pulse oximeter devices use this technique. For example, in [2] and [6] a duty cycle of 3% and 0.8% with a LED switching frequency of 75Hz was proposed in order to dissipate low power. But the main problem arises with low duty cycle as it lowers the Signal to Noise ratio (SNR) of the device logarithmically which is depicted in Fig.1. This lower SNR at low duty cycle exacerbates the output signal remarkably and leads to an inaccurate result [7]-[9]. Our primary objective is to design a device which can measure heart rate and oxygen saturation level simultaneously at low power without sacrificing its accuracy. In order to do that, we have to maintain sufficient SNR at the detector or to increase the number of amplifier-filter block. Increasing the number of amplifier-filter block causes high installation cost as well as more power consumption at working mode.

So in this paper, we prefer to increase the duty cycle of LED drive signal at an optimum value for data accuracy as well as low power consumption. In this regard, we have carried out an investigation to set the perfect duty cycle for both LEDs which will provide sufficient SNR.

At 100 Hz frequency of LED drive signal, we found that 5% duty cycle can provide almost 39dB SNR which ensures low power consumption as well as data accuracy of the device. Variation of collected data and its accuracy (both for heart rate and oxygen saturation level) at 5% duty cycle, less than 5% duty cycle and more than 5% duty cycle have been shown in experimental result section. We have observed the output up to 10% duty cycle because we did not get any significant change in average data error between 10% duty cycle and 5% duty cycle. Moreover, we have got acceptable average error (2.29% for heart rate and 1.90% for SpO_2) at 5% duty cycle. If we would consider more than 10% duty cycle, then there will be a little data accuracy (negligibly small) but the power consumption by LEDs will be very high. This is totally contrary to the objective of our work. At last, a logarithmic transimpedance amplifier (TIA) has been used in the circuit which ensures faithful amplification at low duty cycle of LEDs. The use of logarithmic TIA also leads the energy efficient characteristics of the device. Power consumption at different block of the proposed circuit has also been measured and compared with other existing devices.

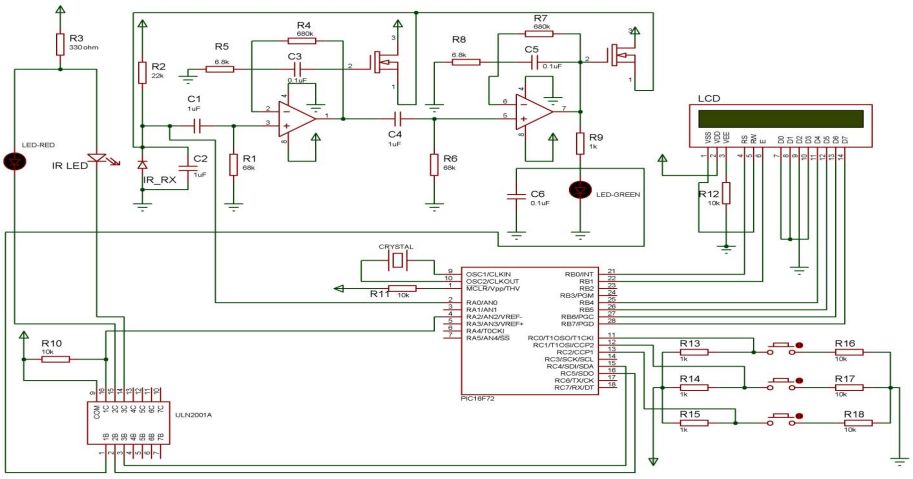

Fig. 2 Proposed circuit architecture

II. Proposed Circuit Architecture and Operating Principle

Fig.2 shows the architecture of the proposed circuit. Its overview has been given below.

A. Signal conditioning Circuit

The circuit consists of a red LED, an infrared (IR) LED and a photo detector. To observe the variation of data accuracy and power dissipation, the LED drive signals are chopped with differentl duty cycle with 100Hz switching frequency. The switching frequency must be kept much higher than the heart rate frequency so that the aliasing effects are minimal. To drive the LEDs, we have used a driver circuit ULN 2003A and to control the driving pulse frequency, duty cycle etc., a low cost microcontroller (PIC16F72) has been used. The microcontroller also assists to count the heart rate and oxygen saturation level. An LCD display is interfaced with microcontroller to display the heart rate and oxygen saturation level simultaneously.

B. Transimpedance Amplifier

In our circuit, a logarithmic transimpedance amplifier (TIA) is used which employs a logarithmic characteristics to convert current to voltage.

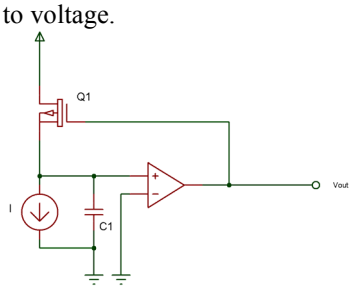

Fig.3 Logarithmic TIA

In Fig.3, the output voltage of logarithmic TIA is-

$$Vout = U_T/K \ln(I_1/I_0) \quad (1)$$

Where K_1 is the sub threshold exponential coefficient of Q_1 and U_T is the thermal voltage. The key incentive behind the employment of the logarithmic TIA is that it is inherently sensitive to the contrast (ac/dc) of the input photo current signal [2].

C. Filter circuit

Both LED consists of a large DC component. To block this DC component, a high pass filter (HPF) has been used in the circuit. C2 and R1 are the HPF components. In addition to that, to extract the blood pulsation signal, a low pass filter (LPF) is used. The cut-off frequency of this LPF needs to be low enough to remove the switching frequency (100Hz) components. The cut-off frequency of the LPF is-

$$f_c = 1/2\pi R_4 C_3 \quad (2)$$

$$= 1/2\times 3.1416\times 680\times 10^3\times 0.1\times 10^{-6}$$

$$= 2.34 \text{ Hz}$$

Where R4 and C3 are the feedback resistance, capacitance of the LPF in Fig.2. The maximum measurable heart rate is about-

$$2.34\times 60 = 140 \text{ bpm}$$

The red LED, IR LED and photo detector are mounted on a finger clip. At first, light is emitted from the LEDs alternatively, passing through the finger and reaches at the photo detector which is placed on the other side of the finger. But a portion of light is absorbed by the finger while passing through it. The signal received by photo detector posses both DC and AC components which have been removed by LPF and HPF. To get an amplified output, energy efficient logarithmic TIA is used. This amplification has been performed by two stage amplifier block. The output of amplifier and filter circuit then feed to microcontroller.

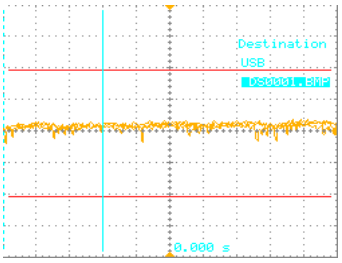
Microcontroller counts the number of pulses over a fixed time interval and thus obtains the heart rate of the subject.

Moreover, by analysing the absorption of two wavelength of two LED, it is possible to measure the actual difference in the absorption spectra of oxihemoglobin (HbO2) and hemoglobin (Hb) which helps to calculate the oxygen saturation level. This value is displayed in LCD with the help of microcontroller.

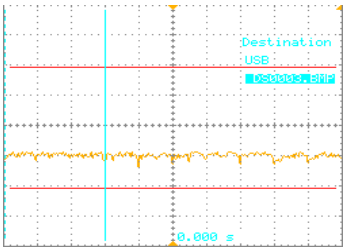
III. Experimental Results and Analysis Details

In this section, experimental analysis has been carried out with the constructed prototype and the collected data has been analysed in details. Real constructed circuit is shown in Fig.5 by which the experiment has been conducted.

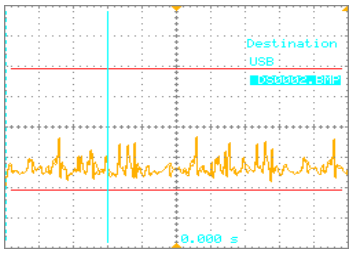
The output of the receiver is connected to an Oscilloscope to obtain the signal wave shape which is depicted in Fig.4. At first, the output of the receiver has been taken at below 5% duty cycle (at 2% duty cycle) of LED drive signal. This raw output signal is demonstrated by Fig.4(a). The signal illustrates that it is corrupted with heavy noise. So the data collected from this signal shows much error which has been summarised in TABLE I and TABLE II.



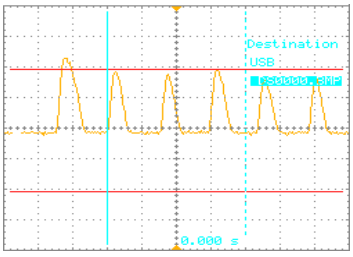
(a) 2% Duty Cycle,y axis 1V/Div.



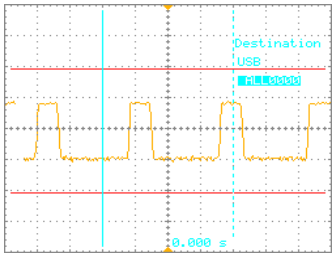
(b) 4% Duty Cycle, y axis 1V/Div.



(c) 5% Duty Cycle, y axis 1V/Div.



(d) Filtered Signal, y axis 1V/Div.



(e) Amplified output, y axis 2.5V/Div.

Fig. 4 Oscilloscope output , X axis 0.427s/Div.

To minimize the error rate, we increase the value of the duty cycle of LED drive signal at 4%. The output signal is now less corrupted compare to previous one. At 5% duty cycle, the device has given a promising result with small error rate. Fig.4(c) shows the raw signal taken at 5% duty cycle where as Fig.4(d) and Fig.4(e) are the filtered and amplified output signal.

The prototype was used to measure the heart rate and SpO2 of 15 healthy subjects at 2%, 4%,5% and 10% duty cycle. At the same time their heart rates were measured by OMRON and SpO2 was measured by Avant®4000. We have selected OMRON and Avant®4000 as a reference device for heart rate and oxygen saturation measurement. Both values were compared in TABLE I and TABLE II. TABLE I shows that at 2% and 4% duty cycle, the device average error is 7.12% and 5.63% respectively where at 5% duty cycle the error comes down at 2.29%. Furthermore, 10% duty cycle gives an error of 2.12%. So statistically it is evident that the error minimizes comprehensively when the duty cycle increases from 4% to 5%. But the error minimization is negligibly small from 5% to 10% duty cycle. Moreover, 2.29% is an acceptable error rate (supported by [9]) which we have got at 5% duty cycle. We can run our device at 10% duty cycle or more instead of 5% to get better data accuracy but at the same time we have to sacrifice high power loss at larger duty cycle by two LEDs. This phenomenon has been depicted in Fig. 6(c).Even there will be no major or substantial improvements in error percentile while the device working at more than 5% duty cycle. So 5% duty cycle is the optimum value for the device. Same analysis is true for oxygen saturation data which is sum up in TABLE II.

Fig. 6 MATLAB plot curves showing variation of heart rate, oxygen saturation and power consumption with duty cycle

To illustrate the variation and error at different duty cycle, we have plotted the data in MATLAB. Fig. 6 displays all the curves with the contrast more vividly. State of power consumption (which is measured) with increasing duty cycle is also depicted in Fig. 6(c).

We carefully measure the power requirement of various stages of our device running at 5% duty cycle which is listed in TABLE III. The table shows just LED and processing power consumption, not LCD display or other equipment's consumption. We have used 50mW two LEDs.

TABLE III
POWER CONSUMPTION CALCULATION

Power Consumption Block	Value
LEDs	5mW
Microcontroller+Driver	15mW
Transimpedance amplifiers	100 uW
Filters	550 uW
Total	20.65mW

Power consumption of our device adds up to 20.65mW which is relatively low. Power mostly spent by the LEDs, driver and microcontroller circuit. Finally, TABLE IV compares the power dissipation of our device with several commercial devices. Power dissipation data for several commercial devices has been collected from [2]. This table of comparison shows that, our device which operates at 5% duty cycle consumes less power relative to other devices.

TABLE IV
POWER CONSUMPTION COMPARISON

Type	**Consumed Power**
Our Devive	20.65 mW
Wrist ox 3100	55 mW
Avant®4000	71 mW
Xpod	60 mW
Device proposed in [2] (works at 3%Duty cycle)	4.8mW

IV. CONCLUSIONS

The main aim of our work was to investigate in to optimum duty cycle of LED drive signals of heart rate and oxygen saturation level measurement device. In order to minimize the power loss and retain the data accuracy, this optimum duty cycle of LED drive signal is a pivotal parameter. After constructing a device prototype, we have observed the heart rate and oxygen saturation level data at different duty cycle and tried to pick up the best possible optimum one. At 5% duty cycle, the device provides a very promising result with an acceptable average error. At last, we have measured the power consumption at 5% duty cycle which exhibits low power consumption property of the device compare to other existing one.

APPENDIX

We have calculated error percentile using the following equation-

$$Error = \frac{ActualData - MeasuredData}{ActualData} \times 100\%$$

The analysis of DNA methylation is becoming increasingly important both in the clinic and also as a research tool to unravel key epigenetic molecular mechanisms in biology. Current methodologies for the quantification of regional DNA methylation are largely affected by comprehensive DNA sequencing methodologies which tend to be expensive, tedious, and time-consuming for many applications. Herein, we report an entirely new DNA methylation detection method referred to as 'Methylsorb', which is based on the inherent affinity of DNA bases to the gold surface (i.e., the trend of the affinity interactions is adenine > cytosine ≥ guanine > thymine) [1]. Since the degree of gold-DNA affinity interaction is highly sequence-dependent, it provides a new capability to detect DNA methylation by simply monitoring the relative adsorption of bisulfite treated DNA sequences onto a gold chip. Because the selective physical adsorption of DNA fragments to gold enable a direct read-out of regional DNA methylation, the current requirement for DNA sequencing is obviated. To demonstrate the utility of this method we present data on the regional methylation status of two CpG clusters located in the EN1 and MIR200B genes in MCF7 and MDA-MB-231 cells. The methylation status of these regions was obtained from the change in relative mass on gold surface with respect to relative adsorption of an unmethylated DNA source and this was detected using surface Plasmon resonance (SPR) in a label-free and real-time manner. We anticipate that the simplicity of this method, combined with the high level of accuracy for identifying the methylation status of cytosines in DNA, could find broad application in biology and diagnostics.

***Index Terms*— DNA methylation • Gold-DNA affinity • DNA adsorption • Surface Plasmon resonance**

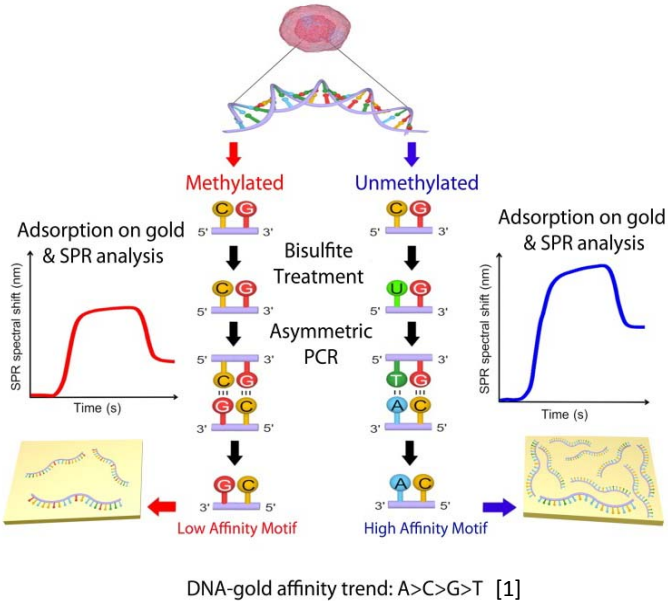
I. Introduction

DNA methylation is a prevalent epigenetic alteration in cancer [2], and hence considered one of the most promising biomarkers for cancer diagnosis, prognosis and therapy monitoring [3]. Early detection of aberrant DNA methylation offers a great potential to improve survival rates and decrease the cost of treatment by ameliorating prescription of ineffective therapies. DNA methylation strategies typically involve bisulfite [4] modification of DNA to convert methylation events to base changes followed by comprehensive sequencing to read each individual base pair in the genomic region of interest [5]. Over the past few years, much attention has also been focused on detecting DNA methylation from bisulfite treated DNA using sequence-sensitive methods such as methylation specific PCR (MSP) [6], combined bisulfite restriction analysis (COBRA) [7], sequencing [5] or bio-sensing [8] coupled with mass spectroscopy, electrochemical or optical readouts. While most of these methodologies have significantly improved the analysis performance, their practical application is restricted due to the complicated surface and conjugation chemistries, multistep analysis procedures or the use of labels. Therefore, we believe that the development of a simple, low cost and robust detection method for DNA methylation is essential to enable the uptake and full utilization of such biomarkers in the clinic.

In this report, we have envisioned an extremely simple method referred to as 'Methylsorb', which is an effective and potential alternative to traditional methods and offers a label-free and real-time detection of DNA methylation. The underlying principle of Methylsorb involves the use of the sequence-dependent affinity interaction of DNA bases towards gold substrates. Since (i) bisulfite treatment converts methylation events into base changes, and (ii) DNA base-gold affinity interaction (*i.e.,* DNA adsorption) is highly sequence-dependent [1], [9]-[10], we hypothesized that the direct detection/quantification of adsorbed (*via* DNA-gold affinity interaction) bisulfite treated-DNA sequences could be an extremely simple way to analyse DNA methylation events. The schematic of the Methylsorb approach is illustrated in Scheme 1. Initially, genomic DNA from cells was treated with sodium bisulfite to convert unmethylated cytosines into uracil, leaving methylated cytosines unchanged. Bisulfite converted samples were then amplified via a subsequent asymmetric PCR amplification step, which converts all uracils into thymines in the sense strand (*i.e.,* the DNA strand running from 5' to 3' end) or into adenines in the antisense strand (*i.e.,* the DNA strand running from 3' to 5' end). Asymmetric amplification ensures that only ss-DNA sequences corresponding to the antisense strand are amplified. This step therefore introduces an accurate and unique way to create specific base changes on DNA, which ultimately can alter DNA-gold affinity interaction, and thus give quantitative information on the original methylation status of the sample. This is because (i) it only generates ss-DNA, which is more prone than dsDNA to uncoil sufficiently to expose its bases and rapidly interact with the gold surface [11], and (ii) it correlates methylation profile with gold-DNA affinity behaviour, as only the antisense strand, which becomes guanine-enriched for methylated or adenine-enriched for unmethylated samples, is amplified. Since adenine bases are

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

reported to have stronger affinity towards gold than guanine [1], [9]-[10], the adenine-enriched ssDNA sequences (*i.e.,* unmethylated sequence) are expected to exhibit higher adsorption on gold than the methylated guanine-enriched sequences. The differential affinity interaction (*i.e.,* differential adsorption) of adenine or guanine-enriched sequences, corresponding to the DNA base-changes associated with DNA methylation, can be determined in a single step via direct quantification of adsorbed DNA sequences in-real time.



Scheme 1. Methylsorb approach. Genomic DNA is derived from breast cancer cell lines. Bisulfite treatment and asymmetric PCR processing of these samples generate adenine-enriched (blue) or guanine-enriched (red) antisense ss-amplicons for unmethylated and methylated templates respectively. The ss-DNA amplicons are directly adsorbed on gold and their adsorption is monitored in real-time using surface Plasmon resonance readout.

We used this approach to quantify the DNA methylation status of two CpG clusters located within the Engrailed homeobox1 (*EN1*) and MIR200B gene promoter regions on DNA derived from MCF7 and MDA-MB-231 cells respectively. As a standard reference for unmethylated DNA sample, we used whole genome amplified (WGA) DNA. To quantify adsorbed DNA sequences on gold chip, we used a surface Plasmon resonance (SPR) biosensing approach that detects changes in refractive index over time (*i.e.,* changes in the SPR spectral shift) at the sensing surface, which are directly proportional to the relative mass increase associated with target adsorption, thus enabling the real-time and label-free monitoring of targets. This method has previously been used to detect regional DNA methylation using proteins with affinity to CpG rich regions [12] or molecular inversion probes [13]. Detecting DNA methylation through this gold-driven adsorption process in combination with SPR offers several critical improvements to conventional methylation technologies that include: (i) minimal sample and operational requirements, (ii) no use of surface-bound receptors and thus avoids modification procedures for the recognition layer of the SPR surface and (iii) label-free and real-time monitoring that avoids any artifacts generally associated with the use of labels.

II. Materials and Methods

A. DNA Sample Preparation

Genomic DNA from MCF7 and MDA-MB-231 cells was extracted from 105 cells plates using the DNeasy blood and tissue kit (QIAGEN Pty. Ltd., Venlo, Netherlands) according to manufacturer's instructions. The purified DNA was bisulfite treated using a MethylEasyXceed kit (Human Genetic Signatures Pty. Ltd., New South Wales, Australia) according to the manufacturer's instructions. To obtain ss-stranded amplified amplicons containing the target sequence, samples were then amplified in a 60 µL reaction containing 1.5 unit Taq DNA polymerase (AmpliTaq DNA Polymerase, Applied Biosystems, Australia), 0.7X PCR buffer (AmpliTaq 10X PCR buffer) 0.2 mM each dNTP, 0.1% tween, 125 nM of forward primer and 375 nM reverse primer (Supplementary table 1). Cycling was carried out in a Bio-Rad thermo cycler (MJ Mini Personal Thermal Cycler) using the following conditions: denaturation at 94 ºC for 10 min followed by 50 cycles of 94 ºC for 30 s, 58 ºC for 45 s and 72 ºC for 30 s.

B. Methylation detection with SPR biosensor

All experiments were performed in a custom-made SPR platform. Initially, the SPR sensor chips (5nm Ti and 50 nm Au) were cleaned by rinsing with hot acetone, ethanol and deionised water and dried under flow of nitrogen gas. Subsequently, the chips were dipped in piranha solution (70% H_2SO_4–30% H_2O_2) for few seconds, rinsed with water and dried under flow of nitrogen gas. Following this step, the chip was placed in the SPR platform and sodium saline citrate (SSC) 5X buffer (0.75 M in NaCl, 0.075 M in sodium citrate, pH 7) was flowed in continuous at a flow rate of 0.6 mL/h. Then, 250 µL of DNA samples (10 µL of asymmetric PCR output spiked in 250 µL of SSC5X buffer) were directly injected in the SPR flow system at the same flow rate. The SPR signals were monitored using custom-made Labview software.

III. Results and Discussion

To investigate the strategy of gold–DNA affinity interactions for detecting DNA methylation levels, we designed synthetic DNA (Fig.1A) similar to the bisulfite treated and asymmetric amplified sequences derived from the *EN1* gene. The *EN1* gene comprises of eight potentially methylated CpG sites within a span of 53 bases downstream to the transcription start site and identified as a potential biomarker in several cancer types [14].

We initially performed our experiment at pH 3 because DNA adsorption extent and kinetics are reported to be facilitated at pH 3 [15]. However, we have observed that adsorption at pH 3 limits the ability of the Methylsorb approach to differentiate methylated and unmethylated targets. At low pH (*i.e.* pH = 3) adenines and cytosines become protonated, leading to high DNA adsorption compared to that under neutral pH conditions [15]. Since both methylated and unmethylated sequences contain large numbers of cytosines and adenines bases, they could be strongly adsorbed on gold substrate within a short period of time at pH <7. Thus, we chose to carry out our experiments at the solution pH 7 that does adsorb the desired unmethylated targets, but do not strongly adsorbed the methylated one.

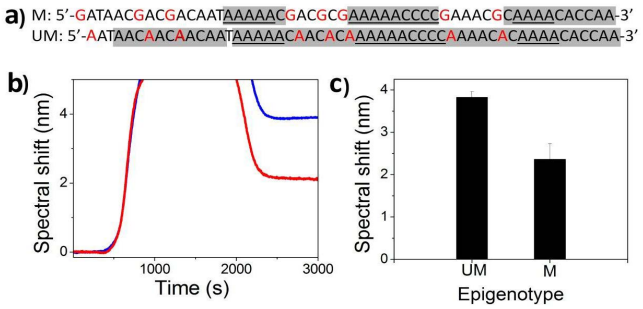


Fig. 1 Detection of DNA methylation in synthetic samples. (a) DNA Sequence. High and low affinity sequence motifs are noted (*i.e.,* DNA sequence motifs of minimum 4 identical bases are underlined; sequence motifs corresponding to poly A/C mixed bases are highlighted in grey colour; the A/G differences between the two strands are highlighted in red font). (b) SPR sensorgrams showing the spectral shift generated during the adsorption of methylated (red) and unmethylated (blue) synthetic *EN1* region onto the gold chip. (c) Corresponding mean values of SPR spectral shift for methylated (M) and unmethylated (UM) regions. Each bar represents the average of three separate trials (n=3), and error bars represent the standard deviation of measurements within experiments (relative standard deviation (%RSD) was found to be <8% for n= 3).

Fig. 1b illustrates the SPR signals obtained for methylated and unmethylated synthetic DNA samples at pH 7. The adenine enriched unmethylated DNA demonstrated 40% enhanced adsorption towards gold surfaces in comparison to the guanine enriched methylated DNA (see Fig. 1c, 3.82 ± 0.13 versus 2.29 ± 0.18 nm). This adsorption behaviour is possibly due to the higher affinity interaction of adenine bases towards gold surface in comparison to guanine. This behaviour is in accordance with the previously observed base-dependent adsorption (*i.e.,* A >C ≥ G >T) of DNA [1] onto gold surfaces. Notably, this outcome indicates that the Methylsorb approach can effectively distinguish methylated and unmethylated epigenotypes in synthetic samples even though they involved only 8 CpG sites. It is also important to note that for a given number of DNA bases, a DNA containing homo-polymer (*e.g.*, a sequence with clustered poly-A motifs) and a DNA containing more distributed DNA bases (*e.g.*, adenine bases spread across the sequence) might essentially not exhibit the same adsorption behaviour. We analysed the sequence composition of the methylated and unmethylated epigenotypes and investigated the presence of any high gold-affinity motif containing (i) homo-polymers (*e.g.*, poly A) with a minimum of four bases and, (ii) polymers enriched with a mixture of adenine and cytosine bases. The identified homo-polymers (underlined) and polymers enriched with A, C bases (highlighted in grey) are represented in Fig. 1a. It is evident that the methylated and unmethylated DNA contains similar homo-polymers both in numbers (*e.g.*, 3 poly A and 1 poly-C motif) and in length. However, the polymers enriched with A,C bases were significantly larger in length for unmethylated sequence. This is because bisulfite treatment and PCR processing of DNA not only lead to A/G-enrichment, but also result in GC or AC enriched motifs in the methylated or unmethylated sequences (Scheme 1 and Fig. 1A). Additionally, bisulfite conversion (followed by asymmetric PCR) of DNA also increases the adenine contents in the antisense strand for both epigenotypes. This enhances the possibility of forming larger AC motifs in the unmethylated sequences. We believe that this differential length of poly-AC motifs in methylated and unmethylated sequences is the key factor to offer a distinguishable SPR signal in our method.

To assess the applicability of this methodology in genomic DNA samples, we chose to investigate (i) *EN1* region in DNA derived from MCF7 cells, and (ii) a region containing 8 CpG sites in a span of 65 bases within the promoter region of the *MIR200B* gene derived from the MDA-MB-231 cells. Both the genes were identified previously as a potential biomarker in several cancer types [14], [16]. We simultaneously analysed the same *EN1* and *MIR200B* regions on whole genomic amplified (WGA) human DNA. This DNA is fully unmethylated (adenine enriched), and hence DNA amplicons derived from WGA are expected to give maximum achievable SPR signal for this region. Since methylated amplicons are guanine-enriched and they have lower adsorption affinity compared to the WGA DNA, there will be a clear correlation between the presence of methylation and lowering of the SPR signal from that of the WGA DNA.

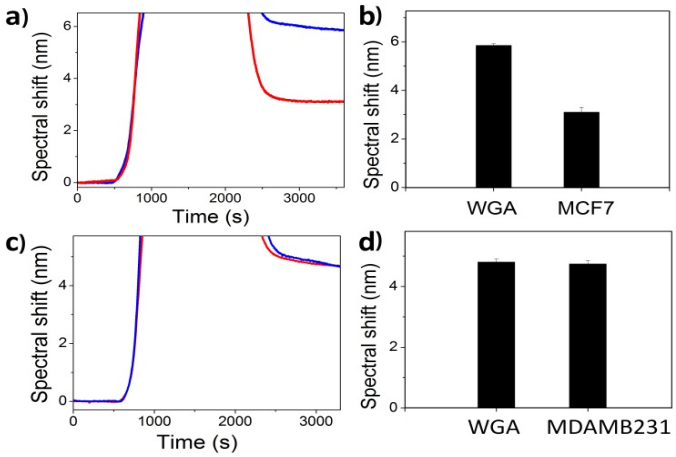

Fig. 2 Quantification of DNA methylation in samples derived from cancer cell lines and whole genome amplified DNA. Representative SPR sensorgrams showing the spectral shift during real-time adsorption of antisense amplicons derived from the (a) *EN1* region in MCF7 cells (red) and WGA (blue) DNA and the (c) *MIR200B* gene region in MDA-MB-231 (red) and WGA (blue) DNA. Corresponding mean SPR spectral shift are shown in the right panels (b, d). Each bar represents the average of three separate trials (n=3), and error bars represent the standard deviation of measurements within experiments (%RSD was found to be <7%).

Fig. 2a illustrates the SPR signals obtained for the direct adsorption of MCF7 and WGA DNA amplicons onto a gold surface. Similar to the responses obtained for *EN1* synthetic DNA samples, we observed an enhanced adsorption behaviour in the case of unmethylated WGA DNA (A>G; dark blue line) that is evident from a larger spectral shift (Fig. 2b, 5.85 ± 0.07 (MCF7) versus 3.1 ± 0.2 nm (WGA)) in comparison to methylated MCF7 DNA (G>A; red line) indicating the methylated status of this region in MCF7 cells. Responses were in agreement with our previous sequencing analysis data of this same region on MCF7 cells (see Supporting Information of reference 21). Subsequently, the Methylsorb analysis of *MIR200B* region resulted in almost identical SPR signals for MDA-MB-231 (Fig. 2c; red) and WGA DNA (Fig. 2c; blue). The negligible difference in SPR spectral shift (Fig. 2d; 4.74 ± 0.09 (MDA-MB-231) versus 4.8 ± 0.1 nm (WGA)) values suggested that the *MIR200B* region in MDA-MB-231 could possibly be unmethylated. Sequencing analysis data confirmed the unmethylated status of *MIR200B* sequence in MDA-MB-231 DNA cell line. This data contrasts with previous observations, where a strong CpG methylation (*i.e.*, hypermethylation) across the promoter of the *MIR200B* in

MDA-MB-231 cell line has been identified [28]. It has been reported that replicas of the same cell line in vitro could exhibit differential DNA methylation at certain regions [17], we believe that this could explain the discrepancy between our results and those from the literature.

Clinical samples often contain a mixture of tumour and normal cells [18] where the presence of unmethylated sequences can potentially influence the sensitivity of the diagnostic assay. Therefore, we investigated the ability of our approach to detect heterogeneous DNA methylation (*i.e.*, methylated targets in the presence of designated proportions of unmethylated DNA) by measuring the adsorption of DNA samples containing mixture of methylated and unmethylated sequences. Samples were prepared by quantifying the copy numbers of MCF7 and WGA DNA followed by mixing designated proportions of methylated and unmethylated targets (*i.e.*, MCF7/WGA DNA at 0%:100%, 25%:75%, 50%:50%, 75%:25%, and 100%:0%).

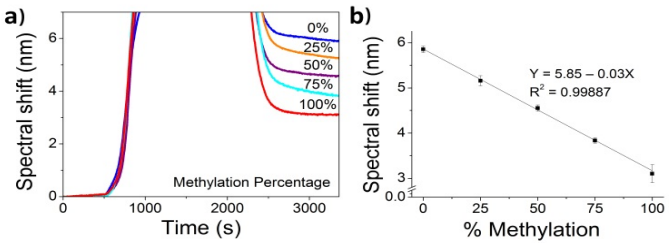

Fig. 3 Detection of DNA methylation in heterogeneous samples. (a) Representative sensorgrams showing the SPR spectral shift for the real-time adsorption of heterogeneous sample mixtures containing designated percentage of DNA derived from MCF7 and WGA (*i.e.,* MCF7:WGA DNA at 0%:100%, in blue; 25%:75%, in orange; 50%:50%, in purple; 75%:25%, in light blue and 100%:0%, in red). (b) Corresponding calibration plot. Each data point represents the average of three separate trials, and error bars represent the standard deviation of measurements within experiments.

Fig. 3a represents the SPR sensograms of the heterogeneously methylated DNA samples. It was evident that the SPR signal was a function of methylation percentage in the heterogeneous mixture. It was also noted that there was a linear correlation (R^2 = 0.9988) in signal enhancement with a decrease in methylation percentage (Fig. 3b). This is presumably due to the increase in the adenine nucleotide content with increase in the percentage of unmethylated DNA in the mixture resulting in an enhanced signal. Additionally, a significant difference in signal for samples containing 25% and 0% methylated targets (Fig. 3b; 5.85 ± 0.07 versus 5.16 ± 0.11 nm) indicate that our approach was sensitive enough to detect at least 25% methylation changes. However, we believe that further optimization to the operating parameters (*e.g.*, flow rate, buffer composition and multiplexed SPR platform) can improve the detection sensitivity of our method and potentially be integrated into clinical settings.

IV. Conclusions

We have developed a simple, cost-effective and real-time approach with the capacity to sensitively detect DNA methylation levels in genomic DNA samples. Our experimental findings demonstrate the accurate interrogation of CpG regions on multiple genes using SPR biosensor and simultaneous validation using conventional bisulfite sequencing. This unique label-free and rapid (*e.g.,* ~40 minutes) approach based on the preferential nucleotide affinity towards gold can effectively detect DNA methylation levels thereby eliminating the need for sequencing approaches. We have demonstrated the feasibility of using this approach to sensitively (*e.g.,* 25% methylated target) and specifically detect methylated targets in the presence of large excess of unmethylated DNA. This method has also the potential to detect global hypomethylation, one of the most important biomarkers of cancer, since the large cohort of CpG regions involved in this type analysis might promote a large difference in the adsorption profiles of normal and hypomethylated samples. We envisage that this simple and rapid approach can potentially find its relevance in diagnostic settings.

Abstract—**Thrombotic stroke, which is caused by blood clot in the cerebral artery, is a major source of increased mortality and morbidity. Considering as efficient and fastest methods, mathematical approaches have gained significant importance for analyzing and understanding the biological events like thrombosis. This paper presents a computational model to analyze the effects of thrombosis using the theory of coupled fluid dynamics-structure interaction. The finite element method is used for the modeling of thrombosis (blood clot) of different stages in the middle cerebral artery with physiological compliance. The developed model is used to investigate the consequences that occur due to the various sizes of clots in the artery in the form of blood flow velocity, blood pressure, and artery wall stress. Such numerical assessment will facilitate better understanding of the biophysical process in case of thrombosis and thus would support medical practitioners to take faster curing steps.**

Index Terms—**Thrombosis, Middle cerebral artery, Blood clot, Finite element modeling, Thrombotic stroke.**

I. Introduction

Thrombosis, which is caused by the formation of blood clot (thrombus) inside a blood vessel, is one of the major health problems around the world. Thrombus formation or blood clot is an inherent characteristic of blood to protect the person from continuous haemorrhage. When a blood vessel is injured, the body uses platelets (thrombocytes) and fibrin to form a blood clot to prevent blood loss. Even when a blood vessel is not injured, blood clots may still form inside the blood vessel due to different associative factors such as repeated formation of calcium, cholesterol and fat carried in the blood, and disorders of blood clotting [1]. Blood clot caught on the plaque of the vessel walls may mostly or fully stop the blood flow. Stopped blood flow for a few minutes may cause neuronal injury (i.e., tissue death) due to the deprivation of oxygen and nutrient from blood, and leads to thrombotic stroke [2].

Diagnosis of stroke can be made by clinical assessment. Different imaging methods such as computed tomography (CT), magnetic resonance imaging (MRI), and contrast venography are widely used for the detection of thrombosis and its effect as stroke [3], [4]. Early prevention of a thrombus formation can be achieved by medical treatment. However, the early detection of thrombosis and prediction of its possible effects is often difficult by medical examination, since it often produces no specific symptoms before neuronal injury or stroke. In most cases, diagnosis processes are done only after the stroke happened. Thus, there arises a necessity to develop a mathematical approach to understand and analyze the effects of various thrombosis states.

A number of works have been devoted to the computational modeling of blood flow and thrombosis [4]–[8]. However, most of these works have considered 2D approaches [4], [6] and concentrated on the analysis of venous thrombosis [5]–[7]. Some of them considered only blood flow without considering the artery wall, which could not give many expected results such as pressure on the artery wall [4], [8]. Thus, the existing works are not sufficient to represent the realistic scenario of thrombosis. Since the works on the computational modeling of thrombosis are in their early stage, more efforts are required for the better understanding of thrombosis.

This paper presents an effective numerical modeling of thrombosis in the middle cerebral artery (MCA) and thus, demonstrates its various effects leading to a thrombotic stroke. The finite element (FE) method is used for the three dimensional (3D) modeling of various clot conditions inside the artery whose result is then employed to investigate a detailed scenario of blood flow including velocity magnitude, pressure distribution along blood and stress to artery wall. The critical conditions for the brain stroke are discussed with the obtained results. Our computational approach may have greater impact in diagnosing the effects of thrombosis in a shorter time period.

II. MCA Anatomy and Clinical Significance

The middle cerebral artery (MCA) is one of the three major paired arteries that supply blood to the cerebrum. Fig. 1 shows a pictorial view of the human brain indicating the MCA. The artery supplies a portion of the frontal lobe and the lateral surface of the temporal and parietal lobes, including the primary motor and sensory areas of the face, throat, hand and arm, and the areas for speech [9].

The MCA is the most common site of stroke [9], [10]. Occlusion of this artery results in MCA syndrome, potentially showing the defects as paralysis, weakness, or sensory loss of the contralateral face and arm, damage to the dominant

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

hemisphere (usually the left hemisphere) resulting in aphasia, damage to the non-dominant hemisphere (usually the right hemisphere) resulting in contralateral neglect syndrome, and large MCA infarcts especially during the acute period.

III. Mathematical Model

The dynamics of the fluid flow plays an important role to identify the degree of obstruction due to blood clot in cerebral artery. Computational fluid dynamics (CFD) is used here as a tool to study the flow dynamics. Fluid flow through veins or artery has the similarity to that of fluid flow through pipes or tubes. Such flow can be of two types as laminar flow and turbulent flow. Laminar flow occurs when a fluid flows in parallel layers, with no disruption between the layers. In laminar flow, the streamlines are straight lines. In turbulent flow, the fluid moves in a random path. Usually, this type of flow can be found at the junction of blood vessels. For the sake of simplicity, we chose the MCA without branch, and therefore considered the laminar flow model of blood. A widely used commercial software COMSOL MULTIPHYSICS is used for the implementation of the model. The model consists of two distinct but coupled procedures: first, a fluid-dynamics analysis including a calculation of velocity field and pressure distribution in the blood and second, a mechanical analysis of the deformation of the artery.

A. Laminar Flow Model

The blood behaves as a non-Newtonian fluid in which the relation between the stress and strain is non-linear or complex. As observed practically, the flow is considered in this model to be non-Newtonian, incompressible, viscous and laminar. Here, we used the 3D Navier-Stokes equation which defines a differential change in momentum within the blood as:

$$\rho\frac{\partial u}{\partial t}+\rho(u\cdot\nabla)u=\nabla\cdot\left[-\rho I+\mu(\nabla u)+(\nabla u)^T\right]+F \quad (1)$$

$$\rho\nabla\cdot u=0 \quad (2)$$

Here ρ is the density of blood, μ is the dynamic viscosity, F is the force, and u is the velocity vector. This relation coupled with the field continuity equation Δu=0, completely defines the dynamics of blood flow through the artery. They are valid for the blood being incompressible laminar flow.

The Navier-Stokes equations are complemented with the following boundary conditions. On the solid wall of artery, the no-slip condition is imposed.

$$u=0 \quad (3)$$

At the inlet of artery, a fully developed velocity profile is assumed. Here U_0 is the normal inflow velocity.

$$u=U_0 n \quad (4)$$

No viscous stress boundary condition specifies vanishing viscous stress along with a Dirichlet condition on the pressure:

$$p=p_0;\quad \left[(\nabla u)+(\nabla u)^T\right]n=0 \quad (5)$$

To solve the Navier-Stokes equation, the boundary conditions being the known values of velocity and pressure are introduced at inlet and outlet respectively [11]-[13].

B. Structural mechanics model

The structural mechanics of the artery is defined by the global equilibrium equations based on the stress components. In a general form, this is given by:

$$-\nabla\sigma=F_v \quad (6)$$

where σ is the stress tensor. The artery itself was taken to consist of a Neo-Hookean hyperelastic material.

The total strain tensor is written in terms of the displacement gradient.

$$\varepsilon=\frac{1}{2}\left[(\nabla u)^T+\nabla u\right] \quad (7)$$

This extension of Hooke's law is thought to better approximate the stress-strain relationship that exists within the artery. The above equations are complemented with following boundary conditions:

Roller boundary condition:

$$n\cdot u=0 \quad (8)$$

Fixed boundary load condition:

$$\sigma\cdot n=F_A \quad (9)$$

The boundary conditions introduced within the structural mechanics module take into account the coupling of the two physics. This is done by taking the computed pressure obtained from the Nervier-Stokes equations and utilizing this as a load onto the artery walls [13].

IV. Finite Element Model of Thrombosis

Figure 2 shows the geometry of the MCA [Fig. 2(a)] considered for the analysis and its finite element model [Fig. 2(b)]. The average length of the MCA is 1.6 cm with a range of 0.5 cm to 3 cm. The diameter ranges from 0.3 cm to 0.5 cm [14]. The average thickness of the MCA tunica media at its origin was 0.012 cm [15]. Here we used artery length 3 cm keeping diameter of inner and outer part at 0.488 cm and 0.5 cm, respectively.

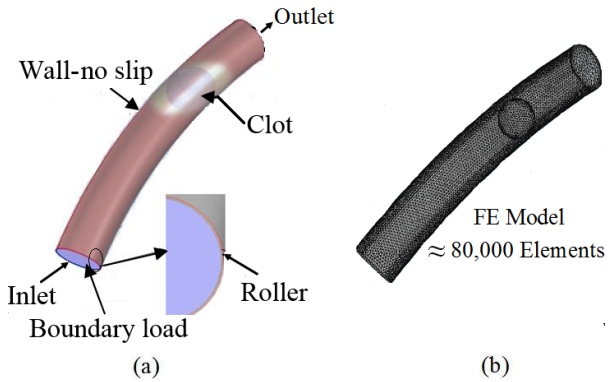

Fig. 2 (a) MCA geometry consisting blood clot inside, and indicating the boundary conditions, and (b) FE model of the proposed MCA geometry.

The velocity of blood flow through MCA has been reported as 0.583 m/s [16]. A time-dependent flow problem was first solved by setting this velocity condition at the inlet and zero pressure condition at the outlet of the selected artery. Flow through the vessel is driven by a pressure difference between the inlet and the outlet of the system. For structural mechanical analysis we used stationary solver. The material properties used in the simulation are summarized in Table I.

TABLE I
Material Properties Used in the FE Analysis [17]

Material	Property	Value
Blood	Density	1060 kg/m^3
	Dynamic Viscosity	0.005 Pa.s
Artery wall	Density	960 kg/m^3
	Poisson Ratio	0.45
	Young's Modulus	100 MPa

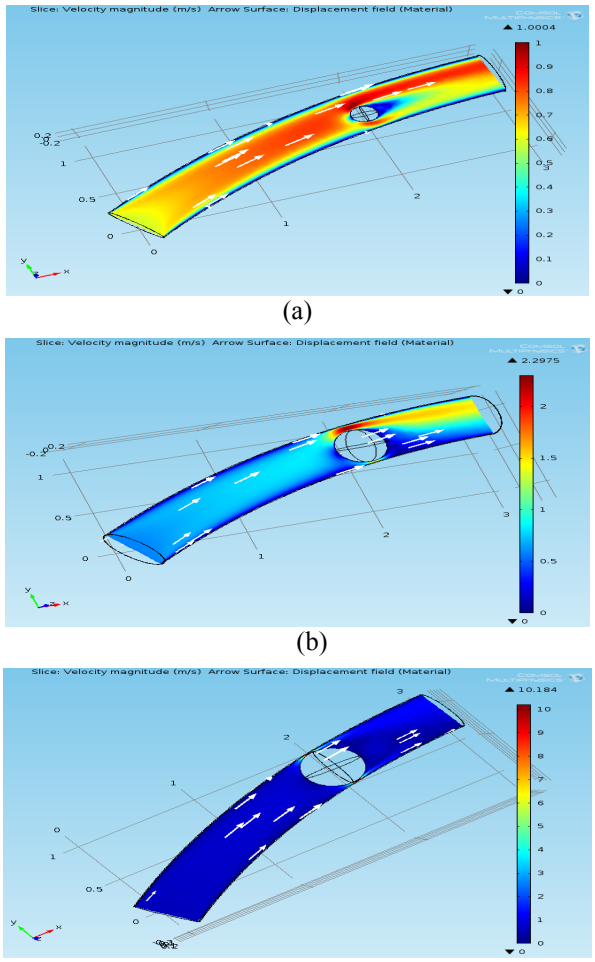

Fig. 3 Velocity magnitude of blood through the MCA with clot radius of (a) 0.1 cm (b) 0.2 cm and (c) 0.23 cm.

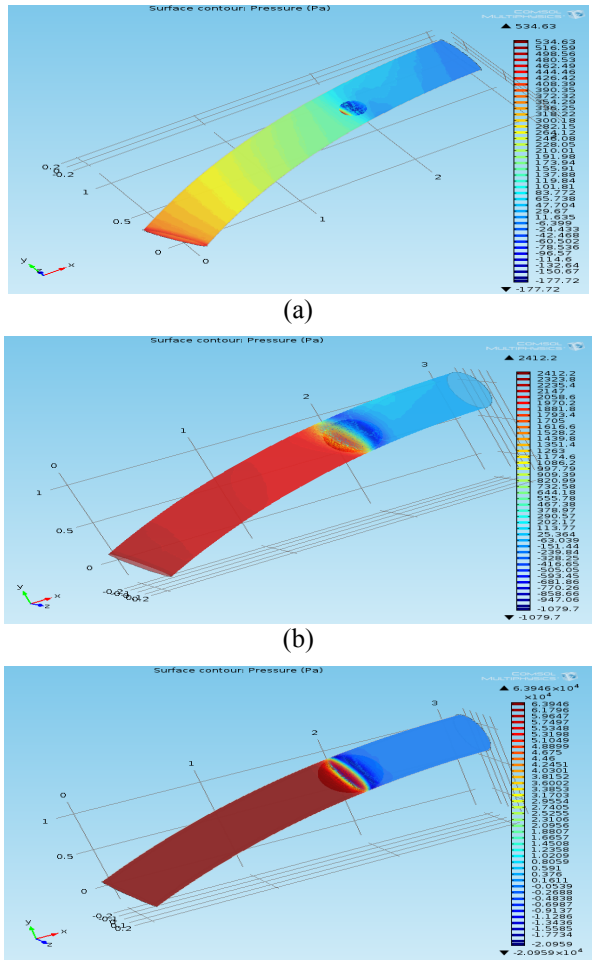

Fig. 4 Influence of blood clot on the pressure distribution along blood for clot radius of (a) 0.1 cm (b) 0.2 cm and (c) 0.23 cm.

The model consists of about 80,000 tetrahedral elements and the mesh for the blood and artery regions enables us to solve for 168960 and 218763 degrees of freedom, respectively.

V. Simulation Results and Discussions

We have designed 3D computational models mimicking an artery, and incorporated different occlusion bodies inside this artificial arterial structure. These occlusion bodies are representative of blood clots or thrombus as seen in a large vessel thrombosis. Figs. 3-5 show the MCA thrombosis mechanism with occlusion of blood into a spherical clot with radius 0.1, 0.2 and 0.23 cm detailing velocity, pressure distribution among blood, and stress to artery wall structure using a colour table. These clot sizes represent a thrombus at its initial formation stage (20 % of artery diameter) to almost blocking stage (92 % of artery diameter). With the rise of clot size, velocity of blood, pressure among blood and stress on the wall increases abruptly. Considering Fig. 3(a)-(c), we can see that the velocity rises by 9 times (1 m/s to 9 m/s) near the clot region when the clot size increases form 20 % to 92 % of the artery diameter (0.5 cm).

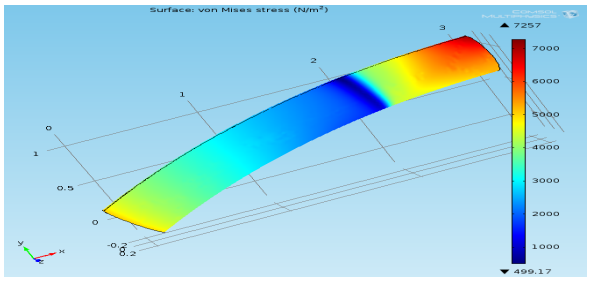
At the same time, developed blood pressures are inversely correlated with the velocity. For the occlusion, blood pressure rises before the clot and decreases after the clot. From Fig. 4(a)-(c), we can see that pressure rises abruptly from 2412.2 Pa to 6.39×10^4 Pa which may cause a thrombotic stroke. Stroke condition varies for different people. When diastolic pressure rises above approximately 12000 Pa (90 mm Hg), it increases the risk of stroke [18].

Fig. 5 shows the variation of stress on artery wall due to thrombus of various dimensions. With the rise of clot size, stress also rises. But this stress rising condition is highly non-linear. Maximum stress on artery wall raises from 3000 to 6.65×10^4 N/m^2 in various clot conditions. It is enough to cause haemorrhage if it finds a weak point on artery wall [19]. Brain haemorrhage is a type of stroke wherein damage induced in the artery results in localized bleeding in the brain and destroys the tissue and cell in the vicinity. It is a severe condition, wherein the person needs immediate medication/treatment. If the person is not subjected to proper treatment in time, it can result in further complications like loss of brain function and cause coma or death. However, the maximum tolerable stress of artery wall is not specified and depends on individuals conditions.

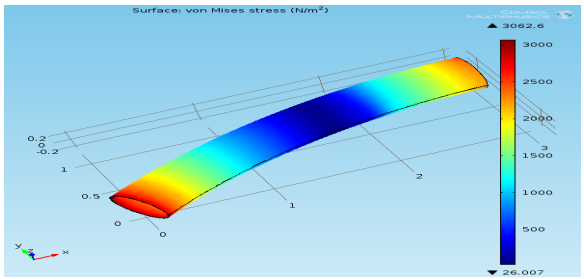
Fig. 6 shows inverse correlation between velocity and pressure with varying coordinates, and displays relative condition of velocity and pressure near clot. We can divide the pressure as positive and negative. Positive pressure works against the flow of blood. On the other hand, negative pressure increases the blood flow velocity. In various clot conditions, near clot we see the rise of negative pressure. That's why velocity there gets increased. With the rise of positive pressure, velocity of blood decreases.

VI. Conclusions

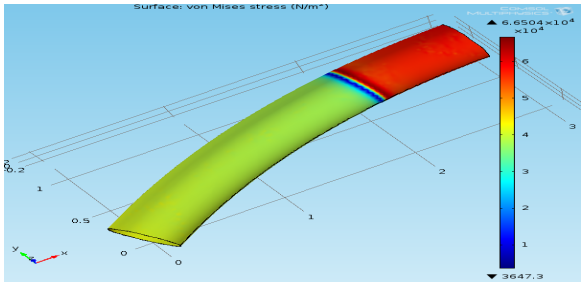
This works presented a three dimensional FE model and its numerical simulation results for the study of the blood flow along the middle cerebral artery (MCA) in the presence of clot



(a)



(b)



(c)

Fig. 5 Variation of stress on artery wall due to blood clot of different sizes of (a) 0.1 cm (b) 0.2 cm and (c) 0.23 cm.

(thrombus) considering fluid-structure interaction. The thrombus formation in the middle cerebral artery causes disturbance in blood flow. The model is used to explore the effects of minimal to maximal clot size formation in the blood flow. With the increase of clot size, the blood pressure before the clot rises significantly which then may result in a stroke. Before the clot, the stress on the artery wall also rises with the increase in clot size. Such stress on the artery wall may cause haemorrhage in a weak point. We believe that our proposed model will be helpful to predict the effects of thrombosis in the shorter period of time, and thus would enable the physicians and the scientists to take a better preventive measure.

Performance Analysis of BPPM and M-ary PPM in Free-Space Optical Communication Systems under Gamma-gamma Distribution Using APD and PIN

Md. Athaharul Islam * and Ashraful Bari Chowdhury

B.Sc. Student, Department of EEE, Ahsanullah University of Science and Technology, Dhaka, Bangladesh.
* E-mail: a1b2i3r45@gmail.com

Abstract—**Free-space optical (FSO) communication offers highly directional, high bandwidth communication channels, which is why it is often used in digital communication systems. However, atmospheric turbulence has a voluminous degradation in the performance of FSO communication system. Therefore, different modulation techniques are introduced to improve the performance of the FSO communication systems. In this paper, the modulation schemes considered for the proposed FSO system, are binary pulse position modulation (BPPM) and M-ary pulse position modulation (M-ary PPM). The channel fading is characterized using gamma-gamma distribution. APD and PIN photodiode are used as photodetectors. Performance of the FSO systems has been compared in terms of their bit error rates (BERs). The results obtained in the paper show the suitability of BPPM over M-ary PPM for both photodetectors and also indicate the suitability of APD over PIN photodiode for the considered modulation techniques.**

Keywords—Avalanche photodiode (APD), Bit error rate (BER), Free-space optics (FSO), Gamma-gamma distribution model, M-ary pulse position modulation (M-ary PPM).

I. INTRODUCTION

A Free Space Optical communication system is generally thought of as a system in which, there are no apertures or materials between the transmitter and receiver, i.e. the transmission medium is the air of the respective environment and the link is line-of-sight (LOS). Though, we assume an LOS path exists between the transmitter and receiver array, the transmitted field from laser will propagate through an atmosphere and may experience several effects [1]. So, the performance of FSO link is inherently affected by atmospheric conditions.

Turbulence is caused by the inhomogeneity of temperature and pressure and is responsible for refractive index variation of the air [2]. Turbulence causes amplitude and phase fluctuations in the optical beam traveling through the atmosphere. Such fluctuations deteriorate signal intensity at the receiver, increase bit error rate (BER). The effect of atmospheric turbulence on light waves has been extensively studied and various models for atmospheric channel have been proposed from time to time. Among them, the most widely used model in FSO communication systems for the probability of density function (PDF) is log-normal distribution due to its simplicity. However, it is only applicable to the weaker turbulence regime [3]. As the strength of turbulence increases, multiple scattering effects become important and significant deviations from log-normal statistics are exhibited in experimental data. Hence, we consider gamma-gamma distribution in this paper. Gamma–gamma distribution is a two parameter distribution which is based on a doubly stochastic theory of scintillation. Moreover, it has been shown that gamma–gamma distribution is valid for both weaker and stronger turbulence regimes [4].

For a high bit rate optical communications, APD is frequently the photodetector of choice due to its internal gain, which provides better sensitivity and fast response times than PIN photodiode. APDs are generally recommended for high bandwidth applications or where internal gain is needed to overcome high pre-amp noise [5]. However, APD has many drawbacks too, some of them are the high cost, the complex circuit, the temperature sensitivity and the need of high voltage power. This makes PIN more reliable than APD especially in lower data rates. Here we use silicon (Si) APD in the system because of the ionization ratio (ς).

Pulse position modulation (PPM) using intensity modulation with direct detection (IM/DD) is among the most widely considered modulation techniques for FSO system. PPM achieves high power efficiency and improves the system performance at the expense of reduced bandwidth efficiency compared to other modulation schemes such as on-off keying (OOK) [6]. Adopting low and high order M-ary PPM for FSO is shown to enhance the power and bandwidth efficiencies as compared to conventional modulation techniques [6], [7].

In this paper, we propose an analytical approach to evaluate the performance of a FSO system, which adopts low and high order M-ary PPM using two different type of receivers (APD and PIN); in order to make a comparison of performance between them. The performance results are evaluated in terms of bit error rate (BER) assuming that, the channel is modelled using gamma-gamma distribution.

II. SYSTEM MODEL

In the proposed FSO system the source bits are modulated using low and high order M-ary PPM. The transmitted light propagates over gamma-gamma distribution channel and additive white Gaussian noise (AWGN) due to shot noise and thermal noise are added at the receiver input. As receiver, we use PIN and APD to convert the light intensity into electrical current. It is assumed that full channel state information is available at the receiver. For M-ary PPM, one data symbol consists of M number of time slots, thereby transmitting

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

$L=log_2^M$ bits per symbol. In the transmitter, the signals are described by the waveforms,

$$X = S_M(t)=\begin{cases} 1, & for\ t \in (\frac{(M-1)T_s}{L}, \frac{MT_s}{L}) \\ 0, & elsewhere \end{cases} \quad (1)$$

At the receiver the received signal P in terms of intensity after optical/electrical conversion, is given by [8];

$$P = \eta h I_o + n \quad (2)$$

Here, $I_0 =$ the average transmitted light intensity, $I = hI_0 =$ the corresponding received intensity in an ON PPM slot, $h =$ the channel fading coefficient, $n =$ receiver noise.

III. CHANNEL MODEL

Gamma-Gamma Distribution:

The gamma-gamma model first proposed by Al-Habash et al. [9] is valid for all turbulence regimes from weak to strong regimes. It is based on the assumption that the fluctuation of the laser beam propagating through the turbulence medium consists of the refraction (I_1) and scattering (I_2) effects. Subsequently, the normalized irradiance is expressed as the normalized product of two independently statistical random processes I_1 and I_2 ; they are given in (3).

$$I = I_1 I_2 \quad (3)$$

Here, I_1 and I_2 represent the refraction and scattering effects, respectively and both are governed by the gamma distribution [9]. Thus, the Probability density function (PDF) of the gamma-gamma model for the received irradiance fluctuation is derived as (4).

$$f(I)=\frac{2(\alpha\beta)^{(\alpha+\beta)/2}}{\Gamma(\alpha)\Gamma(\beta)} I^{\frac{(\alpha-\beta)}{2}-1} K_{(\alpha-\beta)}\left(2\sqrt{\alpha\beta I}\right),\ I>0 \quad (4)$$

Here, I is the signal intensity, $\Gamma(.)$ is the gamma function, and $K_{(\alpha-\beta)}$ is the modified Bessel function of the second kind and order $\alpha\beta$. α and β are PDF parameters describing the scintillation experienced by plane waves [9].

IV. THEORETICAL ANALYSIS

The generalized BER of M-ary PPM in the gamma-gamma channel, P_b^M is given by [10].

$$P_b^M \leq \frac{M}{2}\sum_{i=-N, i\neq 0}^{N} w_i |x_i| Q\left\{\frac{E\{K_s\}x_i^2}{\sqrt{F\,E\{K_s\}x_i^2 + K_n}}\right\} \quad (5)$$

Here, M is the modulation level. In this paper, we have considered the value of M to be 2, 8 and 256.

w_i and x_i $(i = -N, -N+1, \ldots\ldots -1, 1, 2, \ldots\ldots N)$ are the weight factors and the zeros of the Hermite polynomial, respectively. These are well tabulated and are easily available in the literature/internet. The value of N can be chosen depending on the desired value of accuracy.

$E\{K_s\}$ is the average photons per PPM slot and it is a function of the mean (m_R) and the variance of the gamma-gamma distribution and has the form

$$E\{K_s\} = e^{\left(\frac{\sigma_R^2}{2} + m_R\right)} \quad (6)$$

Here, σ_R^2 is the Rytov variance. In (5), K_n is the total noise per PPM slot which results from background noise and thermal noise, is given by [11].

$$K_n = \frac{2\sigma_n^2}{(E\{g\}q)^2} + 2FK_b \quad (7)$$

Here, K_b is the average background noise photons per slot, $E\{g\}$ is the average gain of the APD, q is the electron charge and the variance, σ_n^2 of the thermal noise in a PPM slot is defined by [11]

$$\sigma_n^2 = \left(\frac{2KTT_{slot}}{R_L}\right) \quad (8)$$

Here, T is the effective absolute temperature of the receiver, K is the Boltzmann constant, R_L is the APD load resistance, T_{slot} is the PPM slot duration which is related to the data rate, R_b, by [11]

$$T_{slot} = \frac{\log_2(M)}{MR_b} \quad (9)$$

Considering the statistical nature of avalanche multiplication by using McIntyre formula, the excess noise factor, F in (5) and (7), is given by [12],

$$F = \varsigma E\{g\} + (1-\varsigma)\left(2 - \frac{1}{E\{g\}}\right) \quad (10)$$

Here, ς is the ionization factor. The McIntyre formula can be approximated for $\varsigma < 0.1$ and $E\{g\} > 20$ without significant loss of accuracy and so the noise factor, F, of APD is defined by [11],

$$F \approx 2 + \varsigma E\{g\} \quad (11)$$

Using the derived value of F from (11), first in (7) and then in (5), the BER expression for M-ary PPM using APD photodector is obtained.

Similarly, the BER expression for M-ary PPM using PIN photodiode is attained by setting both noise factor *(F)* and gain ($E\{g\}$) to unity in (10) and then using the obtained values in (7) and (5) [10].

V. RESULTS AND DISCUSSIONS

Based on the described model, the BER of 10^{-9}, which is considered as a practical performance target for FSO link [13], is calculated for gamma-gamma distribution and the obtained results are displayed in Figs. 1-8. The simulation is performed using matlab. System parameters used for computation are shown in Table I [6], [10].

TABLE I. SYSTEM PARAMETERS

Parameter Name	Value
Average gain, $E\{g\}$ (for PIN)	1
Background noise, K_b	10 photons per PPM slot
Data rate	2.4 Gbps
Ionization factor, ς	0.028
Length, L	100 m
Load resistance, R_L	50Ω
Modulation level, M	2, 8, 256
Rytov variance, σ_R^2	0.7
Temperature, T	300 K
Wavelength, λ	850×10^{-9} m

Variations of BER with the average number of photons received per PPM bit (logarithmic), which are equal to $log_{10}E\{K_s\}$/(number of bits in PPM symbol), are shown in the following figures.

Fig. 1, 2 and 3 depict the plots of bit error rate vs. average number of photons per PPM bit for different values of APD gain; respectively for M = 2, 8 and 256. From these figures it is clear that, for all modulation levels (M=2, 8, 256); increase in APD gain causes decrease in average photon number per PPM bit, indicating improvement in power efficiency.

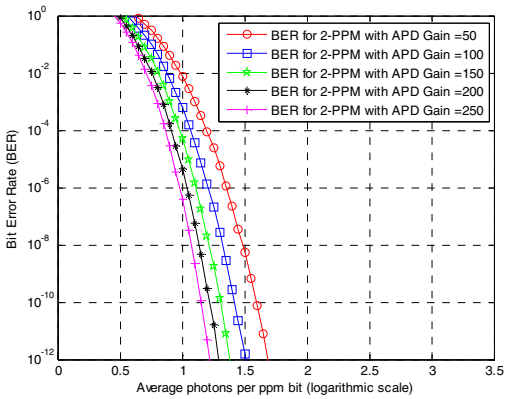

Fig. 1 Plots of BER vs. Average photons per PPM bit for 2-PPM.

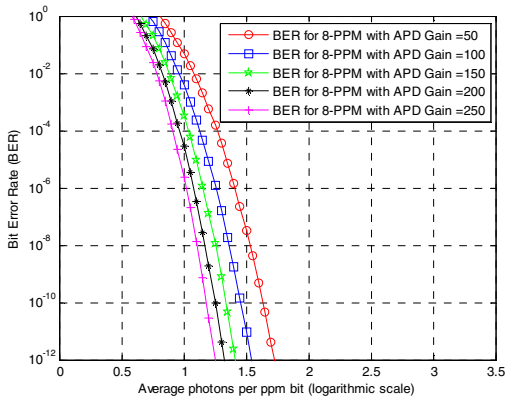

Fig. 2 Plots of BER vs. Average photons per PPM bit for 8-PPM.

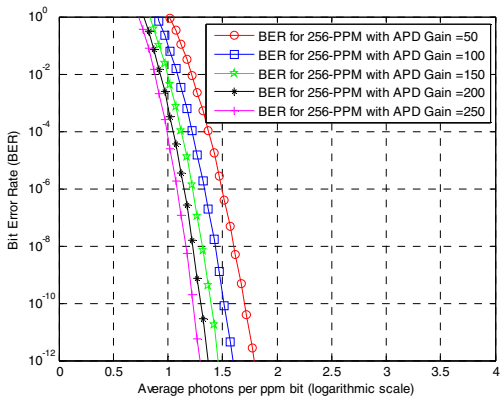

Fig. 3 Plots of BER vs. Average photons per PPM bit for 256-PPM.

Fig. 4 depicts the plots of bit error rate vs. APD gain for 256-PPM with different values of average photons per PPM bit ($E\{K_s\}$). It clearly shows that, up until APD gain ($E\{g\}$) reaches 150; increase in average photons per PPM bit ($E\{K_s\}$) causes decrease in BER. However, from then on, despite the increase in $E\{K_s\}$ along with $E\{g\}$, BER does not decrease anymore. This is because, a large $E\{g\}$ leads to an increase in excess noise factor *(F)*; which impedes the reduction of BER.

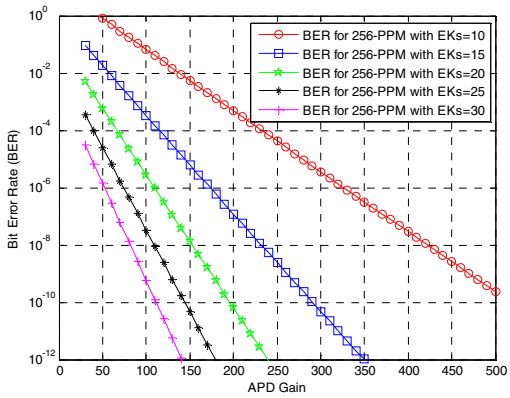

Fig. 4 Plots of BER vs. APD gain for 256-PPM.

Fig. 5, 6 and 7 illustrate the plots of bit error rate vs. average photons per PPM bit for low and high order (M=2, 8, 256) M-ary PPM with the value of gain, $E\{g\} = 150$ for APD under gamma-gamma distribution. From these figures it is clear that, for all cases (M=2, 8, 256), the average number of photons per PPM bit ($E\{K_s\}$) is almost 300 photons fewer, with APD than with PIN photodiode. This significant improvement in performance with APD, is due to the high internal gain ($E\{g\}$) of the APD.

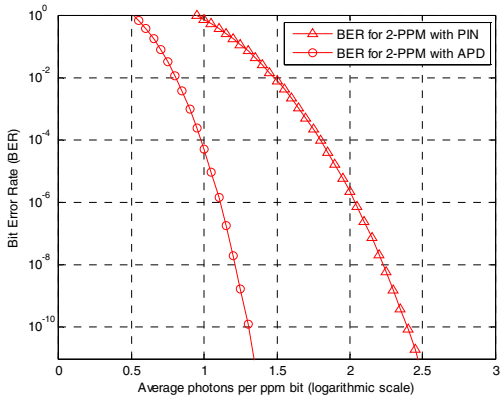

Fig. 5 Plots of BER vs. Average photons per PPM bit for 2-PPM with both PIN and APD photodetectors.

Fig. 8 represents a comparative illustration of Fig. 5, 6 and 7. It portrays the plots of bit error rate vs. average number of photons per PPM bit for low and high order (M=2, 8, 256) M-ary PPM using both PIN and APD photodetectors with the value of gain, $E\{g\} = 150$ for APD; under gamma-gamma distribution. Fig. 8 clearly shows that, as the modulation level (M) increases from 2 to 8 and then finally to 256, average number of photons per PPM bit ($E\{K_s\}$) slightly increases with higher values of M for both PIN and APD photodetectors; which implies that the performance of the system, slightly worsens with higher order PPM.

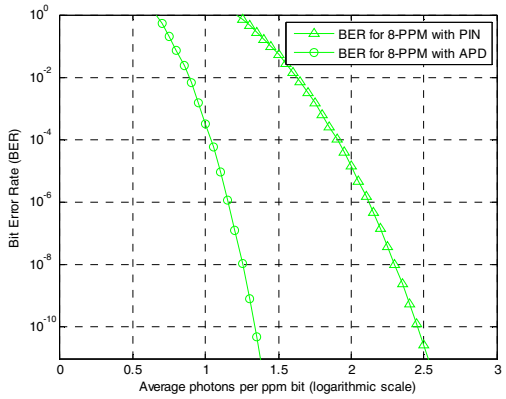

Fig. 6 Plots of BER vs. Average photons per PPM bit for 8-PPM with both PIN and APD photodetectors.

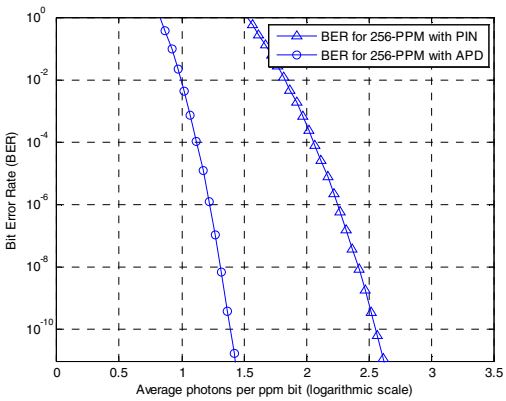

Fig. 7 Plots of BER vs. Average photons per PPM bit for 256-PPM with both PIN and APD photodetectors.

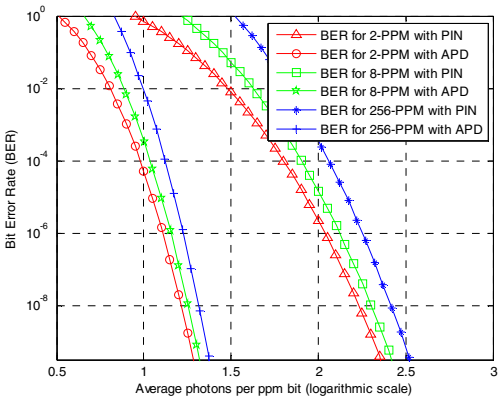

Fig. 8 Variations of BER with Average photons per PPM bit for different values of M with both PIN and APD photodetectors.

VI. CONCLUSIONS

In this paper, we have analyzed a FSO system employing low and high order M-ary PPM under gamma-gamma distribution using PIN and APD photodetectors. From the results we have concluded that, APD is better than PIN photodiode as photodetector with M-ary PPM in the cases of M=2, 8 and 256; due to the significant reduction of average number of photons per PPM bit with APD compared to PIN. It implies that, with M-ary pulse position modulated systems, APD is a more power-efficient solution compared to PIN photodiode. Moreover, we have found the optimal values of the APD gain up to which the excess noise factor does not deteriorate the system performance.

From the results, we have also concluded that, due to the slight reduction in the value of the average number of photons per PPM bit with BPPM compared to the higher order M-ary PPM, BPPM system is preferable over higher order M-ary PPM under gamma-gamma distribution for both PIN and APD photodetectors. Finally, it can be said that the optimal performance of the proposed system is achieved for BPPM with APD as receiver.

***Abstract*— We demonstrated a visible light communication system based on the 'White-Hot Spot' concept, using a commercially available white-phosphorus LED, modulated by an adaptive DMT signal. For a long wireless distance spanning from 1.5 m to 7 m, a record transmission rate was achieved, ranging from 1.2 Gbit/s to 693 Mbit/s, within the Hot-Spot area. The presented results can be useful to design high-speed optical wireless transmission links.**

Keywords*— *Visible Light Communication, Light Emitting Diode, Discerete Multitone Modulation

I. INTRODUCTION

Visible light communication (VLC) using light emitting diodes (LEDs) are considered a potential solution for indoor wireless communications, because it provides a synergy between illumination and communication. Moreover, spectrally efficient modulation formats, mostly Discrete Multi-Tone (DMT) [1], allow VLC to be used for high speed communications [2], [3].

Compared to radio frequency systems, VLC has the advantage of good spatial confinement, with the ability to maintain sufficient power density over quite small areas. Recently, a localized VLC link type, referred as 'White Hot-Spots' (W-HS), was suggested to ensure intense and focused light for data communication [4]. This approach enables very high data rate with reduced channel distortion and interference compared to conventional uniform lighting modes [5]. This W-HS scheme has a great potential for applications that require high-speed wireless links in small beam footprint. Examples can be personal passenger light in the aircraft or illumination of desktops in cubicle offices. Clearly, in order to meet the end-user requirements the W-HS must be shaped, adjusting the distance, the divergence angle and the corresponding illuminated area.

Here we experimentally demonstrate high-speed VLC systems using different W-HS areas by means of a phosphorescent white LED and adaptive DMT modulation. In the hot-spot area the maximum data rate was between 1.2 Gbit/s and 693 Mbit/s for distances spanning from 1.5 m to 7 m. In particular, considering the typical ceiling-desk distance of 2.5 m, the achieved capacity was 1.1 Gbit/s which is the highest capacityobtained at this distance to the best of our knowledge.

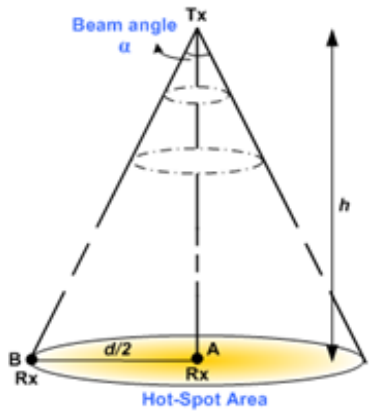

Fig. 1. *White Hot-spot scenario for VLC link. Tx: transmitter source; Rx: receiver.*

II. WHITE HOT-SPOT

Figure 1 shows a W-HS scenario. The power distribution of common LEDs generates a W-HS circular area, whose boundary circle is defined by the radius where the optical intensity is halved (point B) from the value at the centre (point A). This white area will be referred as 'Hot-spot Area' (HS-A). The HS-A diameter d is given by $d = 2h \tan(\alpha/2)$ where α is the beam divergence of the TX, h is the distance between the transmitter and (horizontal) plane where the receiver can be placed. Both parameters may be varied depending on the application (e.g., coverage area diameters of 1.5 m for cubical offices and 0.5 m for aircraft cabin seat [6]). From simple trigonometric calculation these coverage areas will be achieved by the divergence range from 16° to 20°. A spotlight with low emission angle can be used; in our experiment we used a commercial wide Field of View (FOV) LED chips and small FOV lens in order to reduce the divergence of the LEDs. View (FOV) LED chips and small FOV lens in order to reduce the divergence of the LEDs.

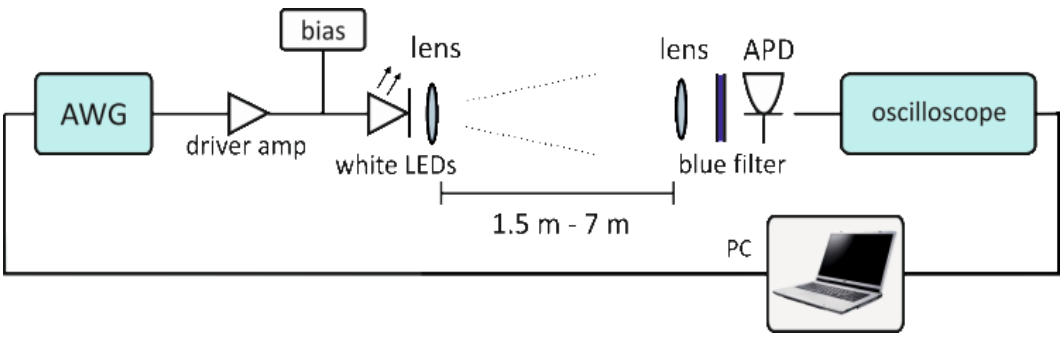

Fig.2: *Experimental setup for W-HS demonstration. AWG: Arbitrary Waveform Generator; APD: Avalanche PhotoDiode*

III. Experimental Set-up

In order to emulate the scenario of a VLC system exploiting the W-HS solution, we realized the experimental set-up shown in Fig. 2. The optical transmitter (Tx) was a board hosting three low cost phosphorus-white LEDs, closely mounted and connected in series. This source generates a total luminous flux of 400 lm at nominal driving currents of 350 mA, with 120° Lambertian emission, reduced down to 18° by using a proper low-cost lens. The receiver module (Rx) was placed in front of the LED and aligned to ensure the direct line-of-sight (LOS) between the Tx and Rx. The analogue receiver was an APD module consisting of an avalanche photodiode (APD, 0.42 A/W responsivity at 620 nm; 3.14 mm^2 active area) and an integrated TIA (Trans-Impedance Amplifier, 280 MHz 3-dB bandwidth). A dichroic optical band pass filter (Semrock, 97% transitivity at 452 nm, with 45 nm FWHM bandwidth) was placed in front of the APD to reject the slow phosphorescent components and a bi-convex glass lens (60 mm focal length) was used to focus the light onto the APD active area

The DMT waveform, consisting of 512 subcarriers within 205 MHz total bandwidth (optimized according to the channel response), was generated offline and uploaded into the Arbitrary Waveform Generator (AWG). The first carrier, corresponding to DC, was not modulated. The received signal was processed offline by a common PC. Before transmission, we first sent a signal probe having BPSK modulation on all the subcarriers; then we measured the Error Vector Magnitude (EVM) values of the received constellations and from these we evaluated the signal-to-noise ratio (SNR) values on the subcarriers [7] . In order to maximize the system capacity we adapted the modulation order and the power level depending on the channel SNR for each subcarrier [8]. The optimization of the system was performed by using the bit-power loading process to maintain the BER below the FEC limit [9]. We also applied a linear power pre-emphasis of 10 dB in the transmitted signal to take advantage of available electrical power. The DMT signal was first amplified by a power amplifier (25 dB gain, and 29 dBm minimum output power at 1-dB compression), then superimposed to a dc bias current (300 mA) via bias-T and sent to the LED. The output signal from the APD module was then sampled and stored by means of a real-time oscilloscope (Lecroy, 2 GSa/s) for offline demodulation. In DMT process the training sequence with zero-forcing equalization was used for estimation and correction of the channel. After the demodulation and signal correction, the BER value was computed comparing the original sequence with the recovered bits.

IV. Experimental Results and Discussions

We experimentally evaluated the system capacity for different HS-A values, keeping the beam divergence (18°) constant and varying the distance between transmitter and receiver *h*. At any HS-A condition, we measured the maximum data rate in the best and worst case; in the first case, we placed the receiver at the centre (point A in Fig. 1) and measured the maximum capacity. Then the receiver was moved to the boundary (point B) and we measured the minimum achievable data rate (worst case). Since the VLC link should not affect the general illumination level, we controlled the intensity level by a lux-meter in front of the Rx to be sure that the above level did not exceed the standard value for the working environments. Indeed we varied the distance *h* from 1.5 to 7 m, with an illuminance level from 460 to 17 lux (at point A) and from 380 to 14 lux (at point B). These values are well below the typical levels of the brightness in working environments (European Standard recommends 500 lx [10]).

Finally we report the results as a function of the height *h*, in order to evaluate the performance at usual distances between ceiling and working plane. We observed a good signal quality at every receiver position (point A and B). For

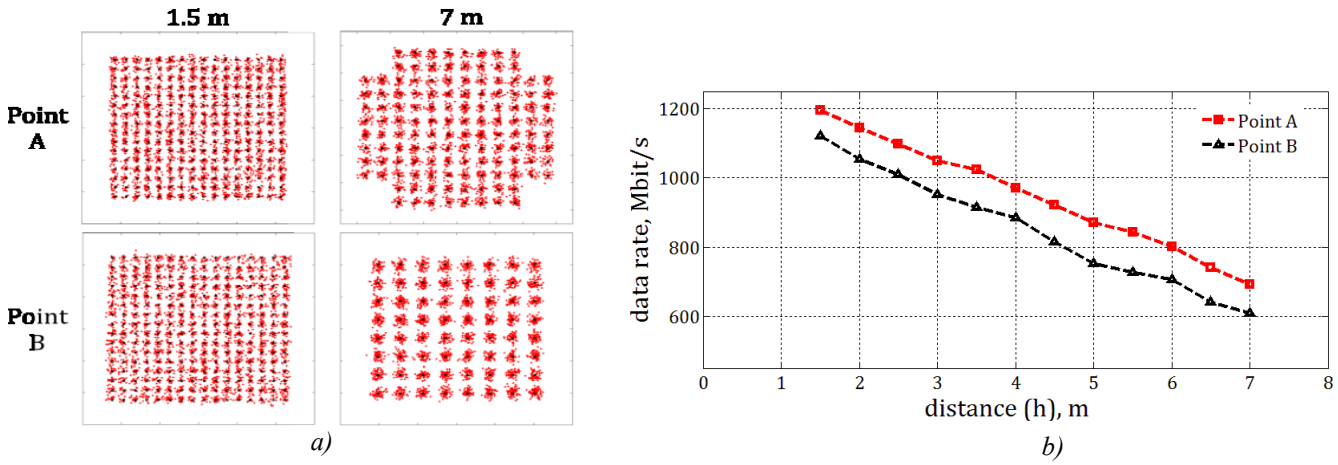

Fig.3: *Achieved capacity.*
a) received constellation diagrams: at point A, h=1.5 m and h=7 m (first row); at point B, h=1.5 m and h=7 m (second row).
b) capacity vs. distance h for both point A and B for each W-HS;

instance, Fig. 3*a* shows the received constellations of 2nd subcarrier at the distance of 1.5 m and 7 m for both the points A and B. In Fig. 3b we show the measured achievable data rate for the two positions i.e., at positions A and B varying h from 1.5 m to 7 m. When increasing the distance, the system capacity was mostly affected by the reduction in the received optical power. Note that the difference of data rate between the positions A and B of HS-A, which is mainly due to difference in the illuminance level, is approximately 100 Mbit/s. The data rate measured in the HS-A, considering *h*=1.5 m, is in the range of 1.1 Gbit/s (point B in Fig. 1) and 1.2 Gbit/s (point A). On the other hand, at *h*=7 m, a record system capacity was achieved within the range of 609 Mbit/s (point B) and 693Mbit/s (point A). The above mentioned data rates and system parameters allow to design a Gbit/s VLC system for LED based lighting. As an example, in an aircraft cabin scenario (h = 1.5 m, d = 50 cm) exploiting LED based lighting system [6], a guaranteed data capacity of 1.1 Gbit/s could be achieved by our VLC system. Moreover, in a typical Indoor application, where the ceiling-desk distance is around 2.5 m, the VLC transmission link can provide more than 1 Gbit/s within a circular area having of 80 cm diameter.

V. CONCLUSIONS

We experimentally demonstrated high capacity LED-based W-HSs for long distance indoor wireless communication. The proposed solution provides a record speed of 1.1 Gbit/s within coverage circle having 50 cm diameter at 1.5 m distance from the source. In a wider circular are (h =7 m) having 2.2 m diameter , 609 Mbit/s was also demonstrated.

Abstract— **The paper analyzes the performance of two forms of orthogonal frequency division multiplexing (OFDM) techniques called as DC biased Optical OFDM (DCO-OFDM) and Flip- OFDM for intensity modulated direct detection (IM/DD) system. The aforementioned OFDM schemes are compared in terms of peak-to-average power ratio (PAPR) and bit error rate (BER) as a function of electrical energy per bit to noise power ratio ($E_{b(elec)}/N_0$) when the signal is affected by additive white Gaussian noise (AWGN). In particular, 7-dB and 13-dB DC bias are used for DCO-OFDM in BER analysis and finally compared with flip-OFDM for the different data formats such as 4-,16-,64-,256- QAMs. The results show that flip-OFDM performs better in BER analysis with reduced value of ($E_{b(elec)}/N_0$) and thus, it can be considered as a power efficient unipolar modulation format. However, Flip-OFDM signal provides a high PAPR value that can deteriorate the overall system performance. Finally, OFDM signal performance tradeoff is measured as a function of transmitted optical power, QAM size, and spectral efficiency.**

Index Terms— **DCO-OFDM, Flip-OFDM, PAPR, BER, Intensity Modulation, Direct Detection.**

I. Introduction

Orthogonal frequency division multiplexing (OFDM) is a fast-progressing multi-carrier modulation scheme that is widely used in most of major wired and wireless communication systems now-a-days [1][2]. Especially in radio frequency (RF) domain, OFDM has been employed as a core part of the physical interface in the communication systems such as worldwide interoperability for microwave access (WiMAX), long term evolution (LTE) mobile network. Moreover, OFDM also has a great potential to use in optical system including optical wireless, multimode and single mode fibre optic communication system [3].

For the cost effective design of OFDM based optical system, the earlier investigations are mainly focused on intensity modulated (IM) optical transmitter with direct detection (DD) optical receiver [4]. For IM/DD system, OFDM signal needs to be unipolar i.e., real and positive, which is quite different from conventional OFDM scheme with bipolar symbols used in RF communication. The real valued OFDM signal is generated by Hermitian symmetric input data with Inverse Fast Fourier Transform (IFFT). However, to generate OFDM signal with positive values, several forms of OFDM schemes have been proposed for IM/DD optical system such as DC-biased optical OFDM (DCO-OFDM), Asymmetrically clipped optical OFDM (ACO-OFDM), flip-OFDM [5][6][7].

In DCO-OFDM, a DC-bias is added to make the OFDM signal positive, where the required bias value depends on the peak-to-average power ratio (PAPR) of OFDM symbols. As the OFDM signal has high PAPR value, the transmit optical power need to be increased, which eventually makes the DCO-OFDM power inefficient. For a power efficient modulation format, ACO-OFDM is proposed to avoid the use of any DC-bias. In ACO-OFDM, only the odd-subcarriers are used to carry the information and clipped the negative values at the transmitter. It is shown that ACO-OFDM is more power efficient than DCO-OFDM, however, in terms of bandwidth utilization, ACO-OFDM is inefficient due to the use of half number of subcarriers for data. Recently, another modulation technique is proposed for unipolar signal called as flip-OFDM, where the positive real time domain signal is transmitted in two consecutive OFDM symbols. It is shown that flip-OFDM provides 50% less implementation complexities compared to ACO-OFDM [5].

This paper provides a comparative analysis between the conventional DCO-OFDM and recently proposed flip-OFDM for IM/DD optical system in terms of bit error rate (BER) performance, PAPR label and optical power efficiency. The BER curves are plotted against electrical energy per bit to noise power ratio assuming that the received signal is corrupted with Additive White Gaussian Noise (AWGN) [8]. The PAPR of DCO- and Flip- OFDM are computed against a range of predetermined threshold values in dB unit. Moreover, the effect of average transmitted optical power on the BER performance is also analysed for both the aforementioned OFDM schemes with respect to normalised bandwidth/bit rate. These results have practical implications in both the wireless and optical fibre IM/DD communication systems.

The rest of the paper is organised as follows. Section II gives a description of system blocks of the two OFDM schemes. Section III provides comparison among those OFDM schemes in terms of BER vs. ($\boldsymbol{E_{b(elec.)}/N_o}$), PAPR and $\mathbf{E_{b(opt.)}/N_0}$ vs. normalised bandwidth / bit rate. Finally, we provide the conclusion in section IV.

II. Study of Direct Detection OFDM Schemes

In this section, we provide brief description about the DCO-OFDM and flip-OFDM systems consecutively.

A. DCO-OFDM

DCO-OFDM transmitter and receiver are shown in Fig.1. At the first step of modulation procedure, a high rate binary

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

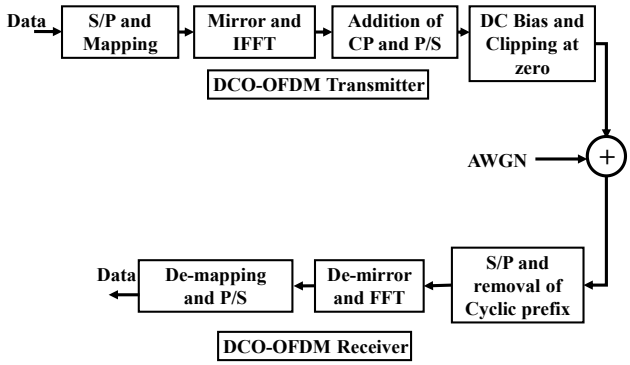

Figure 1: Implementation blocks for DCO-OFDM system

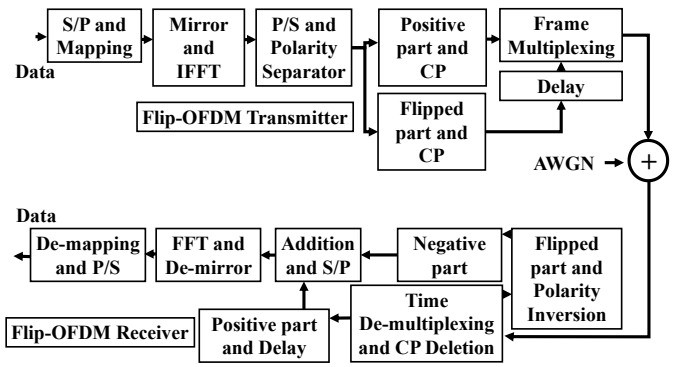

Figure 2: Implementation blocks for Flip-OFDM system

serial data sequence is divided into a number of parallel lower rate data streams that are transmitted simultaneously over a number of subcarriers. Each data stream goes through constellation mapping where every log_2(M) bits are mapped onto complex values according to an M-ary quadrature amplitude modulation technique. For $X_n = A_n + jB_n$, where, $n = 0, 1\ldots, N$-1 denotes the subcarrier number, Hermitian symmetry is taken by complex conjugate mirroring as defined below,

$$X_{N-n} = X_n^* \tag{1}$$

where $n = 0,1,\ldots,N/2$ and $X_0 = X_n = 0$. By taking N-point IFFT, real value k^{th} sample is denoted by x_k as,

$$x_k = \frac{1}{\sqrt{N}} \sum_{n=0}^{N-1} X_n \exp\left(\frac{j2\pi nk}{N}\right) \tag{2}$$

Thus a DCO-OFDM symbol is generated with N point real value bipolar data sequence. Afterwards, cyclic prefix (CP) is added in each OFDM symbol and sends to parallel to serial converter for serial data transmission. Finally, DC bias is added and clipped the signal at zero label to ensure non-negative data transmission.

Additive white Gaussian noise (AWGN) is considered in the propagation channel to include noise effect on received data. At the receiver, DCO-OFDM frame is divided into (N+N_{CP}) parallel data streams. The number of DCO-OFDM symbols obtained from this serial to parallel conversion process is exactly equal to that of symbols transmitted. Cyclic prefix is then removed from each symbols and demodulation is performed successively using N point FFT. The complex valued data streams can be generated from the FFT operation as,

$$X_n = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} x_k \exp\left(\frac{-j2\pi nk}{N}\right) \tag{3}$$

The output of this FFT process is de-mirrored and applied to M-ary QAM demodulator to recover the original transmitted binary data streams. At the end, parallel data streams are again converted into serial data streams in binary form and compare with transmit data for BER measurement.

B. Flip-OFDM

Fig.2 shows the block diagram of the generation and reception of Flip-OFDM signal. In the transmitter, the real bipolar OFDM signal is generated following the same procedure like DCO-OFDM signal. However, the incoming bipolar signal is then decomposed into

$$x(k) = x^+(k) + x^-(k) \tag{4}$$

where the positive and negative parts of the Flip-OFDM are defined as,

$$x^+(k) = \begin{cases} x(k) & if\ x(k) \geq 0 \\ 0 & otherwise \end{cases}$$
$$x^-(k) = \begin{cases} x(k) & if\ x(k) \leq 0 \\ 0 & otherwise \end{cases} \tag{5}$$

where $k = 0,1,2,\ldots,N$-1. Two successive OFDM symbols are used to transmit the aforementioned components. The positive part $x^+(k)$ is transmitted in the first sub-frame, whereas the flipped signal $-x^-(k)$ is transmitted in the second sub-frame. Cyclic prefix is added to both the OFDM frames resulting the length of (N+N_{CP}), where N_{CP} is the length of cyclic prefix. Finally, the frames are multiplexed with all the positive real values and send to the desired propagation channel.

At the Flip-OFDM receiver, bipolar OFDM symbols are reconstructed using two data frames namely positive and flipped parts as shown in Fig.2. Firstly, the cyclic prefixes are removed from both of data frames and after this subtraction operation is performed which provides original bipolar signal as,

$$y(k) = y^+(k) - y^-(k) \tag{6}$$

where $y^+(k)$ and $y^-(k)$ represent positive and flipped data frames respectively. FFT operation is performed on this bipolar signal to generate the original complex conjugate data sequences. De-mirroring and QAM demodulation processes are used to reconstruct the binary stream from the complex valued signal.

III. COMPARISON OF DCO-OFDM AND FLIP-OFDM

A. $(E_{b(elec.)}/N_o)$ *vs. BER :*

The ($E_{b\,(elec.)}$ /N_0) vs. BER curves were computed for both type of OFDM signals to compare their performance in AWGN channel. The BER curves of 7 dB biased DCO-OFDM for 4, 16, 64, and 256-QAM are shown in fig.3. To reach BER at 10^{-4}, 600 OFDM symbols are used with 1024

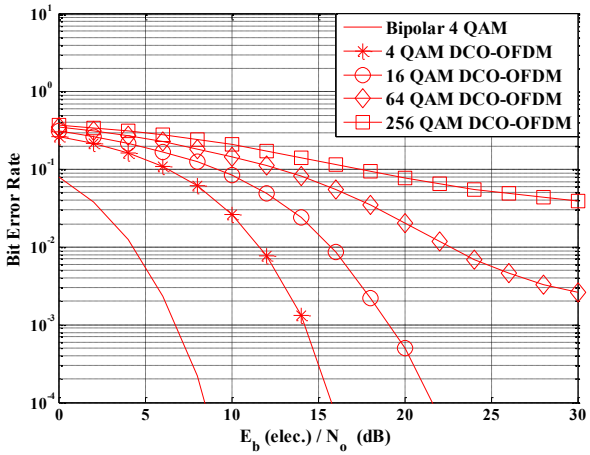

Figure 3: BER analysis for 7 dB biased DCO-OFDM

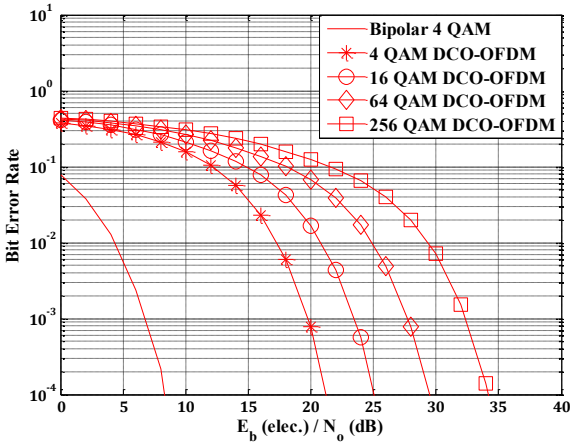

Figure 4: BER analysis for 13 dB biased DCO-OFDM

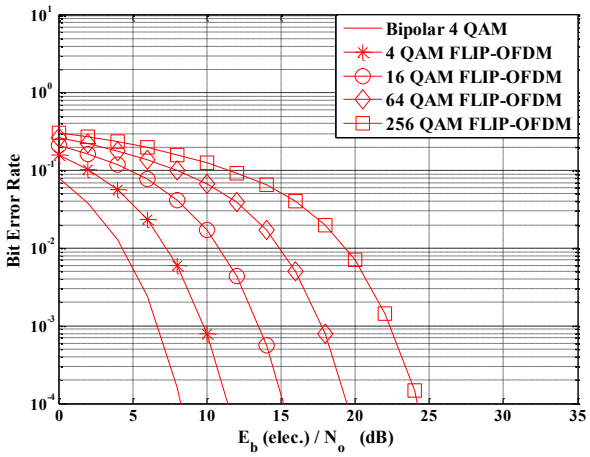

Figure 5: BER analysis for Flip-OFDM

subcarriers in each symbol and the cyclic prefix length was 16. Fig.3 shows that clipping noise dominants for higher constellation size especially in 64- and 256-QAM, which eventually provides the BER floor. However, 4-and 16-QAM modulation formats are still give a better BER performance with the required electrical power higher than the conventional bipolar OFDM. With the increase of DC bias to 13 dB, the clipping noise can be reduced that improves the BER performance for high constellation size modulation formats as shown in Fig. 4. For DCO-OFDM as justified from both the figures 3 and 4, the required $E_b(elec.)/N_0$ for a given BER is approximately equal to the $E_b(elec.)/N_0$ for a bipolar signal plus the bias level in dB. The BER vs $E_b(elec)/N_0$

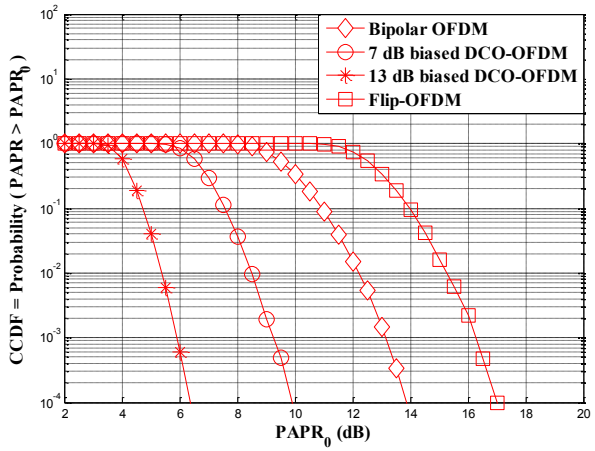

Figure 6: CCDF curves for DCO-OFDM and Flip-OFDM

performance for Flip-OFDM, as shown in fig.5, is more power efficient compare to DCO-OFDM as it requires much less power to achieve the target BER and also to maintain the same data rate. This is mainly due to the average symbol energy which is quite low compare to the DCO-OFDM.

B. *PAPR :*

PAPR is the ratio of peak signal power to average signal power. OFDM signal inherently possess high PAPR as it has large number of subcarriers overlapped to each other. OFDM signal with high PAPR requires a linear power amplifier in the front end transmitter which eventually increases the system implementation cost. Therefore, it is desirable to minimize the PAPR value for the generation of OFDM signal. Fig. 6 shows the PAPR performance for DCO- and Flip OFDM as defined by [9]:

$$PAPR_{dB} = 10 \times \log_{10}\left(\frac{\max[(x_{DCO\,or\,Flip})^2]}{E[(x_{DCO\,or\,Flip})^2]}\right) \qquad (7)$$

The PAPR performance is normally expressed in complementary cumulative distributive function (CCDF). CCDF is defined as the probability that the PAPR exceeds a certain value $PAPR_0$,

$$CCDF = 1 - P(PAPR_{DCO\,or\,Flip}(dB) \le PAPR_0) \qquad (8)$$

For this PAPR measurement, we used an OFDM signal with the IFFT size of 256 and 4-QAM data modulation for each carrier. Fig. 6 shows that Flip-OFDM undergoes PAPR penalty compare to DC biased OFDM signal. In particular, PAPR ratio is around 3.7 dB high than the bipolar OFDM. Moreover, the PAPR value is increased to around 7.2 dB and 10.2 dB for flip-OFDM in compare with 7 dB and 13 dB biased DCO-OFDM. The increase of PAPR for flip-OFDM is mainly due to low value of total average power that arises from many zero values in both positive and flipped frame. However, for DCO-OFDM the large bias voltage improves the average power as well as reduced the negative peaks and thus, 13-dB bias OFDM performs better compare to 7-dB bias for PAPR measurement as shown in fig. 6.

C. *Bandwidth vs.* ($E_{b(opt.)}/N_o$)

We now compare the DCO-OFDM and flip-OFDM in

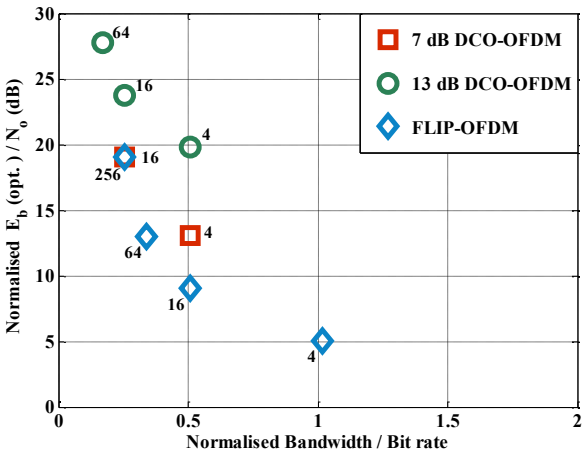

Figure 7: $E_{b(opt.)}/N_0$ for BER 10^{-3} vs Normalized bandwidth per bit rate for DCO- and Flip- OFDM

terms of transmitted optical power to noise power ($E_{b(opt.)}/N_0$) and spectral efficiency as these parameters have the importance in practical implementation. This simulation is performed by adopting unity optical power ($P_{opt.}^{DCO} = P_{opt.}^{FLIP} = 1$) for both Flip and DCO-OFDM. As a result, we can derive the relationship between electrical and optical power for this two OFDM schemes as defined by [7],

$$\frac{E_{b,opt.}^{DCO}}{N_0} = \frac{k^2}{1+k^2}\frac{E_{b,elec.}^{DCO}}{N_0} \tag{9}$$

$$\frac{E_{b,opt.}^{FLIP}}{N_0} = \frac{1}{\pi}\frac{E_{b,elec.}^{FLIP}}{N_0} \tag{10}$$

Here, constant k is obtained by equating the numbers 7 and 13 with the statement $10log_{10}(k^2+1)$ for DCO-OFDM with 7 and 13 dB bias respectively. The simulation results shown in fig.7 clearly reveals that normalised bandwidth per bit rate of 7-dB and 13-dB biased DCO-OFDM with 4-QAM data format are identical and reach to around 0.5. However, Flip-OFDM shows the value of 1.0, which indicates the necessity of double bandwidth for the same modulation format. The reason behind this large bandwidth for Flip-OFDM is the bipolar samples that are divided into positive and flipped parts with equal length each. However, in terms of optical power efficiency, flip-OFDM outperforms the DCO-OFDM as also predicted before. In particular, flip-OFDM shows the power value of 5 dB for 4-QAM data signal, whereas the power increases to 13 dB and 20 dB for the DCO-OFDM with 7-dB and 13-dB bias respectively. With the high constellation size, the performance of flip-OFDM is close to the DCO-OFDM especially with 7 dB bias condition.

IV. Conclusion

In this paper, the performance of Flip-OFDM is compared with DCO-OFDM on the basis of three parameters, BER as a function of ($E_{b(elec.)}/N_o$), PAPR and ($E_{b(opt.)}/N_o$) as a function of normalized bandwidth/bit rate. Flip-OFDM has better BER performance compare to DCO-OFDM, however, it shows high PAPR value mainly due to lower average power. Moreover, flip-OFDM exhibits considerable power gain for the same normalised bandwidth/bit rate with respect to DCO-OFDM. On the other hand, the performance of DCO-OFDM depends on the bias value, where the large bias is useful to reduce the clipping noise.

***Abstract*—To provide higher capacity optical fiber networks, a 107 Gb/s transmission system is simulated by using the combined features of polarization multiplexing (PM), quadrature phase shift keying (QPSK) and forward error correction (FEC). The lower tolerance to linear and nonlinear fiber impairments remains a major concern at a higher bit rate. To address the limitations set by the linear impairments, coherent detection of multilevel modulation formats with polarization division multiplexing appears as a promising solution by reducing the symbol rate to one-forth. Electronic dispersion compensation (EDC) and constant modulus algorithm (CMA) are used at the receiver for the linear dispersion compensation and forward error correction (FEC) respectively. Fiber spans each of 90 km are used in this simulation making the transmission length 1980 km. The bit rate of the modulating signals is kept at 26.75 Gb/s and the aggregate transmission rate of 107 Gb/s by utilizing the combined features of PM and QPSK. The power sharing of both the polarization components in the presence of polarization mode dispersion (PMD), fiber nonlinearities and random birefringence is a very important for the system design. In this paper, the PMD tolerance of the system at different transmitting powers with and without the presence of nonlinearities and birefringence are simulated and evaluated in terms of the bit error rate (BER). Transmitting power of 2.518 mW is found as the optimum value for single channel PM-QPSK systems at PMD 0.05 ps/sqrt(km).**

***Keywords*—Polarization multiplexing, quadrature phase shift keying, coherent detection, electronic dispersion compensation.**

I. Introduction

Transmission in optical fiber communication systems is impaired and ultimately limited by chromatic dispersion, amplified spontaneous emission noise from amplifiers, polarization effects and fiber nonlinearities [1]. The transmitting power level has a direct implication in setting the operating parameters for high bit transmission. At higher power level, the nonlinear parameters play dominant role [2]. For conventional coherent direct-detection single-carrier systems, the impairment induced by a constant differential group delay (DGD) scales with the square of the bit rate, resulting in drastic PMD induced degradation for high speed transmission systems [3,4]. Complementary features of PM and QPSK provide a way out of achieving the bit rate. At this high bit rate, the PMD effects are difficult to analyze because they are stochastic in nature. Hence modeling the effects of PMD is not straight forward. Random change of the fiber birefringence affects the correlation length and the beat length of the fiber [5,6]. The power sharing between the orthogonal polarization components of the optical field along the slow and fast axis becomes important. On the other hand Karr nonlinearity is the main source of nonlinearity is deterministic and can be modeled to analyze its effects on the data transmission. Karr nonlinearity leads to phase rotation that is proportional to the intensity at every point in time [7,8]. When the nonlinearity couples with other transmission impairments such as PMD, it can lead to complex dynamics. Thus PMD which is stochastic in nature and nonlinearity which is deterministic in occurrence should be addressed together for modelling high speed data transmission systems [9,10]. Nonlinear birefringence is another source of impairment in fiber communication [11].

If $A_x(z,t)$ and $A_y(z,t)$ as the complex envelops of the x and y components of the electromagnetic field of the propagating mode, then [12],

$$E_x(z,t) = A_x(z,t)\exp\left[j(k_0 z - \omega_0 t)\right] \quad \text{..... (1a)}$$

$$E_y(z,t) = A_y(z,t)\exp\left[j(k_0 z - \omega_0 t)\right] \quad \text{.....(1b)}$$

In the presence of chromatic dispersion and Kerr third-order nonlinearities, the propagation of light in a single linearly birefringent section is given by the coupled nonlinear Schodinger equation [12]:

$$-j\frac{\partial A_x}{\partial z} = (\beta_x(\omega_0) - \beta_0)A_x + j\left.\frac{d\beta_x}{d\omega}\right|_{\omega_0}\cdot\frac{\partial A_x}{\partial t} - \frac{1}{2}\left.\frac{d^2\beta_x}{d\omega^2}\right|_{\omega_0}\cdot\frac{\partial^2 A_x}{\partial t^2} + j\frac{\alpha}{2}A_x + \gamma\left[|A_x|^2 + \frac{2}{3}\left|A_y\right|^2\right]A_x + \frac{\gamma A_y^2 A_x^*}{3} \quad \text{..... (2a)}$$

$$-j\frac{\partial A_y}{\partial z} = (\beta_y(\omega_0) - \beta_0)A_y + j\left.\frac{d\beta_y}{d\omega}\right|_{\omega_0}\cdot\frac{\partial A_y}{\partial t} - \frac{1}{2}\left.\frac{d^2\beta_y}{d\omega^2}\right|_{\omega_0}\cdot\frac{\partial^2 A_y}{\partial t^2} + j\frac{\alpha}{2}A_y + \gamma\left[\left|A_y\right|^2 + \frac{2}{3}|A_x|^2\right]A_y + \frac{\gamma A_x^2 A_y^*}{3} \quad \text{..... (2b)}$$

where the first terms on the right hand side expresses the phase velocity as well as the effect of the birefringence, the second term the group velocity, third term the dispersion, fourth term the loss, fifth and sixth terms the nonlinearity. Each of these terms has its own length scale. The birefringence, represented by the first term will rotate the state of polarization of the propagating light, completing a full circle around the s_1 axis of the Poincare sphere every beat-length. When power and intensity dependent nonlinear effects in optical fibers become dominant, the optical field can induce nonlinear birefringence.

Digital signal processing along with phase and polarization diverse coherent receiver proved to be a promising technology for high data transmission networks. EDC could compensate 107,424 ps/nm of chromatic dispersion over 6400 km of standard single mode fiber [13]. Enhanced FEC (EFEC) system has excellent error correction capability and can correct an error up to approximately an error rate of 10^{-3} by performing Concatenated Coding [14]. Though PM-QPSK system offers a solution for achieving higher transmission rate, the design of the system needs careful selection of the operating parameters. Increase in transmitting power causes an increase in fiber nonlinearity putting a limiting concern. Hence this paper reports the optimum transmitting power of the system and its PMD tolerance.as a noble techniwu

II. SYSTEM SETUP

Designing WDM channels at 107 Gbit/s rate is more challenging than 26.75 Gbit/s. But the features of PM and QPSK are combined to achieve the same high transmission rate through a network which is designed to handle only one fourth of the transmission rate. In QPSK system, two data streams are taken as input to modulate the phase of the carrier. The phase of each of the bisected part of coherent source light is similar and taken as the reference phase. One part of the bisected light is used as the carrier for one data stream and the data stream amplitude modulates the source light. Another data stream is also used to amplitude modulate (AM) the other part of the bisected source light. The phase of the amplitude modulated optical signal that corresponds to second data stream is further phase modulated by a constant bias voltage. Then the AM optical signal that carries first data stream and the amplitude as well as phase modulated optical signal that carries second data stream are combined by a beam combiner. Figure 1(a) depicts the QPSK modulator module. This modulator takes the source light from a coherent source which is bisected using a polarization maintaining splitter. Upper amplitude modulator implements AM to the coherent optical signal using Data 1. Lower amplitude modulator implements AM to the optical signal using Data 2. Output of the lower modulator is then sent to the phase modulator. The phase shift bias voltage generates 180^0 phase shift on the optical signal. The output of the Phase Modulator and the output of the upper Amplitude Modulator are combined using the Beam Combiner.

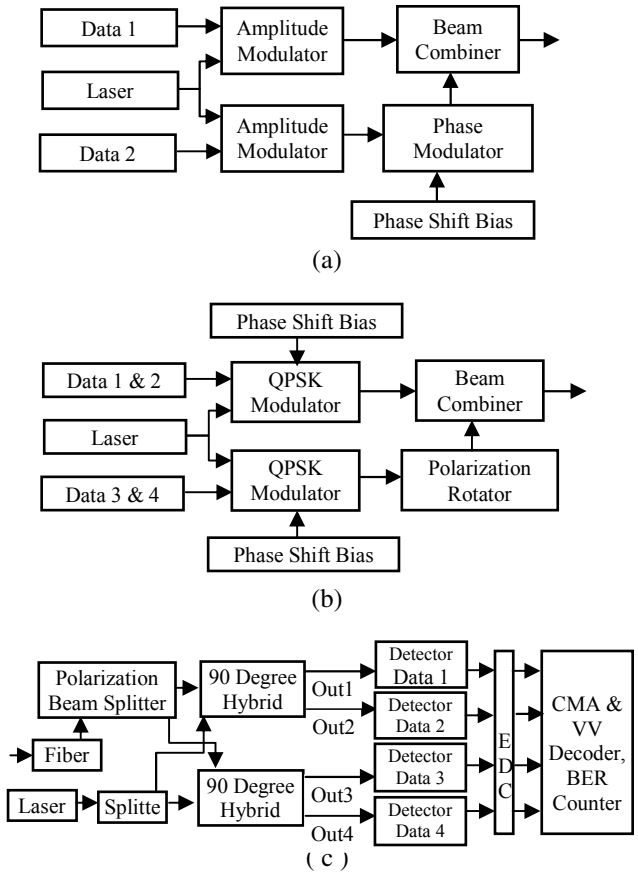

Figure 1. (a) the QPSK modulator section, (b) the polarization multiplexing section and (c) the receiver section.

Fig. 1(b) shows the polarization multiplexing that is consist of two QPSK modulator modules, one polarization rotator and one beam combiner. Both the QPSK Modulators take the coherent light from the same source. Two QPSK modulator modules take four data streams. Output of the lower QPSK Modulator that corresponds to Data 3 and 4 are passed through the polarization rotator. Polarization rotator rotates the angle of the optical field by 180^0 that relates to the S_3 of Poincare Sphere. The beam combiner is used to combine the output of the first QPSK modulator and the output of the polarization rotator. Thus by using the features of PM, two QPSK data are accommodated within the band limit. Finally four data streams are sent within the bandwidth of one data stream. But the maintenance of optimum power level in two polarization modes is essential to keep the error of the transmission with in tolerance.

The receiver section as shown in Figure 1(c), consists of the 90 degree hybrid, detector, EDC) and error correction module. A laser source is used at the receiver section to supply the reference light to two 90 degree hybrids through a splitter. The outputs 1 and 2 from the upper hybrid correspond to the modulated signal of data 1 and 2. Similarly the output 3 and 4 of the lower hybrid corresponds to the modulated signals of data 3 and 4. Four detectors are used to detect the data 1-4. Then the detected data are passed to EDC. Finally constant modulus algorithm is used for implementing the forward error correction. Viterbi and Viterbi algorithm is used for decoding the data. For encoding and decoding data, binary polynomials of degree 11 are used. Polynomials 1-4 are used for input data 1-4 respectively.

To simulate the PM-QPSK system, necessary noise loading is implemented and channel losses are considered. Standard loss of 0.22 dB/km is included in the in the simulation. Uncompensated fiber of dispersion 3.8 ps/nm/km at reference frequency of 193 THz is considered. Fiber spans each of 90 km followed by an amplifier with amplification enough to cover up the loss suffered in the fiber are used. Total 22 spans are implemented resulting the 1980 km of fiber.

III. SIMULATION AND DISCUSSION

The simulation is carried out with the help of OptSim and MATLAB software where total 65536 bits are used. Since the bit error rate (BER) is based on the actual counting of the errors, BER with the probability less than 10^{-6} is shown as zero. But with forward error correction tools as used in this simulation, any error with BER less than 10^{-3} can be automatically corrected [13,14]. 65536 bits are found reasonably sufficient to give reliable results. Parameters like transmitting power, PMD, nonlinearities, birefringence and fiber length are taken into consideration in this simulation. Output of the booster at transmitter end just before the fiber is taken as the transmitting power. The booster amplification is varied from -4 to 5 dBm which corresponds to 0.632556 to 5.02457 mW. The PMD coefficient is varied from 0.02 to 0.2 ps/sqrt(km) to study the change of PMD. To simulate the effect of the variations of nonlinearities, the fiber nonlinear coefficient is varied from 0.05 to 2.5 1/Watt/km. The fiber birefringence is varied statistically following the Maxwell probability distribution. The fiber length is kept 1980 km to study the effect of power, nonlinearity and birefringence. The analytical simulation of Eq 1 is carried out in six steps. Firstly, impact of PMD alone on BER is simulated. The impact of changing PMD in the absence of nonlinearities and birefringence on the BER of the system is depicted in Figure 2. The level is varied within 0.5-5.5 mW and the simulated PMD values are 0.02, 0.1 and 0.2 ps/sqrt(km). The results show that the BER is well below 10^{-3}. Secondly, impact of

PMD and birefringence are simulated as shown in Figure 3. The birefringence are varied following the Maxwell distribution. This addition of birefringence caused the BER to increase. But the BER is well below 10^{-3} for almost all transmitter powers.

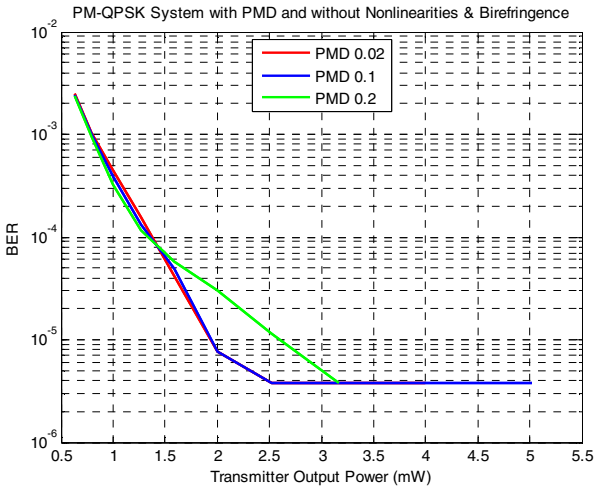

Fig. 2. BER-Power curve of PM-QPSK system with PMD and without nonlinearities & birefringence.

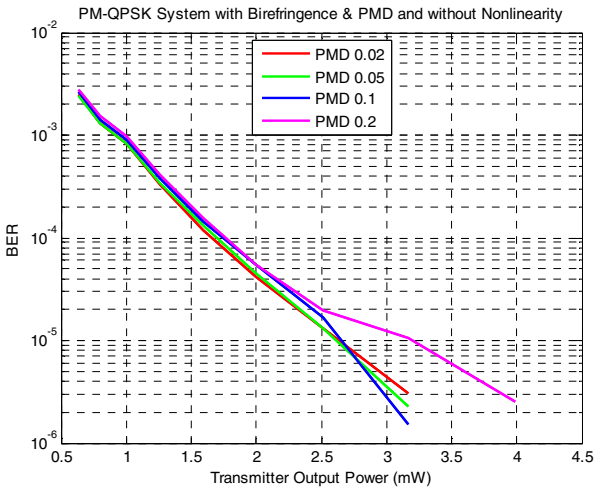

Figure 3. BER-Power curve of PM-QPSK system with PMD & birefringence and without nonlinearities.

In the third step, the simulation is carried out considering then impact of nonlinearities only, in the absence of PMD and birefringence as shown in Figure 4. The BER level goes down at power level around 1 mW. But soon with the increase of the transmitter power, the BER increases almost monotonically. The power level is varied from 0.5-5 mW for nonlinearities 0.5-2.5 1/W/km with interval of 0.5 1/W/km. When the power level is increased with low nonlinearity, the BER remains within the acceptable limit. For nonlinearity around 0.5 1/W/km, the BER remains low. But when the nonlinearity is increased more than 1 1/W/km, the BER rises sharply with the increased power and the BER crosses the acceptable limit. It is also noticeable that for the standard value of nonlinearity of 1.5 1/W/km, the BER goes beyond acceptable level. In the fourth step, PMD and nonlinearities are taken into account. Here the nonlinearities are kept fixed at the standard value of 1.5 1/W/km and the PMD values are changed Figure 5 shows the BER-power curve with nonlinearities and PMD in to consideration but the effect of the random birefringence is omitted. As seen from the Figure 5, with the increase in the transmitting power, the BER increases having the similar pattern caused by the nonlinear effects alone. But the combined effect of nonlinearity and PMD has changed the curve pattern significantly. The effect of the higher

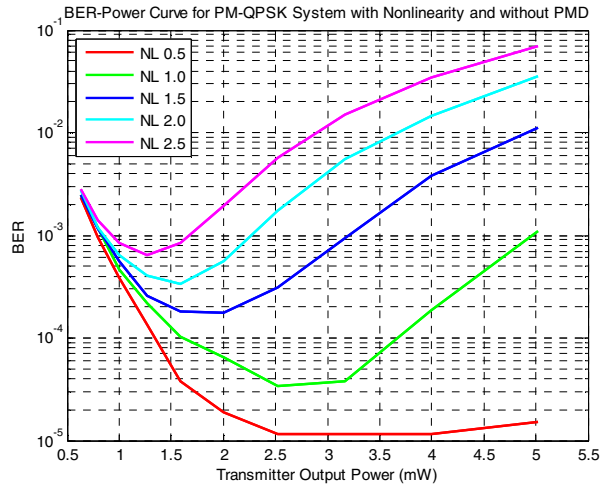

Figure 4. BER-Power curve of PM-QPSK system with nonlinearities and without PMD & birefringence.

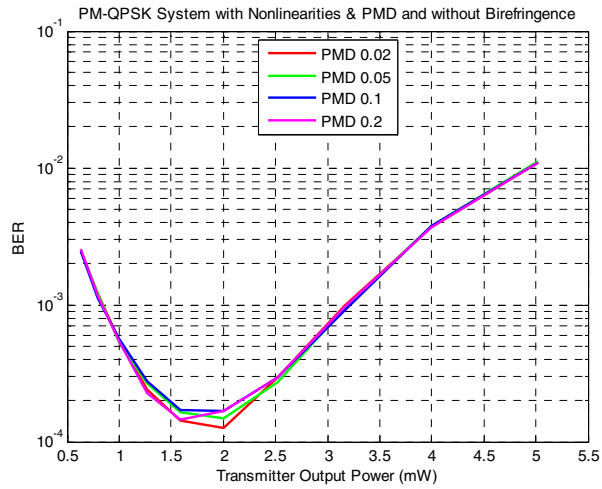

Figure 5. BER-Power curve of PM-QPSK system with nonlinearities & PMD and without birefringence.

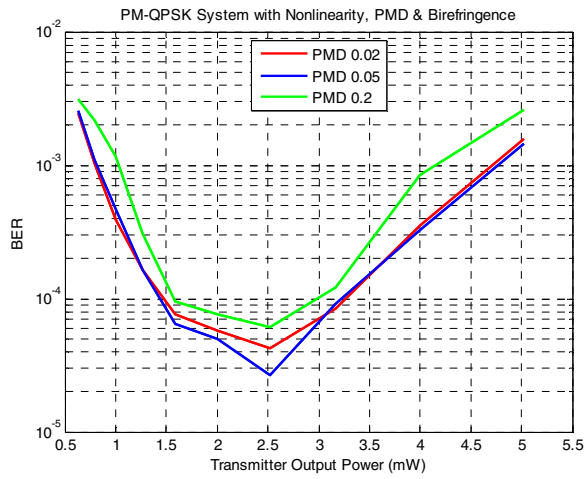

Figure 6. BER-Power curve of PM-QPSK system with nonlinearities, PMD and birefringence.

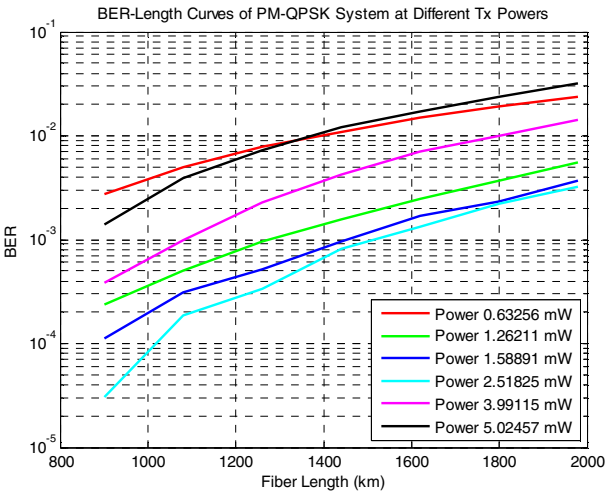

Figure 7. BER-Length curve of PM-QPSK system with nonlinearities, PMD and birefringence for different transmitter power levels.

nonlinearity is reduced in terms of BER and the effect of low nonlinearity is further impaired by increasing the BER. In general the curve pattern follows the effect of the nonlinearities at power level more than 2.5 mW. The reason of such change is due to the fact that in the absence of random birefringence, the impairment caused by the PMD is reduced considerably. In the absence of random birefringence, the nonlinear cross polarization between the polarization components is also reduced.

In the fifth step, the combined effect of PMD, nonlinearity and birefringence are simulated as shown in Figure 6. It shows the BER-power curves describing their combined effect. The nonlinearity coefficient is kept fixed at 1.5 1/W/km. Comparing the Figures 2-6, it is clear that the impact of PMD and birefringence is not detrimental with the increase of power. But nonlinearity alone pushes the BER towards the unacceptable level as the power level increases beyond 1.5 mW. At lower PMD value, the nonlinearities will have dominant effect and the BER increases. But the PMD together with birefringence has a higher tolerance to higher power level and reduces the detrimental effect of nonlinearities and pushes the optimum power level to the higher value. The characteristic curves show that the system gives the best performance for PMD = 0.05 ps/sqrt(km) and nonlinearity = 1.5 1/W/km at transmitting power level = 2.518 mW.

Finally in the sixth step, the simulation is carried out varying the length of the fiber and keeping the PMD set at 0.5 ps/sqrt(km) and the nonlinearity value at 1.5 1/W/km and the birefringence at Maxwell distribution. The simulated transmitted powers are varied 0.63256 - 5.02457 mW as shown in Figure 7. The system has the best performance at transmitter power level of 2.518 mW having the BER within 10^{-3} up to a distance of 1550 km. The results show that if the power level is either increased or decreased from the optimum value of 2.518 mW, the BER increases. Transmitter power levels 0.63256 and 5.02457 show the worst performance and the BER level is unacceptable. Power levels 3.99115, 1.26211 and 1.58891 have the acceptable BER limits of 10^{-3} for fiber lengths 1090, 1275 and 1450 km respectively.

IV. Conclusions

The PM-QPSK system gives an important and easily implementable technique for achieving higher bit rates at 107 Gb/s including 7% overhead for EFEC. The combined features of polarization multiplexing and QPSK in conjunction with EDC and FEC algorithm made it an alternative for future high speed communication. The combined features made it possible to quadruple the bit rate. The overall penalty of PMD-nonlinearity impaired system is lower than the sum of the individual penalties. Impact of increasing transmitter powers on BER in the presence of random birefringence, PMD and nonlinearity is a proven tool. The results show that the PM-QPSK system has the best performance at transmitting power level of 2.518 mW at PMD of 0.05 ps/sqrt(km) and nonlinearity of 1.5 1/W/km.

Unconstraint Adaptive Frequency-Domain Equalizer for Coherent Optical Receivers

Md. Saifuddin Faruk

Department of Electrical & Electronic Engineering, Dhaka University of Engineering & Technology, Gazipur, Bangladesh

Abstract—**In this paper, unconstraint adaptive frequency-domain equalizer (FDE) based on the constant-modulus algorithm (CMA) is investigated for equalization of linear transmission impairments in coherent optical receivers. With unrepeated 200-km transmission of 10-Gbaud quadrature phase-shift keying (QPSK) signal, it is verified that, compared with conventional constraint FDE, the proposed unconstraint FDE causes a very small sensitivity penalty; however, can be applied with much less computational complexity.**

***Index Terms*—optical fiber communication, digital signal processing, equalization, adaptive filter.**

I. Introduction

Recent advancement of digital coherent receivers enable compensation of fiber transmission impairments such as chromatic dispersion (CD) and polarisation-mode dispersion (PMD) in digital domain [1]. Generally we use adaptive finite-impulse-response (FIR) filters which tap coefficients are updated symbol-by-symbol manner using any gradient-decent based algorithm such as constant-modulus algorithm (CMA) or decision-directed least-mean-square (LMS) algorithm. However, the computational complexity of such approach increases rapidly with increase of number of filter taps [2]. Frequency-domain approach can reduce this computation cost significantly by using block-by-block processing and fast implementation of discrete Fourier transform (DFT).

The conventional adaptive frequency-domain equalizer (FDE) such as fast LMS [3] can operate with input signal sampled at symbol rate. However, the receiver with two-fold oversampled input sequences is preferred since such an oversampling rate reduces the aliasing effect significantly. To enable adaptive FDE based on two-fold oversampled input signal, previously we propose the concept of splitting the equalizer in even/odd sub-equalizer [4,5].

In this paper, we further modified the equalizer with even/odd sub-equalizer concept by eliminating the gradient constraint used in the configuration. Such a modification yields a more computational efficient structure. The principle of operation of the proposed scheme is verified with 10-Gbaud quadrature phase-shift keying (QPSK) 200-km unrepeated transmission experiments. It is found that, the bit-error-rate (BER) performance of the proposed unconstraint FDE is very close to that obtained by the constraint FDE; however, the proposed FDE can be implemented with reduced computational complexity.

Throughout the remainder, time- and frequency-domain variables are denoted by lower- and upper-case characters, respectively, while boldface characters denote vectors. Furthermore, the symbol $\otimes$ is element-by-element multiplication; $\mathbf{O}_L$ is a column vector with L zeros; $\mathbf{I}_L$ is a column vector with L ones; superscripts $(\bullet)^e$ and $(\bullet)^o$ correspond to even and odd sub-equalizer parameters, respectively; and conj(•) is the conjugate operator.

II. Adaptive FDE with Even/Odd Sub-Equalizer Concept

The adaptive FDE with even/odd sub-equalizer concept that enable processing of two-fold oversampled input sequence is shown in Fig. 1 [4]. For simplicity of explanation, we consider the configuration for single-polarization transmission; however, the configuration can be easily modified for polarization-multiplexed system by using two-by-two butterfly configuration of the equalizer [5]. The equalizer is composed of two sub-equalizers. Each sub-equalizer processes input sequences at the symbol rate, which are taken from even or odd sequences of data sampled at the rate of two samples/symbol. The overlap-save method is employed to perform linear convolution effectively [6].

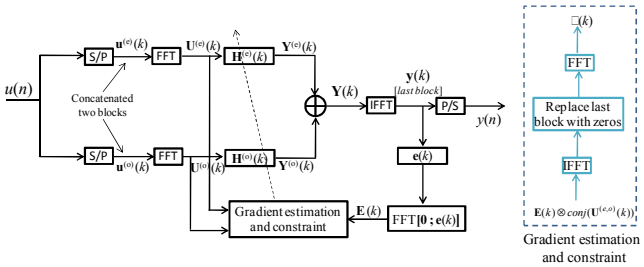

Fig.1: Block diagram of adaptive FDE with even/odd sub-equalizer concept. Inset is the detail of gradient estimation and constraint operation.

Considering that a block length equals the sub-equalizer filter length L, in the case of 50% overlap (hence, FFT length N=2L), the k-th block of the frequncy-domain filter output can be written as

$$\mathbf{Y}(k) = \mathbf{U}^{(e)}(k) \otimes \mathbf{H}^{(e)}(k) + \mathbf{U}^{(o)}(k) \otimes \mathbf{H}^{(o)}(k), \tag{1}$$

where $\mathbf{U}^{(e,o)}(k)$ and $\mathbf{H}^{(e,o)}(k)$ are two column vectors of the length N having elements of the frequency-domain input sequences and filter-tap coefficients, respectively.

Then the time-domain output is computed using overlap-save method as

$$\mathbf{y}(k) = \text{last } L \text{ data of } IFFT\{\mathbf{Y}(k)\}. \tag{2}$$

The error vector in CMA is calculated in the time domain as

$$\mathbf{e}(k) = [\mathbf{I}_L - \mathbf{y}(k) \otimes \text{conj}\{\mathbf{y}(k)\}] \otimes \mathbf{y}(k), \tag{3}$$

which is transformed into the frequency domain as

$$\mathbf{E}(k) = FFT[\mathbf{O}_L ; \mathbf{e}(k)]. \tag{4}$$

The time-domain gradient vectors are then computed as

$$\boldsymbol{\varphi}^{(e,o)}(k) = \text{first } L \text{ data of } IFFT\{\mathbf{E}(k) \otimes conj(\mathbf{U}^{(e,o)}(k))\}. \tag{5}$$

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

Finally, the updating process of frequency-domain filter-tap coefficients based on gradient decent algorithm is expressed by

$$\mathbf{H}^{(e,o)}(k+1) = \mathbf{H}^{(e,o)}(k) + \mu FFT[\boldsymbol{\varphi}^{(e,o)}(k); \mathbf{O}_L], \qquad (6)$$

where μ is a step-size parameter.

III. Proposed Unconstraint Adaptive FDE

For the equalizer configuration shown in the Fig.1, a time-domain constraint is imposed for gradient vector estimation by discarding last L elements of IFFT of $\mathbf{E}(k) \otimes conj(\mathbf{U}^{(e,o)}(k))$ as shown in Eq. (5) and replacing the elements so discarded by a block of L zeros before reapplying the FFT as shown in Eq. (6). However, according to [7], under fairly mild conditions, the FDE algorithm can still work well even this gradient constraint is dropped. Based on it, we propose a unconstraint adaptive FDE having even/odd sub-equalizer concept as shown in Fig.2 which can be consider a modified version of FDE shown in Fig.1. The filtering and filter adaption process for the proposed FDE can be done using the following set of equations:

$$\mathbf{Y}(k) = \mathbf{U}^{(e)}(k) \otimes \mathbf{H}^{(e)}(k) + \mathbf{U}^{(o)}(k) \otimes \mathbf{H}^{(o)}(k)$$

$$\mathbf{y}(k) = \text{last } L \text{ data of } IFFT\{\mathbf{Y}(k)\}$$

$$\mathbf{e}(k) = [\mathbf{I}_L - \mathbf{y}(k) \otimes \text{conj}\{\mathbf{y}(k)\}] \otimes \mathbf{y}(k),$$

$$\mathbf{E}(k) = FFT[\mathbf{O}_L; \mathbf{e}(k)]$$

$$\boldsymbol{\varphi}^{(e,o)}(k) = \mathbf{E}(k) \otimes conj(\mathbf{U}^{(e,o)}(k))$$

$$\mathbf{H}^{(e,o)}(k+1) = \mathbf{H}^{(e,o)}(k) + \mu FFT[\boldsymbol{\varphi}^{(e,o)}(k); \mathbf{O}_L]$$

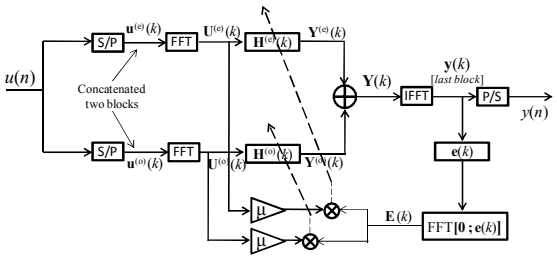

Fig.2: Proposed unconstraint adaptive FDE with even/odd sub-equalizer concept.

It is important to note that, elimination of gradient constraint ensure reduction of 2 FFTs and 2 IFFTs operation. Considering the classic radix-2 algorithm, which requires $N\log_2(N)/2$ multiplications to execute FFT of N complex numbers [2], we can achieve a reduction of computational complexity of $4L\log_2(2L)$ complex multiplications in the proposed unconstraint FDE compare to that in constraint FDE as shown in Fig.1.

IV. Experimental Results and Discussion

In order to verify the effectiveness of the proposed algorithm, a 10-Gbaud QPSK unrepeated transmission experiment is conducted as show in Fig. 3.

In the transmitter side, a continuous wave was generated from a distributed-feedback laser diode (DFB-LD). The wavelength of the DFB-LD was 1552nm and its 3-dB linewidth was about 150 kHz. An NRZ 10-Gbaud QPSK signal was generated by a $LiNbO_3$ optical IQ modulator (IQM). The IQM was driven by two streams of electrical signals generated from two independent ports of an arbitrary waveform generator (AWG) with a pseudo-random binary sequences (PRBS) length of 2^9-1. The optical signal was then transmitted through a 200-km standard single-mode fiber (SMF). The accumulated CD of such system was about 3200 ps/nm.

In front of the receiver, the state of polarization of the incoming signal was controlled manually with a polarization controller (PC) so that it align with that of local oscillator (LO). Then, the received average power P_{in} was controlled by a variable optical attenuator (VOA). After that, the signal was pre-amplified by an Erbium-doped fiber amplifier (EDFA), and detected by a phase-diversity homodyne receiver, where another DFB-LD having the same characteristics was used as a LO. The frequency offset between transmitting laser and the LO was set below 10 MHz. The output from the receiver was asynchronously sampled at 20 Gsample/s by a 2-channel analog-to-digital converter (ADC) with 8-bit resolution. The digitized signals were stored in a personal computer (PC) for offline digital signal-processing (DSP).

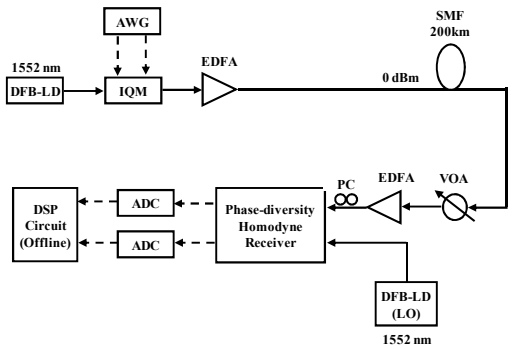

Fig.3 : Experimental setup to verify the effectiveness of the proposed adaptive FDE

In the DSP, clock recovery [8] and equalization is done by either constraint adaptive FDE or proposed unconstraint adaptive FDE. The value of step-size parameter is optimized manually so that the BER is minimum. Then carrier-phase is recovered using Viterbi-Viterbi algorithm. Finally, the symbols are decoded and BER is measured using direct counting method.

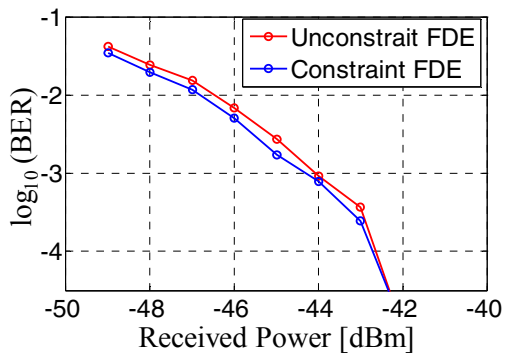

Fig. 4: The BER performance of constraint and unconstraint adaptive FDE

The BER characteristic is shown in Fig. 4. It is found that the constraint FDE has slightly better performance compare to unconstraint FDE. For a BER of 10^{-3} the sensitivity penalty is only 0.3 dB for unconstraint FDE. Such small sensitivity penalty is acceptable since we can implement it with a lower computational complexity.

V. Conclusions

Unconstraint adaptive FDE is successfully introduced in digital coherent optical receivers. Such an equalization approach reduces the computational complexity significantly while keeping the system performance almost same as conventional constraint FDE. The effectiveness of the proposed FDE is confirmed with 10-Gbaud QPSK transmission experiments.

Abstract - **Next generation wireless communication networks (NGN) uses one of the emerging multicarrier multiplexing transmission techniques which is known as orthogonal frequency division multiplexing (OFDM). It provides several advantages such as offering greater immunity to multipath fading & impulse noise, eliminating inter-symbol interference (ISI), inter-carrier interference (ICI) & the need for equalizers. However, OFDM have a generic problem of high peak to average power ratio (PAPR) which is defined as the ratio of the peak power to the average power of the OFDM signal. In this paper, an improved design of amplitude clipping & filtering method is proposed and implemented which shows the significant improvement in case of PAPR reduction compare to an existing method.**

Index Terms - **Bit Error Rate (BER), Complementary Cumulative Distribution Function (CCDF), Peak to Average Power Ratio (PAPR).**

I. Introduction

In this modern era, the explosive growth of new multimedia wireless applications have resulted in an massive demand for technologies that support very high speed transmission rates, mobility and efficiently utilize the available spectrum and network resources. OFDM is one of the best solutions to achieve this goal and it offers a promising choice for future high speed data rate systems. OFDM has been standardized as part of the IEEE802.11a and IEEE 802.11g for high bit rate data transmission over wireless LANs. One of the major drawbacks of OFDM signal is the high peak-to-average power ratio (PAPR) of the transmit signal. As the data rates and mobility supported by the OFDM system raise, the number of subcarriers also raise, which in turn leads to high PAPR. As future OFDM-based systems may push the number of subcarriers up to meet the higher data rates and mobility demands, there is a need to mitigate the high PAPR [1]. If the peak transmit power is limited by either regulatory or application constraints, the effect is to reduce the average power allowed under multicarrier transmission relative to that under constant power modulation techniques. This in turn reduces the range of multicarrier transmission. Moreover, to prevent spectral growth of the multicarrier signal in the form of intermodulation among subcarriers and out-of-band radiation, the transmit power amplifier must be operated in its linear region (i.e., with a large input back-off), where the power conversion is inefficient. This may have a deleterious effect on battery lifetime in mobile applications. As portable devices have a finite battery life it is important to find ways of reducing the PAPR allowing for a smaller more efficient HPA, which in turn will mean a longer lasting battery life. In many low-cost applications, the drawback of high PAPR may outweigh all the potential benefits of multicarrier transmission systems [2]. Several attractive research works have been carried out to reduce PAPR with the expense of increase transmit signal power, bit error rate (BER), computational complexity and data rate loss etc. So, a system trade-off is required. The clipping & filtering method was first introduced by X. Li and L.J. Cimini, showed the effects of clipping and filtering on the performance of OFDM [3]. A repeated operation of clipping and filtering (RCF) technique was then implemented by J.Armstrong resulted that the PAPR of an OFDM signal could be reduced without any increase in the out-of-band power by clipping the oversampled time domain signal followed by filtering using an FFT-based, frequency domain filter designed to reject out-of-band discrete frequency components [4]. A novel iterative clipping & filtering (ICF) at receiver was proposed by H.Chen and A.Haimovich to estimate and cancel the distortion caused by clipping noise [5]. A This SCF shows that actually in one iteration, obtained the same PAPR reduction as that of the previous ICF technique with several iterations. The computational complexity was therefore significantly reduced. Simulations show that, in relatively large clipping cases, SCF technique had better PAPR reduction and out-of-band radiation than and very close BER performance to ICF. Recently, a FIR based bandpass filter achieves better performance used by Yong Soo Cho et. al.[6] . It introduces less noise into the signal, causes less peak regrowth and needs less computation.

In this simulation, a special type of IIR based peak resonator filter is proposed which reduces the PAPR significantly compare to existing method [6] but at the slight increase of BER.

II. OFDM System Model

OFDM is a special form of multicarrier modulation (MCM) with densely spaced subcarriers with overlapping spectra, thus allowing multiple-access. MCM works on the criteria of transmitting data by dividing the stream into several bit streams, each of which has a much lower bit rate and by using these sub-streams to modulate several carriers. In multicarrier transmission, bandwidth divided in many non-overlapping subcarriers but not necessary that all subcarriers are orthogonal to each other shown in figure 1, where Δf shows the frequency spacing between two sub-carriers. In OFDM the sub-channels overlap each other to a certain extent. The information sequence is mapped into symbols, which are distributed and sent over the N sub-channels, one symbol per channel. To permit dense packing and still ensure that a minimum interference between the sub-channels is encountered, the carrier frequencies must be chosen carefully according to their orthogonal properties. By using orthogonal carriers, frequency domain can be viewed so as the frequency

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

space between two sub-carriers is given by the distance to their first spectral null [2].

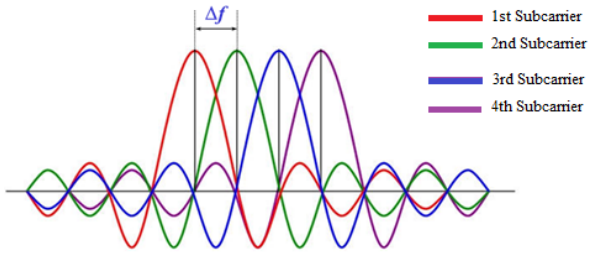

Fig. 1 An OFDM Signal with 4 sub-carriers

III. PROPOSED METHOD

As the main focus of this research work is to reduce PAPR, so, in this simulation, we have done trade-off between PAPR reduction with BER increment. *Yong Soo et.al* [6] show that if clipped signal passes through a composed filter (FIR based BPF) before passing a low pass filter (LPF) to reduce out-of-band radiation, then it causes less BER degradation with medium amount of PAPR reduction. Considering this concept, we have designed a scheme for clipping & filtering method where clipped signal passes through a composed filter (IIR based resonator filter) before passing a LPF, and then it causes a little bit more BER degradation but significant amount of PAPR reduction than existing method [6].

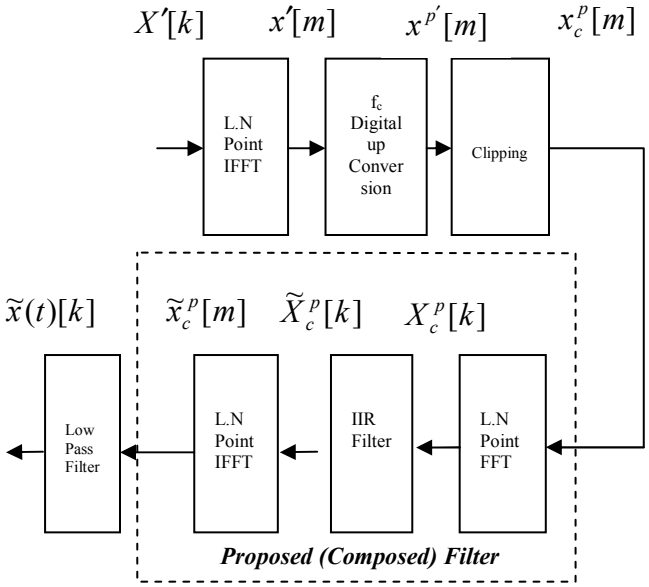

Fig.2 Block Diagram of Proposed Clipping & Filtering Method

This proposed scheme is shown in the figure 2. It shows a block diagram of a PAPR reduction scheme using clipping and filtering, where L is the oversampling factor and N is the number of subcarriers. The input of the IFFT block is the interpolated signal introducing $N(L-1)$ zeros (also, known as zero padding) in the middle of the original signal. Let, $x_c^p[m]$ denote the clipped version of $x^p[m]$ which is expressed as,

$$x_c^p[m] = \begin{cases} -A & x^p[m] \le -A \\ x^p[m] & |x^p[m]| < A \\ A & x^p[m] \ge A \end{cases} \quad (1)$$

Where, A is the pre-specified clipping level. After clipping, the signals are passed through the proposed filter (Composed Filter). The filter itself consists on a set of FFT-IFFT operations where filtering takes place in frequency domain after the FFT function. The FFT function transforms the clipped signal $x_c^p[m]$ to frequency domain yielding $X_c^p[k]$. The information components of $X_c^p[k]$ are passed to a IIR based peak resonator filter producing $\tilde{X}_c^p[k]$.This filtered signal is passed to the unchanged condition of IFFT block and the out-of-band radiation that fell in the zeros is set back to zero. The IFFT block of the filter transforms the signal to time domain and thus obtain $\tilde{x}_c^p[m]$. Table I shows the values of parameters used in the QPSK & QAM system for analyzing the performance of clipping and filtering technique. We have simulated the both methods (Existing and Proposed) with the same parameters.

TABLE I
PARAMETERS USED FOR SIMULATION

Parameters	Value
Bandwidth (BW)	1 MHz
Over sampling factor (L)	8
Sampling frequency, f_s = BW*L	8 MHz
Carrier frequency, f_c	2 MHz
No. of Subscribers (N)	128
CP / GI size	32
Modulation Format	QPSK and QAM
Clipping Ratio (CR)	0.8, 1.0, 1.2, 1.4, 1.6

IV. SIMULATED RESULTS

At first, we simulate the PAPR distribution for CR values =0.8, 1.0, 1.2, 1.4, 1.6 with QPSK modulation & N=128 and then, with QAM modulation and N=128. PAPR distributions for different CR value are shown in figure 3 & figure 4 in case of existing & proposed method respectively.

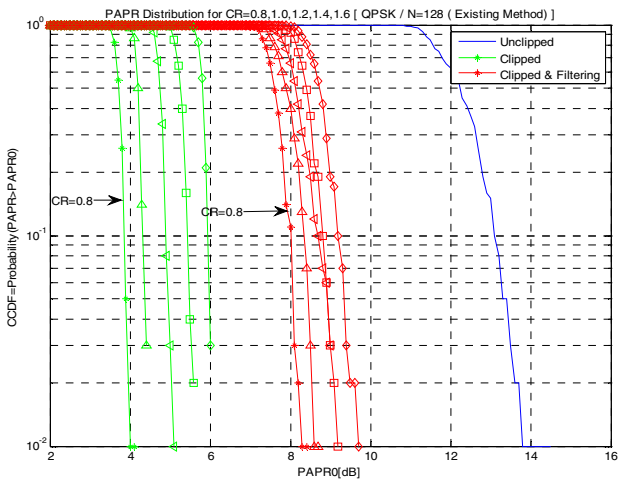

Fig. 3 PAPR Distribution [QPSK /N=128 (Existing)]

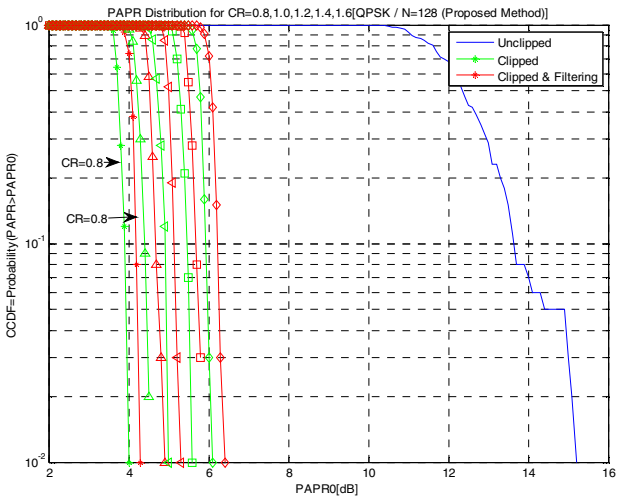

Fig.4 PAPR Distribution [QPSK /N=128 (Proposed)]

From table II, it is clearly observed that the proposed method reduces PAPR significantly with respect to existing method analysis [6].

TABLE II
COMPARISON OF EXISTING WITH PROPOSED METHOD FOR PAPR VALUE [QPSK /N=128]

CR value	PAPR value (dB)(Existing)	PAPR value (dB)(Proposed)	Improvement in PAPR value (dB)
0.8	8.101	4.217	3.884
1.0	8.353	4.679	3.674
1.2	8.721	5.134	3.587
1.4	8.817	5.681	3.136
1.6	9.221	6.225	2.996

TABLE III
COMPARISON OF EXISTING WITH PROPOSED METHOD FOR PAPR VALUE [QAM /N=128]

CR value	PAPR value (dB)(Existing)	PAPR value (dB)(Proposed)	Improvement in PAPR value (dB)
0.8	8.231	4.184	4.047
1.0	8.323	4.652	3.671
1.2	8.652	5.111	3.541
1.4	8.929	5.710	3.219
1.6	9.151	6.272	2.879

Figure 5 & figure 6 shows the simulation results for QAM modulation & N=128 for existing & proposed method. From table III, it is obvious that the proposed method reduces PAPR significantly. Now, if we analyse the values for different CR values in case of QPSK & QAM to show the effect of modulation on proposed filter design, it is observed that QAM provides less PAPR than QAM up to CR value=1.2. But, with the increasing value of CR, QPSK results less PAPR than QAM. So, for low CR value (More amount of clipping), QAM is more suitable than QPSK in case of proposed filter.

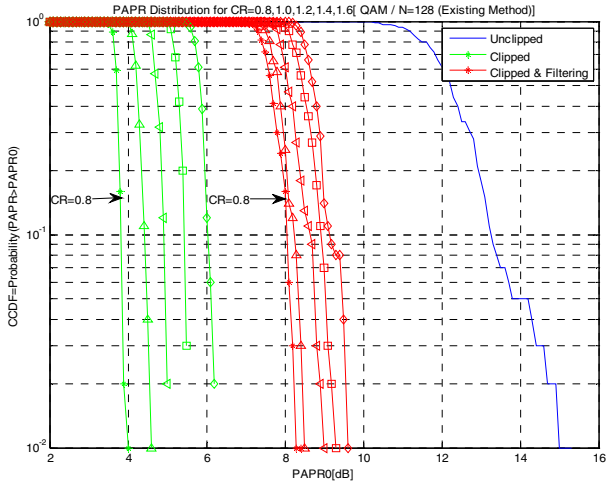

Fig.5 PAPR Distribution [QAM /N=128 (Existing)]

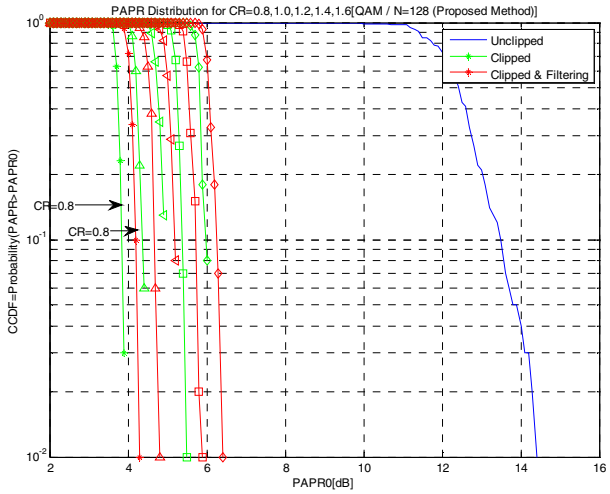

Fig.6 PAPR Distribution [QAM/N=128 (Proposed)]

The clipped & filtered signal is then passed through the AWGN channel and BER are measured for both existing & proposed methods. Figure 7 & 8 shows the BER curve for QPSK in case of existing & proposed method correspondingly. Figure 9 & 10 shows the BER curve for QAM in case of existing & proposed method respectively.

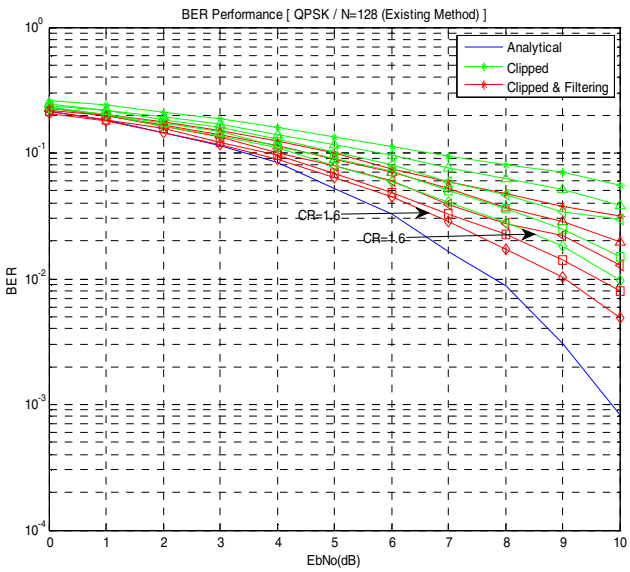

Fig. 7. BER Performance [QPSK /N=128 (Existing)]

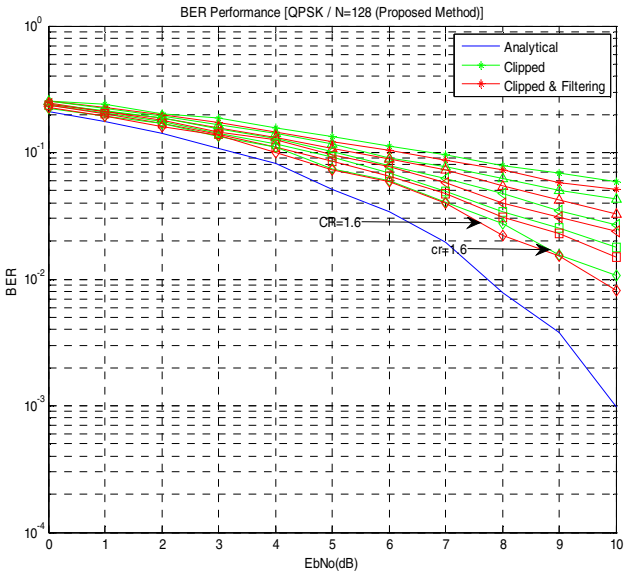

Fig. 8 BER Performance [QPSK /N=128 (Proposed)]

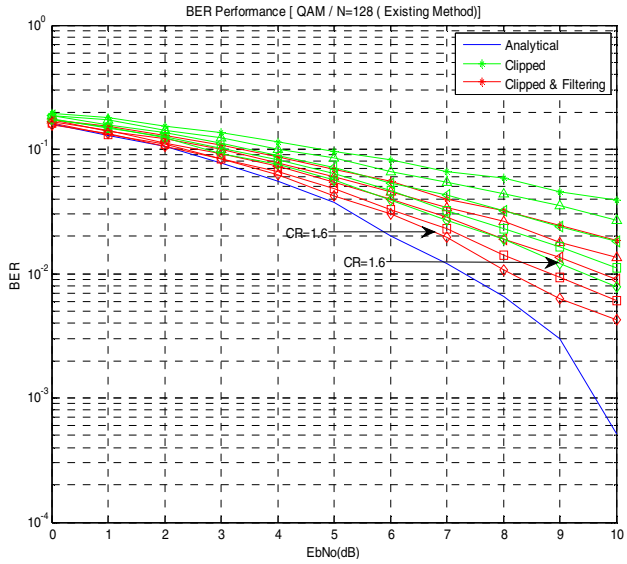

Fig. 9 BER Performance [QAM /N=128 (Existing)]

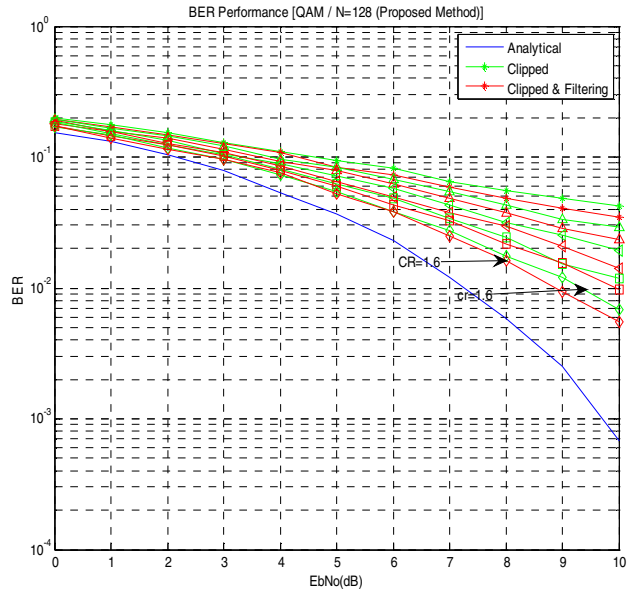

Fig. 10. BER Performance for [QAM /N=128 (Proposed)]

TABLE IV
COMPARISON OF EXISTING WITH PROPOSED METHOD FOR BER VALUE [QPSK /N=128]

CR value	BER value (Existing)	BER value (Proposed)	Difference in BER value
0.8	0.07413	0.10481	-0.03068
1.0	0.06984	0.08886	-0.01902
1.2	0.05982	0.07685	-0.01703
1.4	0.04891	0.06535	-0.01644
1.6	0.04449	0.05937	-0.01488

TABLE V
COMPARISON OF EXISTING WITH PROPOSED METHOD FOR BER VALUE [QAM /N=128]

CR value	BER value (Existing)	BER value (Proposed)	Difference in BER value
0.8	0.05563	0.07354	-0.01791
1.0	0.04614	0.06244	-0.0163
1.2	0.04016	0.04961	-0.00945
1.4	0.03268	0.04346	-0.01078
1.6	0.03055	0.03799	-0.00744

From table IV and table V, it is noted that BER are increased in both the cases. Now, if we compare the values for different CR values in case of QPSK & QAM to show the effect of modulation on proposed filter design, it is observed that for the same simulation parameters, QAM provides less BER degradation than QPSK in all cases. So, QAM is more suitable for proposed method in all aspects.

V. CONCLUSIONS

In this paper, an improved scheme of amplitude clipping & filtering based PAPR reduction technique has been analysed where PAPR reduces significantly compare to an existing method with slightly increase of BER in case of both QPSK & QAM modulations. It is also observed from this simulation, that for low CR (more amount of clipping), QAM is better candidate in case of PAPR reduction as well as BER performance for all amount of clipping. In order to estimate the OFDM system performance in real world, multipath Rayleigh fading can be a major consideration in next time.

A Simple Wideband Microstrip Bandstop Filter for WLAN and WiMAX Band Rejection Purpose

Lakhindar Murmu[1*] and Sushrut Das [2]
[1, 2] Department of Electronics Engineering
Indian School of Mines, Dhanbad, India.
[*]lakhndar.kgec25@gmail.com

Abstract— **In this paper, a simple hexagonal wideband microstrip bandstop filter with an open-end stepped impedance stub has been proposed for the rejection of WLAN and WiMAX bands. Controlling the dimensions of the shunt open-end stepped impedance stub, the rejection bandwidth and the level of rejection can be controlled. The structure is very simple and is also easy to fabricate. The final filter structure provides a stop band that extends from 3.19 GHz to 5.36 GHz within and more than -20dB rejection and hence it can reject the 3.5 GHz WiMAX bands and 5.2 GHz WLAN frequency bands. The simulated response has been validated after comparing it with the measured data.**

Index Terms—**Open loop hexagonal filter, bandstop filter (BSF), stepped impedance resonator (SIR).**

I. Introduction

With rapid growth of communication technologies, WLAN and WiMAX communications have been developed a lot. These technologies have become so popular that in present days it has become almost a part of our life and almost every corner of the world is flooded with the signals from WLAN and WiMAX. These high speed WLAN and WiMAX signals propagate rapidly through the infrastructure of office and home environments and couple with other RF systems. These coupled signals propagate along the transmission line and circuits of the RF system and may result in an undesired behaviour of the system. Therefore to protect the RF systems from these signals bandstop filters can be used.

Recently, numerous methods and structures have been proposed for realizing the bandstop filters [1-2]. Based on the formulae of SIR, bandstop filters with high skirt selectivity as well as wide rejection bandwidth and miniature circuit configuration were presented in [1,2]. Divyabramham et al. [2] presented a design technique of sharp-rejection wideband bandstop filters by using a lossless transmission line model. In the year 2008, a new compact bandstop microstrip filter using two cascaded ring resonators was presented and the equivalent circuit model was developed to characterize the proposed bandstop structure [3]. One year later, in [4] a technique to design a dual-band bandstop filter (DBBSF) was presented with a dual-mode loop resonator.

The hexagonal geometry promises better confinement in the microstrip circuits due to their large interior angles (as compared to rectangle and square counterparts).Open loop hexagonal multiplexer for communication system were proposed by R. Kumar and G.A. Edae [5]. In that paper they have presented the tri-band band multiplexer topology based on the hexagonal close loop resonators of different size which were capacitive coupled from a single input. In [6] a novel microstrip bandstop filter was proposed, where signal interference technology was applied for achieving the bandstop behaviour. Two open loop resonators were introduced to the conventional transmission line with larger electrical length. Then, two transmission zeros were obtained in the stopband. Meanwhile, several transmission poles were used to improve the flatness of the passband. In comparison with the traditional bandstop filters using signal interference technique, the proposed filter has wider stopband and flat passband. In the same year, a new and miniature circuit configuration for wideband bandstop filter (BSF) operating at X-band range was presented [7]. The presented planar microstrip filter consists of a three-section stepped impedance resonator (SIR) paralleled with three open-circuited stepped impedance stubs (SISs).

In this paper the authors have proposed a compact open loop hexagonal resonator filter with open-end stepped impedance stub which has been designed for the rejection of 3.5 GHz WiMAX band and 5.2 GHz WLAN frequency band. Commercial IE3D simulator has been used to design the structure.

II. Open Loop Hexagonal Filter Design

An open loop hexagonal loop filter with direct coupled tapered ports is shown in Fig.1. The length L (total loop length, L= [(6×a) –g]) determines the centre frequency of filter. A Pair of 50-Ω collinear tapered lines feed with the resonator. RT/Duroid 6010 with a thickness of 1.27 mm and a relative dielectric constant of 10.2 has been used as the substrate. The simulated response i.e. insertion loss and return loss versus frequency is shown in Fig.2. The figure reveals that it has a band pass response from DC to 2.2 GHz (up to 2.2 GHz) and a band stop response from 2.2GHz to 5.4 GHz.

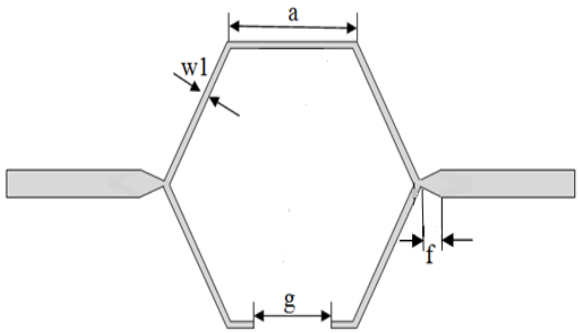

Fig.1. Hexagonal open loop bandstop filter (Filter A).

Inspired by the band stop behaviour of a simple hexagonal open loop, a second hexagonal bandstop filter, but this time loaded with open ended stepped impedance stub, has been

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

developed as shown in Fig.3. The filter structure has been studied by varying the dimensions of the stubs of the hexagonal resonator. The frequency response of the proposed filter is shown in Fig.4 for different parameter values. The respective filter parameters are tabulated in table 1.

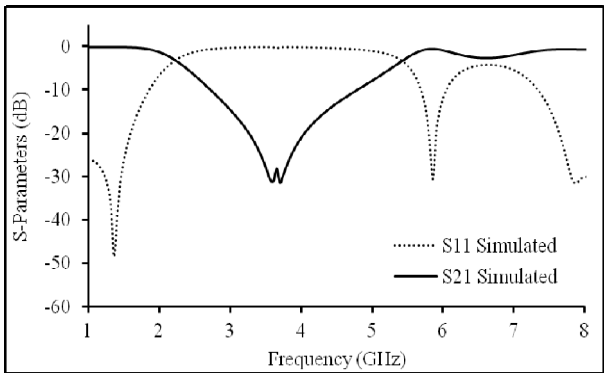

Fig.2. Simulated response of hexagonal open loop bandstop filter (Filter A).

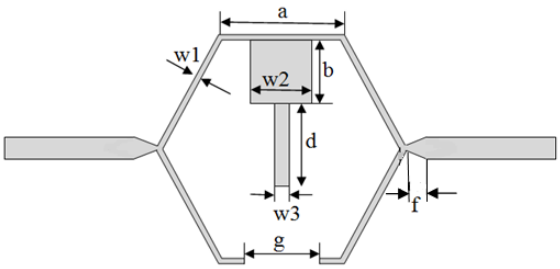

Fig.3. Hexagonal resonator bandstop filter with open-end stubs (Filter B).

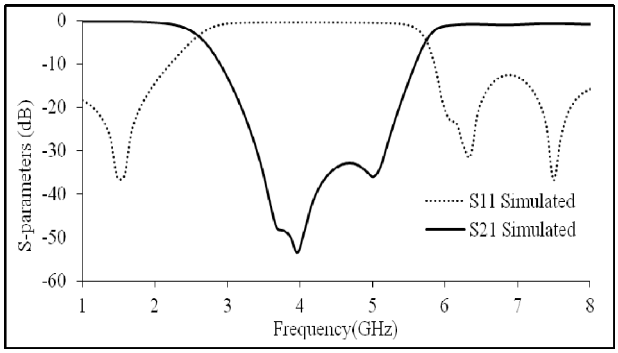

Fig.4. Simulated frequency response of the proposed (Filter B).

Table 1: Geometrical dimensions of the filters A-B

Filter	A	B
a	6mm	6mm
b	--	3mm
d	--	4mm
f	2.05mm	2.05mm
g	1mm	2mm
w1	0.85mm	0.2mm
w2	--	3mm
w3	--	1mm

III. Fabrication and Measurement Results

All Based on the simulated results obtained from IE3D, the filter has been fabricated with the proposed dimensions: a=6mm, b=3mm, d=4mm, w1=0.2mm, w2=3mm, w3=1mm, g=2mm (Filter B) as shown in Fig. 5 and then measured for frequency response. The measurement was carried out using an Agilent E5071C Vector Network Analyzer and the measured response is shown in Fig.6. Simulated frequency response of the proposed filter is also shown in same figure. The measure frequency response shows the 3dB cut-off frequencies of 2.62 GHz and 5.63 GHz. The highest insertion loss in the low and in the high frequency pass-band is better than 0.3 dB and 1.5 dB, respectively. The highest return loss in the stop-band is better than 0.4 dB. The measured result provides a stop band that extends from 3.03 GHz to 5.28 GHz within and more than -20dB rejection and hence it can reject the 3.5 GHz WiMAX bands and 5.2 GHz WLAN frequency bands. The measured result shows a good agreement with the simulated data. The result shows a passband return loss of about 20dB & stopband return loss about 0.4 dB.

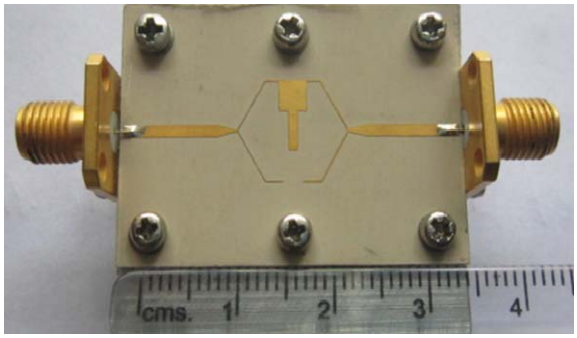

Fig.5. Photograph of bandstop filter (Filter B).

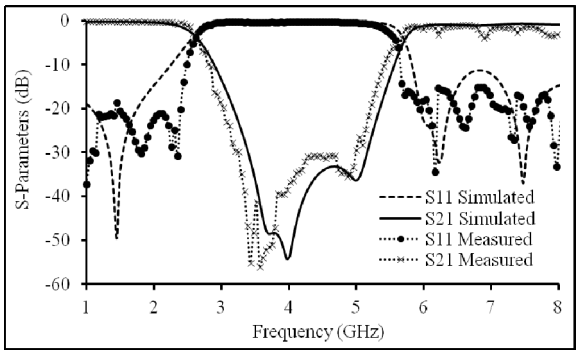

Fig.6. Measured and simulated frequency response of the proposed filter (Filter B).

The stop band insertion loss is better than 30dB. Fig. 6 also shows that at the rejection band plenty of ripples are present whereas the simulation is smooth. The ripples are due to the connector's flanges and screws that are missing in the simulation model.

IV. Conclusions

A Compact open loop hexagonal resonator bandstop filters with and without a loaded open stub have been presented in this paper. The bandwidth of the filter with a loaded open stub has been observed to have a better performance. The optimization of the various parameters of the filter has been accomplished to achieve a good response. The proposed filter is compact, easy to fabricate and easy to integrate with MIC/MMIC microwave circuits. The final filter structure provides a stop band that extends from about 3.19 GHz to 5.36 GHz and hence it can reject the 3.5 GHz WiMAX and

5.2 GHz WLAN frequency bands. The simulated response has been validated after comparing it with the measured data. In the measured results, the centre frequency of the fabricated filter has been shifted towards a lower frequency. This is due to the fabrication tolerance.

Abstract- **With the increasing popularity of power line communication technologies, modifications over Spread Spectrum Technologies were made so as to develop a suitable alternative for power line communication. Differential Code Shift Keying (DCSK) is one such technology developed by Yitran Technologies & patented on May 16th, 2000. In this paper, it is proposed to develop this DCSK Communication Scheme which can be used for PLCC system for DAS application.**

Keywords- **Power Line Carrier Communication (PLCC), DCSK, Chirp, Superchirp, Spread Spectrum Technology**

I. INTRODUCTION

In this modern world, digital communication is an interesting field of research as it plays a crucial role in our daily life. New technologies are developing day to day to reduce the effect of noise present in the transmission medium on the modulated signal. The effect of noise becomes more prominent if the transmission medium is a power line cable as it not designed for it. Noise levels in the networks are often excessive; cable attenuation in the systems at the frequencies of interest is often very large; important channel parameters such as impedance and attenuation are hard to predict due to their unpredictable nature [1].

But modern day automation prefers the power line carrier communication i.e. PLCC for low power remote monitoring & control. But due to noisier environment, the quality & speed of data transfer reduces significantly with the conventional modulation techniques. So in order to overcome these problems, new modulation techniques are developed. Differential Code Shift Keying (D.C.S.K.) is one such technique which is suitable especially for PLCC.

In this paper attempt has been made to develop a system for implementing DCSK modulation scheme employing MATLAB software. Separate programs are designed at transmitting & receiving end for single character & string. Then the principle is applied to design a multi-drop system where device address & the corresponding data are merged together in a single string at transmitting end, which is then separated at the receiving end to display the device address & the data value from the particular device.

II. POWER LINE CARRIER COMMUNICATION

In the recent times, there are various communication technologies for transmitting information from one point to another through suitable communication medium which may be wired or wireless. As mentioned previously, PLCC is a method of communication via power line. In today's world, every house and building has properly installed electricity connections. If the existing AC power lines can be used as a medium to transfer the information, it becomes easier to connect the houses with a high speed network access point & hence eliminating the need of Ethernet cable. So, it can also be used in building/home automation [7, 11]. The data collected from different sensors is transmitted on these power lines thereby reducing the maintenance cost of the additional wiring arrangements. This technology is also used to provide Internet connection in some countries [2]. PLCC can be employed successfully in automatic meter reading, home automation & control, voice or data communication etc. While dealing with PLC communication, commonly used digital communication techniques like FSK & PSK suffers with serious problems due to power line characteristics. At high frequencies (i.e. at communication frequencies), power line characteristics varies greatly if compared with that at power frequency. The difference in characteristic impedance & load impedance at such high frequencies often results high attenuation at such communication frequencies. Apart from it, significant noise is produced by various devices connected to the system thereby degrading the performance of conventional digital communication techniques. It was found that 'Spread Spectrum Modulation Technique' is gives better results under power line conditions [1, 10].

III. DIFFERENTIAL CODE SHIFT KEYING (D.C.S.K.) MODULATION TECHNIQUE

Spread-spectrum techniques spreads any signal (electrical, electromagnetic, or acoustic signal) generated with a particular bandwidth deliberately in the frequency domain,

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

resulting the formation of a signal with wider bandwidth [8]. Spread spectrum uses wideband, noise-like signals which are hard to detect, intercept, or demodulate. It was its anti-jam feature which made it popular, especially in military environments [3, 12].

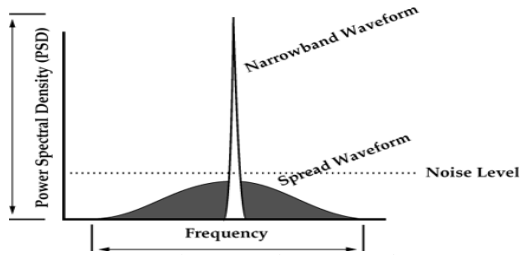

Fig.1. Spread-spectrum scheme

The high bandwidth of spread spectrum results a much lower spectral power density (in Watts per Hertz), than narrow band transmitters. Due to this low spectral power density, spread-spectrum and narrowband signals can occupy the same band, with little or no interference [5]. The block diagram of spread-spectrum scheme is as shown below.

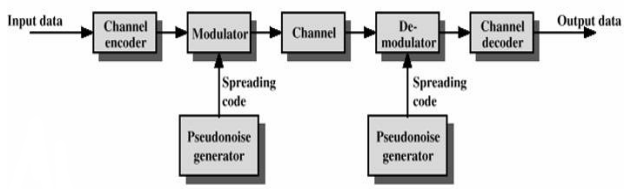

Fig.2. Block diagram of Spread-Spectrum Communication scheme

In the block diagram it is clearly visible that spreading codes are required at both modulating & demodulating ends which must be supplied from same source or different sources producing same spreading codes & thus need some synchronization mechanism. This synchronization can be implemented by using an acquisition method in combination with a tracking loop or other tracking mechanism. In noisy, unpredictable environment like that in AC power line, the tracking loop often fails frequently causing loss of information. The system compensating these problems is generally large, complex & expensive. Apart from it, these systems can transmit only one or two bits per symbol [3]. These drawbacks led to the development of a modified spread spectrum technology, Differential Code Shift Keying (DCSK) that is especially meant for power line communication scheme [6]. It modulates the symbol by cyclic shifting of the basic symbol in the transmitter, and detecting that shift in the receiver [4].

As mentioned previously, in this modulation technique data transmission is by the cyclic shifting of the spreading waveforms which may be any waveform having suitable auto correlation. Chirp is the commonly used waveform for this purpose, which is a frequency modulated signal segment whose frequency increases or decreases with time [9]. These chirp waveforms of constant length are then rotated suitably depending on the data value & are termed as 'Unit Symbol Time' (UST) [3].

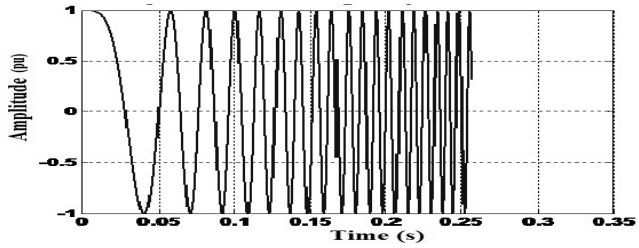

Fig.3. A linear chirp waveform

Let us illustrate this chirp rotation of the linear chirp as shown above. For performing the rotation, let us divide the chirp waveform in 255 equal segments each of time interval of 1ms. This rotation of waveform may in clockwise or counter-clockwise direction. In counter-clockwise rotation, segments are circularly rotated by 1 place in counter-clockwise direction. The anti-circularly rotated chirp rotated by 100 units counter-clockwise will be is as shown below.

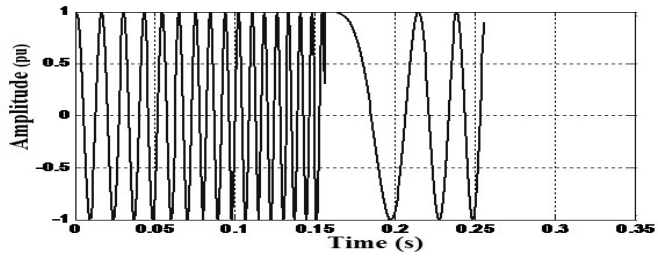

Fig.4. Counter-clockwise rotated chirp by hundred units

In clockwise rotation, segments are circularly rotated by 1 place in clockwise. The circularly rotated chirp will be rotated by 100 units clockwise is as shown below.

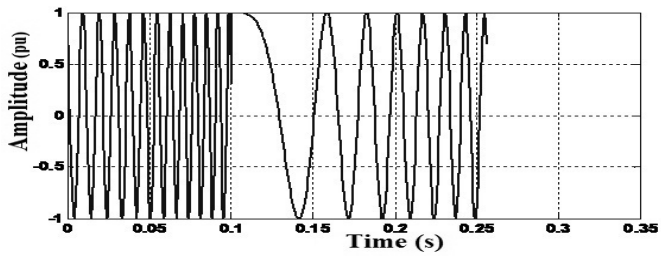

Fig.5. Clockwise rotated chirp by hundred unit

There may be two alternatives for designing DCSK communication scheme. In the first arrangement, the data is conveyed in the amount of rotation of the chirp. Alternatively, data may be conveyed in the differential shift between two consecutive chirps [3]. In this paper, the first case is only considered. Generally data is in the form of string which can be transmitted is in the form of a collection of a no. of shifted chirp waveforms (USTs) forming a superchirp or symbol stream [3]. A superchirp of character string "$jS" is shown below. As the given string possesses three characters, so three

shifted chirp waveforms placed in sequences will form the superchirp waveform. The arrows drawn in the bottom of superchirp indicates the amount of rotation of individual chirps corresponding to the ASCII value of the characters present in the string.

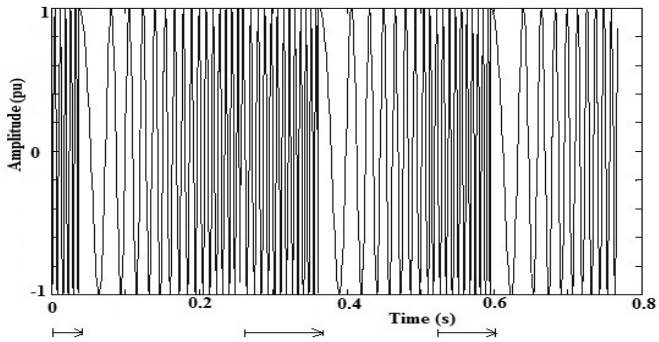

Fig.6. A superchirp or symbol stream of character string "$jS"

At the receiving end, demodulation is done by comparing the individual USTs with the non-rotated chirp waveform to determine the amount of rotation. This is done by the series of rotations & simultaneous comparison gives the transmitted data [3]. This modulation scheme has the following advantages:

a. High transmission reliability
b. Simple & fast synchronization
c. Immediate recovery from severe fading
d. Higher data throughput rate using the same symbol time duration as in direct sequence spread spectrum communication system.
e. Robust against channels characterized by frequency varying signal to noise ratios.
f. Low cost implementation in a single VLSI ICs.

IV. RESULT AND ANALYSIS

At the transmission end, the character is encoded in waveform as shifted chirp & is transmitted. The algorithm of transmitting a character employing DCSK communication scheme is as below.

ch: Input character
fi: Initial frequency of chirp waveform
ff: Final frequency of chirp waveform

STEP 1: Enter ch, fi & ff.
STEP 2: Determine the ASCII value of ch.
STEP 3: If the no. of significant bits of ff is n, then chirp length is given by 255.99 $X10^{-n}$ s.
STEP 4: Produce chirp of desired length with given fi & ff.
STEP 5: Divide chirp in 256 equal sections.
STEP 6: cnt:=0
STEP 7: do cnt!=ASCII
STEP 8: : Rotate the chirp 1 unit counter clockwise.
STEP 9: : Increment cnt by 1.
STEP 10: End of the loop.
STEP 11: Transmit rotated chirp.
STEP 12: End.

At the receiving end, the transmitted waveform is obtained & is continuously compared with the non-shifted chirp signal as used at the transmitting end to determine the amount of rotation. The algorithm of decoding the modulated signal at the receiving end employing DCSK communication scheme is as below.

r(t): Non-shifted reference chirp
u(t): Shifted received chirp

STEP 1: Obtain r(t) & u(t).
STEP 2: Split u(t) in 256 equal sections.
STEP 3: cnt:=0.
STEP 4: do r(t) & u(t) are same.
STEP 5: : Rotate u(t) 1 unit clockwise.
STEP 6: : Increment cnt by 1.
STEP 7: End of the loop.
STEP 8: ASCII value of transmitted character=cnt.
STEP 9: Obtain the character.
STEP 10: End.

The very same logic can be implemented for string transmission using DCSK communication scheme. Then output will be a superchirp, comprising a no. of chirps rotated corresponding to the characters in the string.

str: Input string
fi: Initial frequency of chirp waveform
ff: Final frequency of chirp waveform

STEP 1: Enter str, fi & ff.
STEP 2: Obtain chirps for each character in str of desired length with given fi & ff.
STEP 3: Merge individual chirps for each character to form a superchirp.
STEP 4: Transmit superchirp.
STEP 5: End.

At the receiving end this received superchirp is sub-divided in the corresponding chirps. These chirps are then continuously compared with the non-shifted chirp signal to determine the amount of rotation & hence the ASCII value of character. Thus all the characters of the data string can be obtained. The flowchart of the demodulating end is as below.

s(t): Superchirp
r(t): Non-shifted reference chirp

STEP 1: Split s(t) in individual chirps.

STEP 2: Determine the characters transmitted via individual chirps by comparing with r(t) & store the characters separately.
STEP 3: Merge the characters to form the string.
STEP 4: End.

Utilizing the above communication method, a PLCC based data acquisition system can be implemented consisting of PLCC modem, microcontroller, sensor arrays and indicators as shown in fig. 7. Here a single phase 230V, 50 Hz A.C. supply has been utilized for communication channel run over the moderate distance within the site area.

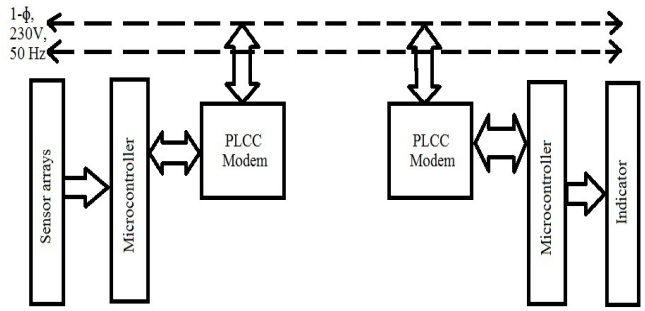

Fig.7. Proposed system: PLCC base DAS

V. DISCUSSION AND CONCLUSION

The algorithm is employed for developing MATLAB programs for character/string transmission & reception using PLCC scheme. For single character transmission & reception programs, the execution time is very small. But while executing the string transmission & reception program, it was found that the execution time required varies as some function of no. of characters in the string. The variation of execution time with the increase of characters in the string for both transmission & reception program is shown below.

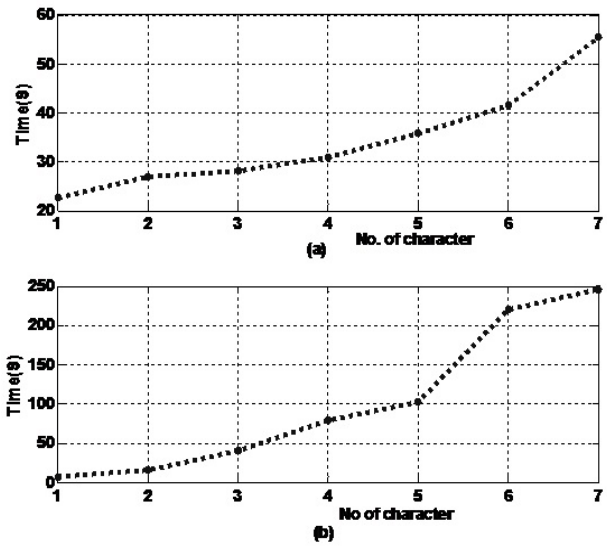

Fig.8. Variation of execution time with the variation of no. of characters in (a) Transmission program; (b) Reception program

From fig. 8, it is clearly visible that though the system is running successfully, it suffers serious problems regarding rate of data transfer for string transmission & reception. With increased no. of characters in the string, the execution time also increases significantly for both transmission & reception programs thereby limiting its rate of data transfer. Thus modifications are needed to overcome its limitations.

***Abstract*—Wireless communication system consists of wireless communicating entities that transmit data through bandwidth flexibly and conveniently. Wireless entities have the freedom to change their position which implies wireless communications support mobility in the system. With such benefits, wireless communication systems are challenged by many security issues. In this paper, we have prevented malicious behaviour of compromised communicating entity or any other malevolent entity to disrupt the communication system with our probabilistic approach of trust based security management. We have proposed Probabilistic Trust Management (PTM) in wireless communication system with consideration of current and previous interactions along with indirect evaluations depending on timing constraint. Our simulation results show the efficiency of proposed PTM in wireless communication system.**

Keywords—probability; direct interaction; indirect interaction; posetive interaction; negative interaction; trustor; trustee.

I. INTRODUCTION

In wireless communication system, wireless entities communicate flexibly and conveniently with each other. Wireless communication system gives flexibility to change position of entities on their need and provides convenient communication between them. Wireless communication is already influence our social interaction but it has many security issues. When wireless entities communicate with each other, any misbehaving entity can falsify them and degrade the expected performance of the communication system. The communicating entities may also be compromised. These necessitate a level of belief or trust in between communication entities.

To prevent such malicious behaviour in wireless communication system, we have proposed PTM (Probabilistic Trust Management) in wireless communication system. Trust [1] is a security approach in which a binary relationship is maintained between communicating devices based on computed trust level with respect to their interactions. Trust level evaluating entity is considered as trustor (TR) and interacting entity with TR for trust evaluation is considered as Trustee (TE). The major disadvantage of traditional trust management is the consideration of trust and untrust notion. The long chain of trustor and trustee necessitates the security analysis with a probabilistic approach. There exists uncertainty to be trusted of trustee to trustor which implies that there is always the probability of being untrusted of trustee to trustor. In our approach, evaluated probabilistic value decides the trust level in qualitative manner rather than quantitative. Our probabilistic trust evaluation is not bound to current direct interactions depending on expectations, but extended to previous direct interactions and notifications with respect to timing constraint.

Related works are discussed in section II . Our proposed probabilistic Trust Management (PTM) is discussed in section III. Section IV shows the simulation results and section V concludes the presented work.

II. RELATED WORK

In [3], authors proposed a probabilistic framework that models agent inter actions as a Hidden Markov Model (HMM). They maintain trust with fully probabilistic representation and reputation while modeling agents with dynamic behaviour. In [5], authors present probability theory and statistics based a novel Peer to Peer trust model to warrant the density of transaction data and the accuracy of computing results. The history records of transactions are considered to form out the trust value of peer with maximum likelihood estimation and hypothesis testing. In [6], authors proposed a probabilistic trust prediction model depending on trust-message passing which takes advantage of the two types of information considered as explicit information and implicit information. In [4], authors proposed probabilistic model to handle trust in P2P system. This proposal supports local computation and simple propagation form of the trust of peers into classes of other peers. In [2], authors quantified the uncertainty of probabilistic trust models using confidence intervals. Here, authors proposed an uncertainty driven method which reduces the risk of the trust-based utility maximization.

III. PTM: PROBABILISTIC TRUST MANAGEMENT

In our probabilistic approach, trust is measured at TR with its computed probability on TE's legitimacy. ${}_{TR}^{c}FP_{TE}^{t_{cur}} \in [0,1]$, where ${}_{TR}^{c}FP_{TE}^{t_{cur}}$ is final probability of legitimacy about TE evaluated by TR at current time t_{cur} on context c. ${}_{TR}^{c}T_{TE}^{t_{cur}} \propto {}_{TR}^{c}FP_{TE}^{t_{cur}}$, T denotes trust value which directly proportional to ${}_{TR}^{c}FP_{TE}^{t_{cur}}$. Our approach defines highest negative Trust: ${}_{TR}^{c}HNT_{TE}^{t_{cur}}$, highest positive trust: ${}_{TR}^{c}HPT_{TE}^{t_{cur}}$,

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

Positive trust: ${}_{TR}^{c}PT_{TE}^{t_{cur}}$, Negative trust: ${}_{TR}^{c}NT_{TE}^{t_{cur}}$ and uncertain trust ${}_{TR}^{c}UT_{TE}^{t_{cur}}$.

$$ {}_{TR}^{c}FP_{TE}^{t_{cur}} = \begin{cases} {}_{TR}^{c}HNT_{TE}^{t_{cur}}, & For\ {}_{TR}^{c}FP_{TE}^{t_{cur}} = 0 \\ {}_{TR}^{c}NT_{TE}^{t_{cur}}, & For\ 0 < {}_{TR}^{c}FP_{TE}^{t_{cur}} < 0.5 \\ {}_{TR}^{c}UT_{TE}^{t_{cur}}, & For\ {}_{TR}^{c}FP_{TE}^{t_{cur}} = 0.5 \\ {}_{TR}^{c}PT_{TE}^{t_{cur}}, & For\ 0.5 < {}_{TR}^{c}FP_{TE}^{t_{cur}} < 1 \\ {}_{TR}^{c}HPT_{TE}^{t_{cur}}, & For\ {}_{TR}^{c}FP_{TE}^{t_{cur}} = 1 \end{cases} \quad (1) $$

$$ {}_{TR}^{c}FP_{TE}^{t_{cur}} = f({}_{TR}^{c}FDP_{TE}^{t_{cur}}, {}_{TR}^{c}DIP_{TE}^{t_{cur}}) \quad (2) $$

Describing "(2)", final probability is the function of probability of TE's legitimacy in direct monitoring (${}_{TR}^{c}FPD_{TE}^{t_{cur}}$) and probability of TE's legitimacy in indirect monitoring (${}_{TR}^{c}FPI_{TE}^{t_{cur}}$). Following Bernoulli's probability combination we can formulate final probability as per "(3)".

$$ {}_{TR}^{c}FP_{TE}^{t_{cur}} = \sum_{i=1}^{n} Wi \times P_{Si} \quad (3) $$

where, $P_{Si} \in ({}_{TR}^{c}FPD_{TE}^{t_{cur}}, {}_{TR}^{c}FPI_{TE}^{t_{cur}})$ and i = 1...n and n=total numbers of probabilities for TE. For our work, n=2 and we have referred $Ps_1 = {}_{TR}^{c}FPD_{TE}^{t_{cur}}$ and $Ps_2 = {}_{TR}^{c}FPI_{TE}^{t_{cur}}$.

A. Probability in Direct Monitoring

We assume total numbers of past interactions is n[Int] and current interaction is $(n[Int]+1)^{th}$ interaction. TR has the knowledge about total n[Int] numbers of direct interactions with TE at different past time instances. $n[Int_P] \in n[Int]$, where $n[Int_P]$ is the total numbers of positive direct interactions. Total numbers of negative direct interactions $n[Int_N]=n[Int]- n[Int_P]$. Bernoulli distribution governs the probability of positive direct interaction as per "(4)".

$$ P(Int_i = true) = p $$
$$ P(Int_i = false) = 1 - p $$

$$ where\ \ i = 1,2, \ldots (n[Int] + 1) \quad (4) $$

P is an unknown measure of interaction being positive and p denotes probability. Int_i denotes ith direct interaction. True value denotes 1 and false value denotes 0.

- Int_i = true , it denotes the ith interaction is positive by legitimate TE.
- Int_i = false , it implies that TE's misbehaviour is identified and it is negative interaction by malevolent TE.
- $n[Int]_{lgtm}$ = number of interactions that returns true value with respect to legitimacy of TE.

Every Int_i is independent to each other for all i's. Since binomial distribution provides discrete probability distribution, we can represent the observation of success that $n[Int]_{lgtm} = n[Int_P]$ among n[Int] numbers of interactions as $P(n[Int]_{lgtm}=$ true | p) following binomial distribution shown in "(5)".

$$ P\left(\left(n[Int]_{legitimate} = n[Int_P] \middle| p\right) \right) = $$

$$ \binom{n[Int]}{n[Int_P]} p^{n[Int_P]} (1-p)^{n[Int]-n[Int_P]} \quad (5) $$

The probability of $(n[Int]+1)^{th}$ interaction that returns true value after performing n[Int] numbers of interactions by TE towards TR, is represented as $P(n(Int)+1_{lgtm}=$ true). Using Bayesian approach TR can evaluate $P(Int_{(n[Int]+1)}=$ true | $n[Int]_{lgtm} = n[Int_P]$) for TE. From Bayes' theorem TR calculate the probability distribution function for $P(Int_{(n[Int]+1)}=$ true) as follows:

$$ P\left(Int_{(n[Int]+1)} = true \,\middle|\, n[Int]_{lgtm} = n[Int_P] \right) $$

$$ = \frac{P(Int_{(n[Int]+1)}=true\,, n[Int]_{lgtm}=n[Int_P])}{P(n(Int)_{lgtm}=n[Int_P])} \quad (6) $$

From marginal distribution we get "(7)".

$$ P\left(n(Int)_{lgtm} = n[Int_P] \right) $$

$$ = \int_0^1 P\left(n(Int)_{lgtm} = n[Int_P] \middle| p \right) f(p) dp \quad (7) $$

On considering other hand, the evaluation of $P\left(Int_{(n[Int]+1)} = true\,,\ n[Int]_{lgtm} = n[Int_P]\right)$ as follows:

$$ P\left(Int_{(n[Int]+1)} = true\,,\ n[Int]_{lgtm} = n[Int_P]\right) = $$

$$ \int_0^1 P\left(Int_{(n[Int]+1)} = true \middle| p\right) P\left(n[Int]_{lgtm} = n[Int_P] \middle| p\right) f(p) dp \quad (8) $$

Since, $Int_{(n[Int]+1)}$ = true = p, we get "(9)" from "(8)" as follows:

$$ P\left(Int_{(n[Int]+1)} = true\,,\ n[Int]_{lgtm} = n[Int_P]\right) $$

$$ = \int_0^1 p.P\left(n[Int]_{lgtm} = n[Int_P] \middle| p\right) f(p)\, dp \quad (9) $$

Replacing the respective values in "(6)" from "(7)" and "(9)" we get "(10)" as belolow:.

$$ P\left(Int_{(n[Int]+1)} = true \,\middle|\, n(Int)_{lgtm} = n(Int_P) \right) $$

$$ = \frac{\int_0^1 p.P(n[Int]_{lgtm}=n[Int_P]|p) f(p)\, dp}{\int_0^1 P(n(Int)_{lgtm}=n[Int_P]|p) f(p)\, dp} \quad (10) $$

Here no prior information exists about p's distribution for TE. As a consequence, with an uniform prior distribution, f(p)=1, similar to [7] is shown in "(11)".

$$ P\left(Int_{(n[Int]+1)} = true \,\middle|\, n(Int)_{lgtm} = n(Int_P) \right) $$

$$ = \frac{\int_0^1 p.P(n[Int]_{lgtm}=n[Int_P]|p)\, dp}{\int_0^1 P(n(Int)_{lgtm}=n[Int_P]|p)\, dp} \quad (11) $$

Replacing the value of $P(n[Int]_{lgtm} = n[Int_p] \mid p)$ in "(11)" by the value of "(5)" we get "(12)".

$$P\left(Int_{(n[Int]+1)} = true \mid n(Int)_{lgtm} = n(Int_P) \right) = \frac{\int_0^1 p \binom{n[Int]}{n[Int_P]} p^{n[Int_P]} (1-p)^{n[Int]-n[Int_P]}\, dp}{\int_0^1 \binom{n[Int]}{n[Int_P]} p^{n[Int_P]} (1-p)^{n[Int]-n[Int_P]}\, dp} = \frac{n[Int_P]+1}{n[Int]+2} = \frac{n[Int_P]+1}{(n[Int_P]+n[Int_N])+2} \quad (12)$$

From "(12)", final probability in direct interaction ${}_{Ri}^{c}FPD_{TE}^{t_{mr}}$ is evaluated as per "(13)".

$${}_{Ri}^{c}FPD_{TE}^{t_{mr}} = f\left(P\left(Int_{(n[Int]+1)} = true \mid n[In]_{lgtm} = n[Int_P] \right), W\right) = \frac{\sum_{i=1}^{n}\left(\frac{n[Int_P]_{total.i}}{n[Int]_{total.i}} \times n_i[Int_P]\right) + 1}{\sum_{i=1}^{n}\left(\frac{n[Int_P]_{total.i}}{n[Int]_{total.i}} \times n_i[Int_P]\right) + \sum_{i=1}^{n}\left(\frac{n[Int_N]_{total.i}}{n[Int]_{total.i}} \times n_i[Int_n]\right)) + 2} \quad (13)$$

where, $n[Int_P]_{total.i}$ denotes the total number of positive interactions upto ith interaction. $n[Int_N]_{total.i}$ denotes the total number of negative interactions upto ith interaction. $n[Int]_{total.i}$ denotes the total number of interactions upto ith interaction.

B. Probability in Indirect Interactions

TR's 1-hop distant nodes (except TE) having the evaluated final probability knowledge about TE considered as recommenders ($R=\{R_1,R_2,....R_n\}$). Ri (ith recommender) sends the evaluated final probability about TE to TR as recommendation probability (${}_{Ri}^{c}P_{TE}^{t_0}$, t_0 is the computing time instant). Allowance of giving recommendation probability by every recommender follows exponential distribution as in "(14)".

$$f(t,\alpha) = \alpha e^{-\alpha t} \quad , for \;\; t \geq 0 \;\; and \; \alpha > 0 \quad (14)$$

Time $t = t_0, t_1, t_2, ... , t_{cur}$. when $t = t_{cur}$, t is considered as current time instant and when $t = t_0$, t is considered as computing time instant. α is the rate parameter of the distribution.

Using "(14)", the allowed recommendation probability distribution curve over time follows f{t} as shown in "(15)".

$$f\{t\} = f_R\{ \left({}_{Ri}^{c}P_{TE}^{t_0} \times \alpha e^{-\alpha t_0}, t_0\right), \left({}_{Ri}^{c}P_{TE}^{t_0} \times \alpha e^{-\alpha t_1}, t_1\right) , \dots\dots\dots , \left({}_{Ri}^{c}P_{TE}^{t_0} \times \alpha e^{-\alpha t_{cur}}, t_{cur}\right) \} \quad (15)$$

Here, Ri is the ith recommender and ${}_{Ri}^{c}P_{TE}^{t_0}$ is the recommendation probability from Ri. Since nature of the curve is decaying over time, we are considering the lastly evaluated final probability of Ri as recommendation probability.

Allowed recommendation probability by Ri at current time instant is shown in "(16)"

$${}_{Ri}^{c}AlRP_{TE}^{t_{cur}} = {}_{Ri}^{c}P_{TE}^{t_0} \times \alpha e^{-\alpha t_{cur}}, for \; t \geq 0 \; and \; \alpha > 0 \quad (16)$$

Every ith recommender sends their ${}_{Ri}^{c}AlRP_{TE}^{t_{cur}}$ to TR as recommendation. After getting allowed recommendation from different recommenders, TR considers every Ri's ${}_{Ri}^{c}AlRP_{TE}^{t_{cur}}$ as accepted probability (${}_{Ri}^{c}AcPi_{TE}^{t}$) with respect to its acceptance rate according to "(17)".

$${}_{Ri}^{c}AcRP_{TE}^{t} = {}_{Ri}^{c}AlRP_{TE}^{t_{cur}} \times acceptance\ rate \quad (17)$$

where, acceptance rate on i[th] allowed recommendation probability is evaluated as per "(18)".

$$Acceptance\ rate = acceptance\ level \times \alpha e^{-\alpha t} \quad (18)$$

Acceptance level of TR on Ri is the lastly evaluated final probability by TR for Ri (${}_{TR}^{c}Pi_{Ri}^{t_0}$). Acceptance level of any recommender follows similar exponential distribution as in "(14)". Cumulative accepted recommendation probability (${}_{R}^{c}CAcRP_{TE}^{t}$) for TE is evaluated by TR as per "(19)".

$${}_{R}^{c}CAcRP_{TE}^{t} = \frac{1}{n}\sum_{i=1}^{n} {}_{Ri}^{c}AcRP_{TE}^{t} \quad (19)$$

Final probability on indirect monitoring (${}_{R}^{c}FPI_{TE}^{t}$) is evaluated by TR for TE as per "(20)".

$${}_{R}^{c}FPI_{TE}^{t} = \sum_{i=1}^{n} W_i \times {}_{R}^{c}IP_{class:i}\,{}_{TE}^{t} \quad (20)$$

where class:i denotes the ith class. i=1,2.... n. Here n=2. class:1= positive and class:2=negative. $W_2 = (1-W_1)$. W_1 and W_2 are the corresponding weight.

IV. Simulation

Our simulation result shows the probability of legitimacy from direct monitoring with consideration of positive and negative type of interaction. In Fig.1, we have shown the probabilities of legitimacy where TE performs continuous positive and continuous negative direct interactions with TR. Fig.2 shows the probability of legitimacy with a situation where a TE start to interact negatively after 5th continuous positive direct interactions with TR. Similarly, Fig.3 shows the probability of legitimacy where a TE start positive interaction after 5th continuous negative direct interactions with TR.

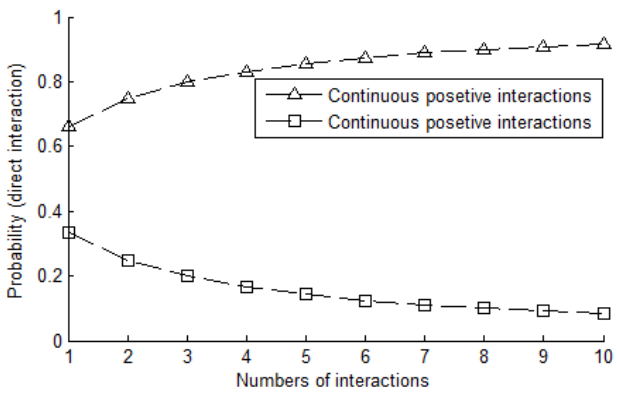

Fig. 1. Simulation Results

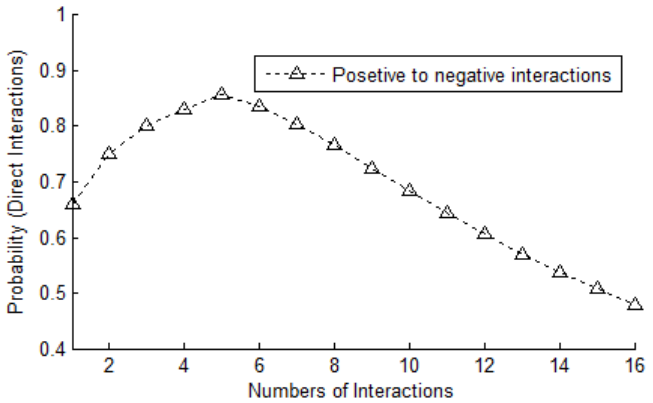

Fig. 2. Simulation Result

V. CONCLUSION

Our proposed Probabilistic Trust Management (PTM) in wireless communication system efficiently defends against malicious behaviour of compromised wireless entity or any other malevolent entity. Proposed PTM isolates malicious behaviour from system by isolating compromised or any other malevolent wireless entity from communication. Our PTM efficiently isolates malicious behaviour depending on direct indirect interactions with their timing constraint and the consideration of legitimacy level of interactions. Our Simulation results have shown the efficient performance of proposed PTM in wireless communication system.

Abstract—**A simple novel compact three-order microstrip bandpass filter is proposed using half wavelength microstrip line resonators coupled through parallel stub lines. The filter has two signal paths, one through the parallel coupled lines of resonators and other through the electrical coupling between feed lines for which the filter shows two transmission zeros. The proposed filter has a bandwidth of 1GHz covering WLAN 5.2/5.8 GHz and WiMAX 5.5 GHz bands. The filter is compact and simple structure having very low insertion loss in the passband makes it suitable for wireless application.**

Index Terms— **Bandpass filter, Transmission Zero, Wireless Local Area Network (WLAN) and Worldwide Interoperability for Microwave Access (WiMAX).**

I. Introduction

In modern communication systems planner microstrip bandpass filter (BPF) are widely studied and used because of their low cost, simple structure and easy integration. Different types of compact bandpass filter have been proposed [1-11]. Dual behaviour resonators based on stepped impedance and different-length stub is used for dual transmission zero, given in [1]. In [2], radial-line stubs are used for multimode BPF design. In [3] additional transmission zeros are generated using double split-end quarter-wave-length resonator. It is possible to increase transmission pole with the help of square-loop resonator [4]. The novel compact stub coupled microstrip square open loop BPF is proposed for single pole with dual transmission zeros [5]. Open stub inverter between quarter wave length resonator [6], half wavelength microstrip line resonator and end coupling resonator [7], a half-wavelength transmission line resonator with a pair of tap-connected open-ended stubs [8], dual-mode stub-loaded resonators [9], are used for multiple pole BPF with double transmission zeros. Two order BPF with three finite zero point is achieved in [10].

In this paper, a novel compact three-pole microstrip fed bandpass filter with two transmission zeros is proposed. The proposed BPF uses three parallel resonators coupled by stub lines. Three resonators are used to implement three poles in passband which improves the filter characteristics. The dual transmission zeros are generated by two different signal paths one via parallel resonators and other through the direct signal path by electrical coupling in feed lines. The proposed microstrip band pass filter is covering 10 dB bandwidth of 1.02GHz, starting from 4.87 to 5.89 GHz. The filter can be used for WLAN 5.2/5.8 GHz and WiMAX 5.5 GHz applications. The operating bandwidth covers WLAN bands of 5.15 – 5.35 GHz and 5.725 – 5.825 GHz (IEEE 802.11a) and WiMAX band of 5.25 – 5.85 GHz (IEEE 802.16), have been exempted from licensing. The WLAN 5.2 GHz band is restricted to indoor operation with a maximum EIRP (Effective Isotropic Radiated Power) of 200 mW and the WLAN 5.8 GHz band could be used for both indoor and outdoor applications with EIRP up to 4 watt. Recently, the World Radio communication Conference 2003 has approved a new co-primary allocation in the 5.47 – 5.725 GHz band for mobile service for the implementation of wireless access systems. It is also possible for WiMAX systems to operate in the 5.5GHz band on an uncoordinated and unprotected basis.

CST microwave studio is used for all the simulation and optimization purposes. The proposed filter is designed on a $25\times28mm^2$ low-cost FR4 substrate with thickness of 1.59 mm, dielectric constant of 4.4 and the loss tangent is 0.02. The filter modelling and its results are described in section II and the paper is concluded in Section III.

II. Filter Modelling and Results

The microstrip filter loaded with a single $\lambda/2$ resonator is shown in figure 1. The signal is coupled to the resonator through the parallel stubs from the feed line. The signal is also directly coupled through electrical coupling via gap g_3 in the feed line. The simulated s-parameters are given in figure 2. It is a single pole bandpass filter with dual transmission zero. The pole of the proposed filter can be increased by increasing the no of resonators. The optimized parameters are W_1= 1 mm, W_2=0.8 mm, W_3=2.9 mm, g_1=0.8 mm g_2=0.5 mm, g_3=1.6 mm, L_1=14.5 mm, L_2=8.3 mm.

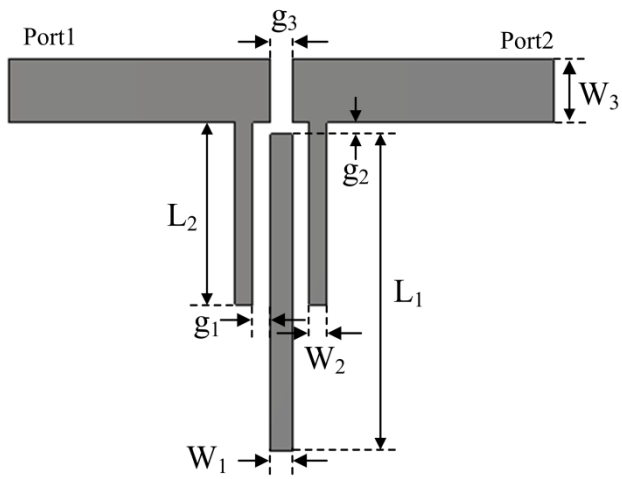

Fig. 1 Single pole bandpass filter.

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

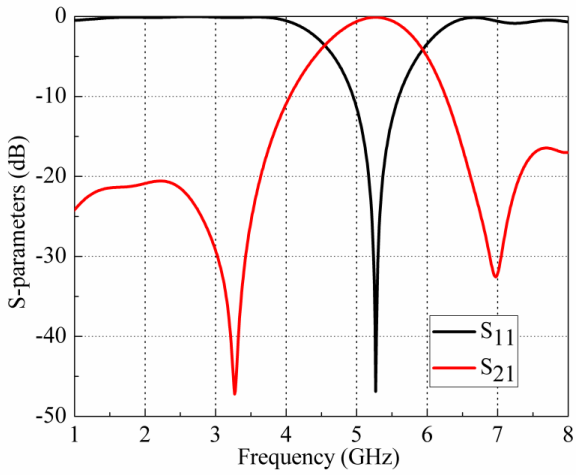

Fig. 2 S-parameters of single pole bandpass filter.

A dual-pole bandpass filter is achieved by using two $\lambda/2$ resonators in place of one used in single pole bandpass filter. It improves the filter bandwidth with sharp out of band rejection. The dual-pole bandpass filter is shown in figure 3 and its s-parameters is given in figure 4. The insertion loss is near to 0 dB level and return loss below -20dB level in the passband. Two transmission zeros are realised at 3.32 GHz and 6.83 GHz. The filter covers the 10 dB bandwidth from 5.03 to 6 GHz. The optimized parameters are W_1= 1 mm, W_2=0.8 mm, W_3=2.9 mm, g_1=0.8 mm g_2=0.5 mm, g_3=1.6 mm, g_4=1.4 mm, L_1=13.8 mm, L_2=8 mm.

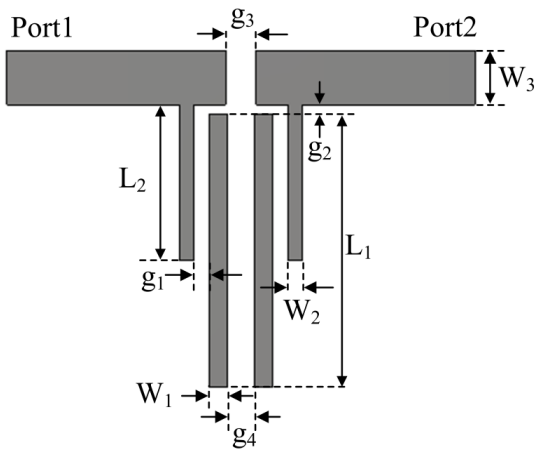

Fig. 3 Dual-pole bandpass filter.

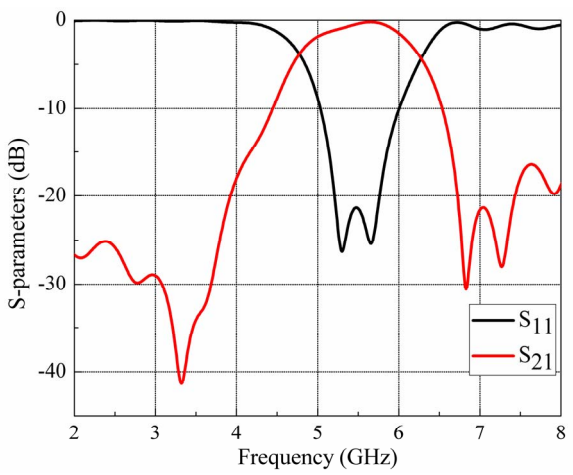

Fig. 4 S-parameters of dual-pole bandpass filter.

The filter performance can still be improved by increasing the no of $\lambda/2$ resonators. A three-pole bandpass filter is achieved by using three $\lambda/2$ resonators in the structure, shown in figure 5. The insertion loss is near to 0 dB level and return loss below -20dB level in the passband. Two transmission zeros are realised at 3.49 GHz and 6.3 GHz. The filter covers the 10 dB bandwidth from 4.87 to 5.89 GHz. So, the proposed triple-pole bandpass filter shows that the transmission zeros come closer to the passband, thus improves the sharp out of band rejection. A comparative study of dual-pole and triple-pole bandpass filter is shown in figure 6. The final optimized parameters for the proposed filter are W_1= 1 mm, W_2=0.8 mm, W_3=2.9 mm, W_4=1.3 mm, g_1=0.8 mm g_2=0.5 mm, g_3=1.6 mm, g_4=1.4 mm, L_1=13.8 mm, L_2=8 mm.

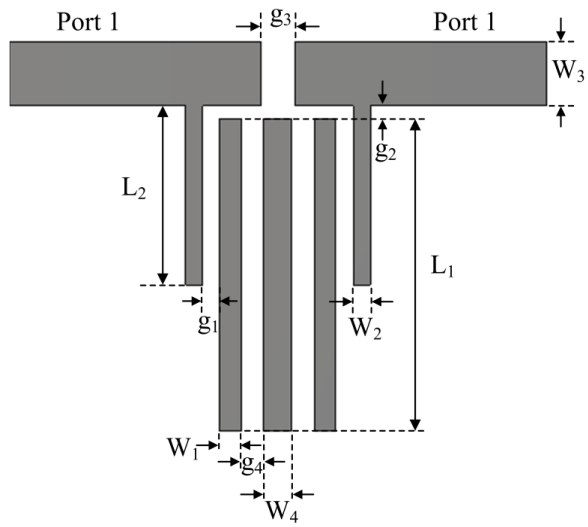

Fig. 5 Proposed three-pole bandpass filter.

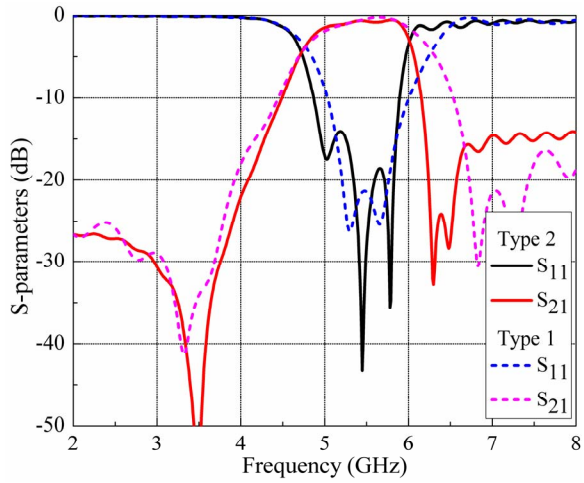

Fig. 6 Comparison between dual-pole (Type 1) and proposed triple-pole (Type 2) bandpass filter.

III. Conclusions

A new compact low cost single band bandpass filter with dual transmission zero is introduced here. The transmission zeros are controllable by the filter poles. The filter poles are increased by increasing the no of $\lambda/2$ resonators. The proposed simple structure is suitable for the use in WLAN and WiMAX applications.

***Abstract*—In this paper, the optimal scheduling problem is studied in multi-user MIMO (MU-MIMO) single-hop uplink cellular networks. An optimization framework is developed to compute the optimal max-min throughput and the optimal scheduling of the users. The optimization problem is found to be a very complex linear program. The optimization problem is solved for several medium size cellular networks using an optimization tool. The numerical results show that MU-MIMO technique provides a significant throughput gain over SU-MIMO technique. To avoid the complexity of computation and implementation, a user grouping based simple scheduling algorithm is also proposed for MU-MIMO cellular networks. The performance of the proposed algorithm is evaluated and found to be very efficient.**

***Index Terms*—Multi-user MIMO, scheduling, throughput, optimization.**

I. Introduction

Multiple-input and multiple-output (MIMO) communication technique has made the most significant breakthroughs in terms of channel capacity and reliability in modern wireless communication [1]. Multiple antennas at transmitter and receiver can increase the channel capacity by transmitting independent data streams over multiple spatial channels from transmitter to receiver [2]. If the number of transmitting antennas is M and the number of receiving antennas is N, it is possible to achieve $min(M, N)$-time capacity of single transmitting and receiving antenna configuration [3]. Due to the advantages of the MIMO communication, it has been adopted in the current standards of cellular and other wireless networks.

Throughput is an important performance metric in wireless cellular networks to support voice, video, and data services. The throughput performance in a MIMO cellular network significantly depends on the scheduling algorithm and MIMO technique. MIMO technique can be classified as: single user MIMO (SU-MIMO) and multi-user MIMO (MU-MIMO) and further, MU-MIMO technique can be classified as MU-MIMO with single antenna transmission (MU-MIMO-SA) and MU-MIMO with combined single and multi-antenna transmission (MU-MIMO-SA-MA) [4]. In [5], it is shown that the MU-MIMO-SA scheme provides better throughput than the SU-MIMO scheme in random access based wireless local area networks. In [4], joint routing and scheduling problem is studied in uplink wireless mesh networks and it is found that (i) the MU-MIMO techniques provide significantly higher max-min throughput than the SU-MIMO technique and (ii) the MU-MIMO-SA-MA scheme provides better max-min throughput than the MU-MIMO-SA scheme. The scheduling problem of MU-MIMO cellular networks has been studied in [6]- [9] with various aspects. In [6], a fair scheduling algorithm is proposed for uplink MIMO network. An interference-aware optimal user selection scheme is proposed in [7] for MIMO system in multicell environment. In [8], an scheduling algorithm is proposed for heterogeneous users in MIMO downlink network. In [9], users are scheduled in pairs to achieve the optimal throughput where the resource will be underutilized if the number of base station (BS) antennas are more than two. In the available studies on MU-MIMO scheduling in wireless cellular networks, there is no clear indication on which MIMO scheme is better for single hop cellular networks and on how to perform optimal scheduling.

Usually, throughput-optimal scheduling problem of any wireless network is a very complex linear program (LP) [10]. The complexity of the problem increases significantly with the number of nodes in the network. The optimal solution of the scheduling problem may be achievable for a medium size network by using optimization tools and different optimization techniques, e.g., column generation technique [10]. However, it is very difficult to implement these approaches in practice. Low-complexity scheduling algorithm is necessary for practical solution.

In this paper, single cell uplink MIMO cellular networks with multiple transmission rates is considered to study the optimal scheduling problem. The contributions in this paper are as follows:

- An optimization framework is developed to compute the optimal max-min throughput and the optimal scheduling of the users of a network with the SU-MIMO, MU-MIMO-SA and MU-MIMO-SA-MA schemes.
- The optimization problem is solved numerically using the optimization tool MINOS [11] for several medium size networks under the three different MIMO schemes and the throughput performance of the MIMO schemes is compared.
- Due to the limitation of installing a powerful computing device at a BS, it is difficult to implement the tool dependent based solution approach of the optimization problem in practice. For practical implementation, a user grouping based simple scheduling algorithm is proposed for MU-MIMO cellular networks. The performance of the proposed algorithm is evaluated and found to be very efficient.

The rest of the paper is organized as follows. The system model is presented in detail in Section II. The optimization problem of optimal scheduling is formulated in Section III. In section IV, the numerical results are presented and the various engineering insights are provided. The grouping based simple scheduling algorithm is described and analyzed in Section V. The paper is concluded in Section VI.

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

II. System Model

A. Network Topology

A single-hop cellular network consisting of U stationary users and a BS is considered. The set of users $\mathcal{U}$ is given as $\mathcal{U} = \{1, 2, ..., U\}$. The transmission power of each user is P_t. The number of antennas at the BS and at each user is assumed to be N. The antennas are omni-directional and cannot transmit and receive simultaneously. Only uplink communication is considered in the network, i.e., only the users transmit data to the BS.

B. MIMO schemes

1) SU-MIMO: In this scheme, only one user communicates with the BS at a time through its N antennas. The transmitter first encodes the input bits with one encoding block, generates N data streams and transmits through N antennas to the BS. The transmission power at each antenna for each data stream is P_t/N.

2) MU-MIMO-SA: In this scheme, a user transmits using only one of its antennas. So the BS can successfully retrieve data streams from N users at a time. The transmission power at the transmitting antenna is P_t.

3) MU-MIMO-SA-MA: In this scheme, a user can transmit through one or more of its antennas [4]. For a transmission, in this scheme, a transmitter encodes the input bits with one coding block, generates N' data streams, where $1 \leq N' \leq N$ is the number of antennas to be used in transmission, and transmits in parallel with the N' antennas. For this scheme, the transmission power at each antenna of the transmitter is P_t/N'.

C. Physical Layer Model

The number of simultaneous data stream transmission is assumed to be less than or equal to the number of antennas in the BS. Due to its simplicity, zero forcing (ZF) MIMO decoding technique is considered at the BS. Hence, the success or failure of a data stream transmission depends on only to the signal to noise ratio (SNR) of the data stream, not on the signals of the other data streams and the SNR must not be less than a threshold for successful reception [4], [5]. The SNR threshold depends on the modulation and coding scheme, i.e., data rate of the data stream. Let β be the SNR threshold for a data stream i. Thus, the data stream i is successful if [4], [5]

$$\frac{g_i E\left[|s_i|^2\right]}{N_0} \geq \beta \tag{1}$$

where, g_i is the channel gain between the user of data stream i and the BS, $E[|s_i|^2$ is the transmitted power of the received data signal s_i of the data stream i and N_0 is the background noise power. The channel gain between the user of data stream i and the BS is given by $g_i = \left(\frac{d_i}{d_0}\right)^{-\eta}$, where, d_i is the distance between the user of data stream i and the BS, η is the path loss exponent, and d_0 is a reference distance in the far field of the antenna.

D. Rate Selection for a Data Stream

It is assumed that a user can transmit with R different rates. The set of the rates $\mathcal{R}$ is given by $\mathcal{R} = \{r_1, r_2, ..., r_R\}$. The set of the required SNR's for the available data rates is given by $\mathcal{B} = \{\beta_1, \beta_2, ..., \beta_R\}$, where β_j is the SNR threshold for the rate r_j. It is assumed that a user selects the highest possible rate for a data stream based on the SNR of the data stream at the BS, i.e., the rate of a data stream i is r_j if

$$\beta_j \leq \frac{g_i E\left[|s_i|^2\right]}{N_0} \leq \beta_{j+1}. \tag{2}$$

The value of $E\left[|s_i|^2\right]$ in (1) and (2) depends on the MIMO scheme used in the system. It is equal to P_t/N and P_t for the SU-MIMO and MU-MIMO-SA schemes, respectively. For the SU-MIMO-SA-MA scheme, it depends on the number of antennas to be used for transmission.

E. Scheduling

The set of users that can transmit simultaneously without any collision is defined as an independent set (ISET) and denoted by v. For the SU-MIMO scheme, an ISET consists of only one user and there are U ISETs in the cellular network. For the MU-MIMO-SA scheme, a set of users $v \subset \mathcal{U}$ is an ISET if $|v| \leq N$. For the MU-MIMO-SA-MA scheme, a set of users $v \subset \mathcal{U}$ is an ISET if $\sum_{u \in v} {M'}_u^v \leq N$, where ${M'}_u^v$ is the number of data streams to be transmitted by the user u in ISET v. For scheduling, the users of an ISET will be allowed to transmit for a given time duration in a regular interval.

III. Problem Formulation

In this section, the optimization problem is formulated for the SU-MIMO and MU-MIMO schemes.

A. Optimal Scheduling Problem

Let the set of all the ISETs for the network is $\mathcal{I}$ and α_v be the fraction of time that the ISET v will be scheduled by maintaining $\sum_{v \in \mathcal{I}} \alpha_v = 1$. Denote the vector of α_v's by $\boldsymbol{\alpha}$. Let $\mathcal{I}_u \subset I$ be the set of ISETs containing user u. Let the throughput of user u is λ_u and the vector of λ_u's is $\boldsymbol{\lambda}$. The throughput of a user u can be expressed as $\lambda_u = \sum_{v \in \mathcal{I}_u} C_{u,v} \alpha_v$, where $C_{u,v}$ is the selected rate by the user u for ISET v. The value of $C_{u,v}$ can be calculated as $C_{u,v} = {M'}_u^v R_{u,v}$, where $R_{u,v}$ is the data rate of each stream of user u which can be calculated from (2).

Let λ be the minimum throughput of the users for the cellular network. The optimization problem to maximize λ with any MIMO scheme can be expressed as

$$\max_{\boldsymbol{\alpha}, \boldsymbol{\lambda}} \quad \lambda \tag{3}$$

$$\lambda \leq \lambda_u \quad \forall u \in \mathcal{U} \tag{4}$$

$$\lambda_u = \sum_{v \in \mathcal{I}_u} C_{u,v} \alpha_v \quad \forall u \in \mathcal{U} \tag{5}$$

$$\sum_{v \in \mathcal{I}} \alpha_v = 1 \tag{6}$$

$$0 \leq \boldsymbol{\alpha} \leq 1 \quad ; \quad 0 \leq \boldsymbol{\lambda} \tag{7}$$

The objective function in (3) and the constraints in (4) ensures that the minimum throughput of the users is maximized. The constraints in (5) represent the rates of the users. The constraint in (6) relate the fraction of times of the different ISETs and it states that ISETs must be scheduled over a unit period of time. The constraints in (7) define the range of the variables.

The problem (3)-(7) is a LP and the complexity of the problem mainly depends on the number of ISETs in the network. The number of ISETs in a network depends on the number of users and MIMO scheme of the network. For the SU-MIMO

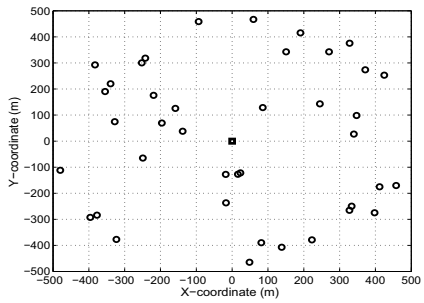

Fig. 1. The positions of the nodes in Network-1.

TABLE I
DATA RATES AND THE CORRESPONDING SNR THRESHOLDS.

Modulation	Coding rate	Data Rate	SNR Threshold (dB)
BPSK	1/2	1	6.4
QPSK	1/2	2	9.4
	3/4	3	11.2
16-QAM	1/2	4	16.4
	3/4	6	18.2

scheme, the number of ISETs is only equal to the number of users and the optimal solution can be obtained easily with some calculations (described later) without any optimization tool. On the other hand, the number of ISETs for the MU-MIMO-SA and MU-MIMO-SA-MA schemes are $\sum_{n=1}^{N}\binom{U}{n}$ and $\sum_{n=1}^{N}\binom{U}{n}\binom{N-1}{n-1}$, respectively. Thus, the complexity of the optimization problem is $O(U^N)$ for the both MU-MIMO schemes.

B. Solution of the Problem for SU-MIMO Scheme

Let j and k are two different users in the network. In the SU-MIMO scheme, the number of ISETs for a user is only one and the ISET contains only the user. Let the fraction of times to be scheduled by users j and k are α_j and α_k, respectively and the data transmission rates of users j and k are C_j and C_k, respectively. Since the minimum throughput need to be maximized, it is assumed that $\lambda^* = \lambda_j = \lambda_k$. Thus, $\alpha_j^* C_j = \alpha_k^* C_k$. Since $\sum_{i\in\mathcal{U}} \alpha_i^* = 1$, it can be shown that $\alpha_k^* = \frac{1}{1+C_k \sum_{i\in\mathcal{U}\setminus k} \frac{1}{C_i}}$. Then the max-min throughput of each user can be calculated as $\lambda^* = C_k \alpha_k^*$.

IV. NUMERICAL RESULTS

A. Networks and Parameters

Twenty networks are considered each consisting of 40 users and a BS. The BS is located at the centre surrounded by the users. The positions of the users are determined by a uniform random distribution. One of the networks (Network-1) is shown in Fig. 1 where the BS is labeled as a box. It is assumed that a user can use five different modulation and coding schemes. The normalized data rates and the SNR thresholds for the different modulation and coding schemes are taken from [10] and are illustrated in Table I. The number of antennas at the BS and at each user is assumed to be 4. The noise power (N_0), path loss exponent (η) and reference distance (d_0) are considered as -100 dBm, 3 and 1m, respectively.

B. Advantages of MU-MIMO Schemes

For the Network-1, the optimal max-min throughput is computed by solving the optimization problem (3)-(7) using the optimization tool MINOS [11] for different transmit power levels under the different MIMO schemes. The max-min throughputs and the throughput gain of the MU-MIMO schemes with respect to the SU-MIMO scheme for Network-1 are shown in Fig. 2 for different transmission power levels. The results show that the MU-MIMO-SA and MU-MIMO-SA-MA schemes provide the same max-min throughput for any transmission power. The same result is found for the other 19 networks. Thus, the MU-MIMO-SA scheme is preferable in cellular networks to avoid the complexity of the MU-MIMO-SA-MA scheme. It is observed that the MU-MIMO schemes improves max-min throughput significantly at a low transmission power. For Network-1, the MU-MIMO schemes provide upto 138.3% throughput gain over the SU-MIMO scheme. One of the important advantages of the MU-MIMO schemes is that the network becomes connected approximately 6 dB lower transmission power than the SU-MIMO scheme.

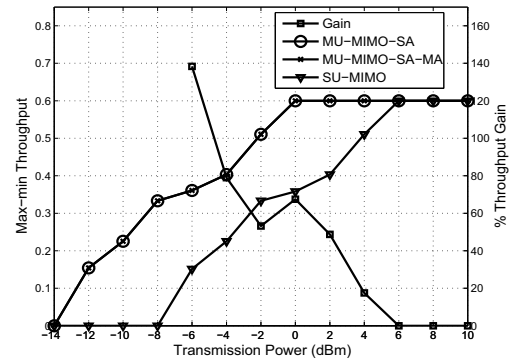

Fig. 2. Throughput comparison of the SU-MIMO, MU-MIMO-SA and MU-MIMO-SA-MA schemes for Network-1.

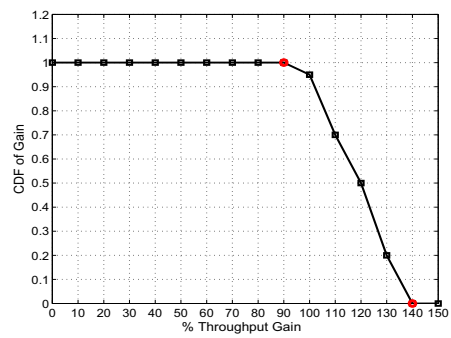

Fig. 3. Cumulative distribution function of gains of the MU- MIMO scheme over SU-MIMO scheme.

The optimal max-min throughputs for the other 19 networks are also computed at $P_t = -6$ dBm and the throughput gain of the MU-MIMO schemes over the SU-MIMO scheme are determined. The cumulative distribution function (CDF) of throughput gain for the 20 networks at $P_t = -6$ dBm is shown in Fig. 3. The results show that in all the networks the throughput gain of the MU-MIMO schemes is more than 90% and less than 140%. The average throughput gain is found to be 118.63%. Thus, MU-MIMO technique provide a significant benefit over SU-MIMO technique in term of max-min throughput.

V. Grouping Based Scheduling

It is difficult to apply the optimization tool based optimal scheduling approach in practice due to the limitation of installing a powerful computing device at a BS. However, the optimization tool is not able to provide a solution for a large network. In this section, a user grouping based simple scheduling algorithm is proposed and the performance of the algorithm is evaluated.

A. Rate Based User Grouping

The number of groups of the users is assumed to be R with R different data rates. The distances of the users and their data rates are assumed to be known to the BS. The sets of users having data rates $r_1, r_2, \ldots$, and r_R are denoted by $\mathcal{U}_1, \mathcal{U}_2, \ldots$, and $\mathcal{U}_R$, respectively. The number of users in group i is given by U_i and $U_i = |\mathcal{U}_i|$.

B. Grouping Based Scheduling and Throughput

It is assumed that at a time only the users of a group are scheduled. An ISET of group i is denoted by v^i. It is also assumed that an ISET contains N users, i.e., $|v^i| = N$. Thus, the number of ISETs in group i is $\binom{U_i}{N}$. Let σ_{v^i} be the fraction of time that the ISET v^i to be scheduled. The throughputs of the users of a group are assumed to be equal and hence, the fraction of times for all the ISETs of a group are equal, i.e., $\sigma_{v_1^i} = \sigma_{v_2^i}$. In the following, notation σ_i is used instead of σ_{v^i} for simplicity of presentation. Since all the ISETs must be scheduled within a unit period of time,

$$\sum_{i=1}^{R} \binom{U_i}{N} \sigma_i = 1. \tag{8}$$

The throughput of a user of group i is denoted by λ_i^s. The number of ISETs that contain the user $u \in \mathcal{U}_i$ of group i is $\binom{U_i-1}{N-1}$. Thus, the throughput of each of the users of group i is given as

$$\lambda_i^s = \binom{U_i - 1}{N - 1} \sigma_i C^i \tag{9}$$

where, $C^i = r_i$ is the data transmission rate of a user of group i. Thus, the objective of the scheduling algorithm is to determine all the values of λ_i^s's and σ_i's.

C. Scheduling Algorithm

Since the minimum throughput of the users need to be maximized, the throughputs of all the users are assumed to be equal, i.e.,

$$\lambda_i^s = \lambda_j^s. \tag{10}$$

for two groups i and j. Using (9) in (10), it can be obtained that

$$\binom{U_i - 1}{N - 1} \sigma_i r_i = \binom{U_j - 1}{N - 1} \sigma_j r_j \tag{11}$$

By replacing all the σ_j's in (8) in term of σ_i using (11), it can be shown that

$$\sigma_i^* = \frac{N}{\binom{U_i-1}{N-1}\{U_i + r_i \sum_{j=1, j\neq i}^{R} \frac{U_j}{r_j}\}}. \tag{12}$$

Using (12) in (9), the max-min throughput of the users can be calculated. Thus, scheduler can calculate the scheduling parameters and the max-min throughput of the users by knowing only the number of users in different groups.

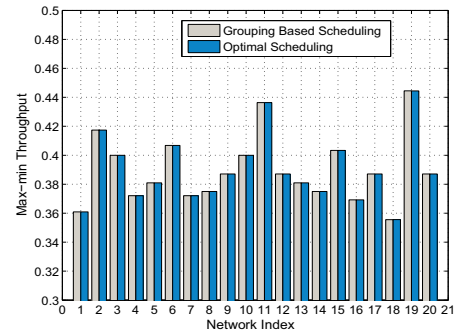

Fig. 4. Throughput comparison of grouping based scheduling algorithm and optimal scheduling.

D. Performance Evaluation of the Algorithm

To evaluate the performance of the simple scheduling algorithm, the max-min throughputs of the 20 networks are determined using the algorithm. The throughput obtained by the simple algorithm and the optimal throughput are shown in Fig. 4. The results show that the simple algorithm can achieve the optimal throughput for all the 20 networks. Thus, the proposed simple algorithm is very efficient.

VI. Conclusion

In this paper, the optimal scheduling problem in single-hop uplink MIMO cellular networks is studied under different MIMO schemes. By formulating an optimization problem and solving the problem for several medium size cellular networks, it is demonstrated that MU-MIMO technique provides a significant throughput gain over SU-MIMO technique in cellular networks. For practical implementation, a very simple and efficient optimal scheduling algorithm is also developed for MU-MIMO cellular networks.

Automatic Transmission Power Control Management Scheme for Mitigating Co-Layer Interference in Femtocell Network

Hossain Mohammad Mahbub, Chowdhury Ahad Ibne Alamgir, Atiqur Rahman

ECE Department, North South University, Bangladesh

mahbub_eee091@outlook.com,chowdhury910@northsouth.edu,atiqur@northsouth.edu

Abstract– **A significant proportion of data traffic originates indoor. Poor signal reception caused by penetration losses through walls severely obstructs the operation of indoor data service in macrocell network. So, the femtocell is a worthwhile solution to improve indoor coverage, increase network capacity and also to enhance user throughput. The random deployment of femtocell inside residence and enterprise environment will cause co-layer and cross-layer interference. We have executed our proposed model in two steps to mitigate co-layer interference. We use automatic transmission power control management scheme. In proposed model, we work with reference femtocell and layer-1 femtocells (HNB$_s$) to regulate its transmission power. It helps to achieve optimum SINR and data rate value. Simulation results validate our proposed scheme, which can effectively control the transmit power of reference femtocell and layer-1 femtocells. We have been considered optimum SINR and throughput as performance indicator in our proposed scheme.**

Keywords– **Reference Femtocell, Automatic Transmission Power Control Management, SINR, Layer-1 Femtocell.**

I. INTRODUCTION

Femtocell is an advancing technology to increase the indoor coverage area and handle the rising demand of indoor multimedia traffic, since more than 80% of wireless communication is reported to be originated in residence area [1]. Femtocell is a low-power wireless access point, which works on licensed spectrum to connect mobile devices to a mobile operator's network using residential DSL or cable broadband connections [2]. There is a possibility of creating interference between femtocells by deploying large-scale femtocells in indoor environment. The overall voice quality and throughput of the network will decrease to user level, if co-layer interference will occur. Main purpose of our proposed model is to improve channel quality by reducing co-layer interference between femtocells and finally we decided to use Automatic Transmission Power Control Management (ATPCM) mechanism. Using this method, we adjusted the transmitted power of femtocell in accordance with the interference level from surrounding femtocells. In this paper, we have been worked on minimizing the power consumption as well as maintaining the SINR requirement for our users. In order to ensure QoS to user end, we have worked on improving SINR for communication channel, better data rate to the user end and regulating transmission power of femtocell.

We organize the paper as follows: In Section II we describe our proposed model, we show simulation parameters and analysis in Section III and we conclude with a summary in Section IV.

II. PROPOSED MODEL

In our research work, co-layer interference mitigation is being taken as main concern. In this section, we will discuss in details about our proposed scheme. We consider a scenario where we have r number of femtocell subscribers for reference femtocell and q number of femtocell base stations in layer-1. Based on these, general SINR formula [3] for communication channel of reference femtocell is written below:

$$\psi_{r,q}^{(i)} = \frac{T_{signal,r}^{(i)}}{n_0 \times \Delta f + \sum_{U=1}^{q} \mathbf{I}_{signal,r*}^{(U)}}$$

$$\Rightarrow \psi_{r,q}^{(i)} = \frac{P_r^{(i)} \times G_r^{(i)}}{n_0 \times \Delta f + \sum_{U=1}^{q} \mathbf{P}_{r*}^{(U)} \times \mathbf{G}_{r*}^{(U)}} \quad (1)$$

Where, $\Psi_{r,q}^{(i)}$ is the signal-to-interference-plus-noise ratio for i^{th} reference femtocell to femtocell subscriber, r with respect to q^{th} number of layer-1 femtocell; $T_{signal,r}^{(i)}$ is transmitted signal from transmitter of reference femtocell; $P_r^{(i)}$ is assigned transmission power of reference femtocell base station to user, r; $G_r^{(i)}$ is the gain for reference femtocell access point to user, r; $\mathbf{P}_{r*}^{(U)}$ is the corresponding transmission power of layer-1 femtocell base station to user, r*; $\mathbf{G}_{r*}^{(U)}$ is the gain for layer-1 FAP to user, r*; n_o is the spectral efficiency of white noise power; Δf is the sub-carrier spacing.

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

A. Automatic Transmission Power Control Management (ATPCM) Mechanism

Automatic Transmission Power Control Management Approach is a dynamic interference reduction technique which can be used to mitigate co-layer interference where the femtocells provide good service to user in accordance with the interference signal from neighboring femtocells. In phase I, initially the transmitted power and gain of reference femtocell is set. When the SINR of reference or layer-1 femtocell goes below our defined standard level, then this information is sent to Femtocell Service Manager (FSM). Because, the FSM has administrative privilege to control the Femtocell Access Point (FAP). After receiving these informations from FAP, then FSM sends its command to FAP for improving SINR of communication channel by deploying effective interference mitigation algorithm for a certain femtocell deployment scenario. To reduce interference, transmitter of femtocells mainly adjust its transmission power with a proper procedure which can be accomplished by using Eq. (3) and Eq. (6). The transmission power of all layer-1 femtocells will adjust accordingly.

For developing path loss formula for femtocell in indoor environment, few approximations has been taken. Our Path loss formula [4] is expressed as:

$$PL(\mathrm{dB}) = 38.5 + 20\log_{10}(\mathbf{D}) + \text{Penetration loss} \qquad (2)$$

Where, **D** (in meter) displays the distance between two transmitters of two femtocells or the distance between femtocell and subscriber equipment (SE). Penetration loss is indoor penetration loss through the wall, which is supposed to be 17dB in our proposed scheme [4].

In paper [5], authors considered 15dB SINR as the minimum threshold value for communication channel.

Fig. 1 shows algorithm I flow chart for reference femtocell. In this scheme, the distance between reference femtocell and layer-1 femtocell is specified by us, which is between 14m and 25m. All femtocells are working in close access scenario. In phase I, reference femtocell has worked according to algorithm I and in phase II, the layer-1 femtocells has worked according to algorithm II (Fig. 3). Calculation of SINR for reference femtocell can be accomplished by using Eq. (1).

The adjusted SINR for reference femtocell has been calculated using the formula written below:

$$\psi_{r,q}^{(\mathrm{i})} = \frac{\dfrac{P_r^{(\mathrm{i})} \times \sum_{U=1}^{q} G_{\mathrm{r}*}^{(U)}}{q}}{n_0 \times \Delta\mathrm{f} + \sum_{U=1}^{q} \mathbf{P}_{\mathrm{r}*}^{(U)} \times \mathbf{G}_{\mathrm{r}*}^{(U)}} \qquad (3)$$

Here, $\Psi_{r,q}^{(i)}$ is adjusted signal-to-interference-plus-noise ratio of ith reference femtocell to femtocell subscribers, r with respect to q^{th} layer-1 femtocell.

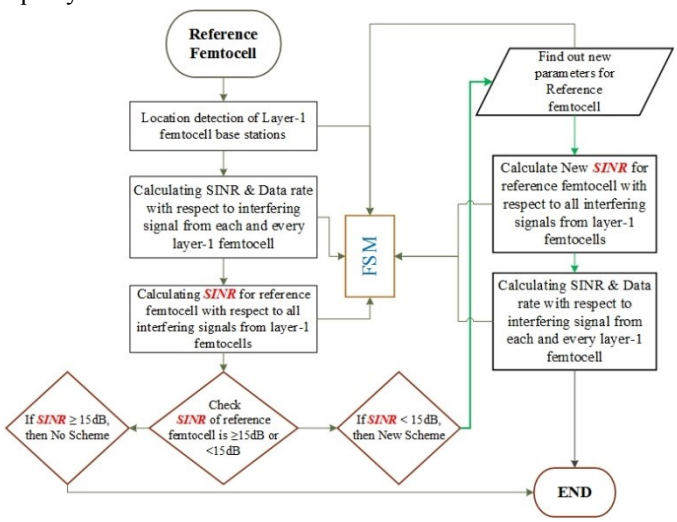

Fig. 1: Algorithm I Flow-chart for Reference Femtocell in Phase I

Data-rate for reference femtocell users in phase I is written below:

$$C_{r,q}^{(i)} = \Delta\mathrm{f} \times \log_2(1 + \alpha * \psi_{r,q}^{(i)}) \qquad (4)$$

Where, α is a constant of Bit Error Rate (BER) and can be defined, α = –1.5/ln (5 BER). So, the setting of BER is 10^{-6} . $C_{r,q}^{(i)}$ is the data rate for reference femtocell with respect to layer-1 femtocell or femtocells.

In phase II, our goal is to increase channel quality by improving signal-to-interference-plus-noise ratio. In proposed model, a femtocell scenario with 12 layer-1 femtocells is considered. Let's about for a layer-1 femtocell, the remaining eleven layer-1 femtocell signals are interference signal. For further development of proposed model, we need to know the distance between layer-1 femtocells. To calculate these distances we have introduced a formula (Fig. 2) which is named as 'Distance Calculating Formula: Femtocell' [4]:

$$\mathrm{D}_{differ} = \sqrt{d_3^2 + d_6^2 - 2 \times d_3 \times d_6 \times \cos(\delta)} \qquad (5)$$

Where, δ is the angle between the length of two sides d_3 and d_6 and can have value from 0 to 360 degrees. d_6 and d_3 is two distances between reference femtocell and layer-1 femtocells, D_{differ} is the distance between two layer-1 femtocells.

The adjusted SINR formula for layer-1 femtocells has been calculated using the formula written below:

$$\varsigma_{t,L}^{\mathrm{K}} = \frac{P_t^{(\mathrm{K})} \times [\max\langle \mathbf{G}_t^{(L)} \rangle]}{n_o \times \Delta\mathrm{f} + \sum_{L \to N^{rem_\mathrm{layer1femto}}} \mathbf{P}_t^{(L)} \times \mathbf{G}_t^{(L)}}$$

$$\Rightarrow \varsigma_{t,L}^{K} = \frac{T_{signal_Layer1,t}^{(K)}}{n_o \times \Delta f + \sum_{L \to N^{rem_layer1femto}} \mathbf{P}_t^{(L)} \times \mathbf{G}_t^{(L)}} \qquad (6)$$

Where, $\varsigma_{t,L}^{K}$ is adjusted signal-to-interference-plus-noise ratio for K^{th} layer-1 femtocell to femtocell users, t with respect to L^{th} number of remaining layer-1 femtocells; $T_{signal_Layer1,t}^{(K)}$ is transmitted signal of Kth layer-1 femtocell to femtocell users, t; $\mathbf{G}_t^{(L)}$ is the corresponding gain of Lth layer-1 femtocell base station to users, *t;* $\mathbf{P}_t^{(L)}$ is the corresponding transmitted power of Lth layer-1 femtocell access point to users, t; $N^{rem_layer1femto}$ is the set of all remaining layer-1 femtocells.

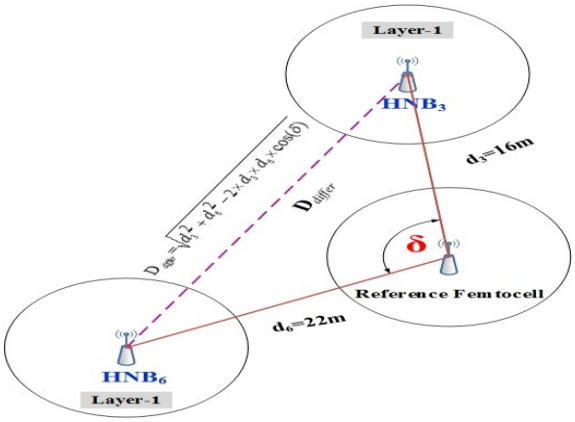

Fig. 2: 'Distance Calculating Formula: Femtocell' in Phase II

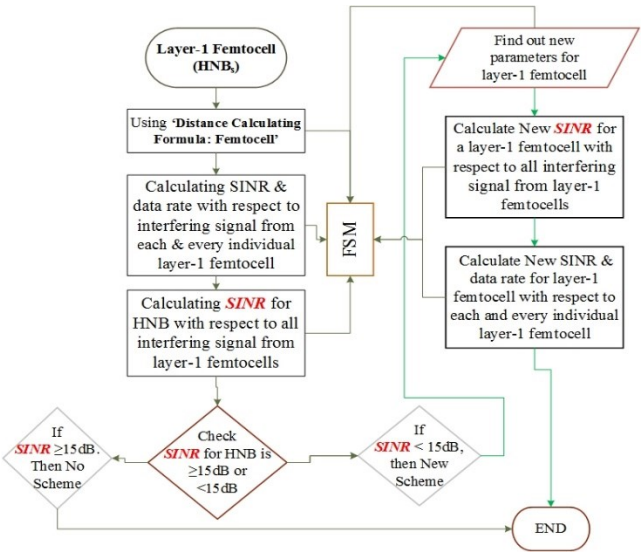

Fig. 3: Algorithm II Flow-chart for Layer-1 Femtocells in Phase II

In phase II, we calculate the data rate for femtocell users by using the formula [Eq. (7)] is presented below:

$$C_{t,L}^{K} = \Delta f \times \log_2[1 + \alpha * \varsigma_{t,L}^{K}] \qquad (7)$$

Where, $C_{t,L}^{K}$ is the throughput of serving K^{th} layer-1 femtocell to users, t with respect to remaining L^{th} number layer-1 femtocells. Fig. 4 and Fig. 5 has shown the femtocell scenario before and after our proposed model (applicable for both phase I and II), which we want to achieve by applying our Automatic Transmission Power Control Management (ATPCM) scheme.

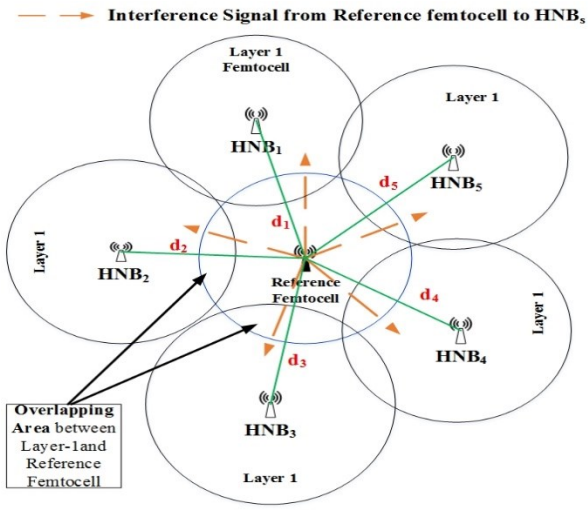

Fig. 4: Femtocell Network before Proposed Scheme

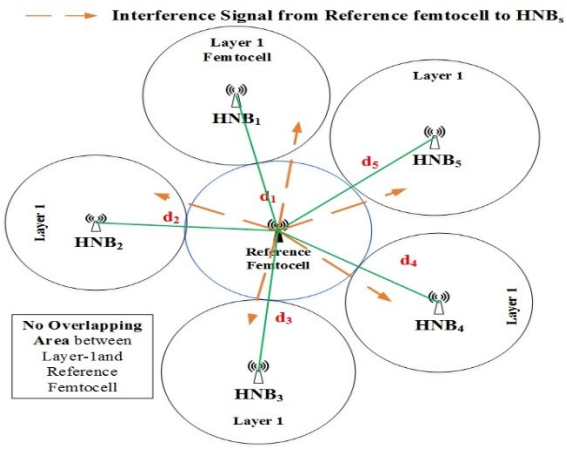

Fig. 5: Femtocell Scenario after Proposed Scheme

III. SIMULATION PARAMETERS and ANALYSIS

The simulation parameters for reference femtocell and layer-1 femtocells are given below:

TABLE I. Simulation Parameter for Reference femtocell and Layer-1 Femtocell

Parameter	**Value (Reference Femtocell)**		**Value (Layer 1 Femtocell)**
	Reference Femtocell	Layer 1 Femtocell	Layer-1 Femtocell
No. of Cells	1	8	8
No. of Users	8	64	64
Channel Bandwidth	15 MHz		15 MHz
Sub Carrier Spacing	15 KHz		15 KHz
White Noise Spectral Density	-174 dBm/Hz		-174 dBm/Hz

Before applying our proposed model, the gain of reference femtocell is calculated using $\mathbf{G}_{reference}=10^{(PL/10)}$. We have considered that the primary transmission power for all femtocells is 20mW and antenna pattern of all femtocells is Omni-directional.

From Fig. 6, we can be perceived that our proposed model has shown noteworthy improvement in femtocell scenario which is considered here. Before applying the scheme there were SINR below 15dB for a reference femtocell, whereas after applying the model SINR of a reference femtocell has achieved 2.60dB improvement.

In addition, data rate has increased successfully for a reference femtocell by our proposed model. Before the proposed model, it was 1.62×10^4 bps (bits per second). After the scheme, it has improved to 1.82×10^4 bps to provide better throughput [Fig. 7].

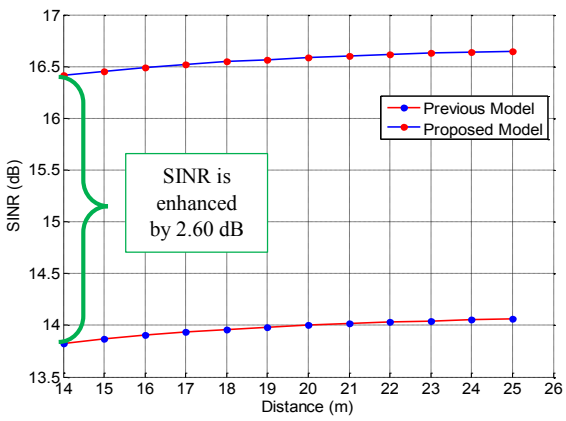

Fig. 6: SINR Improvement graph for a Reference Femtocell

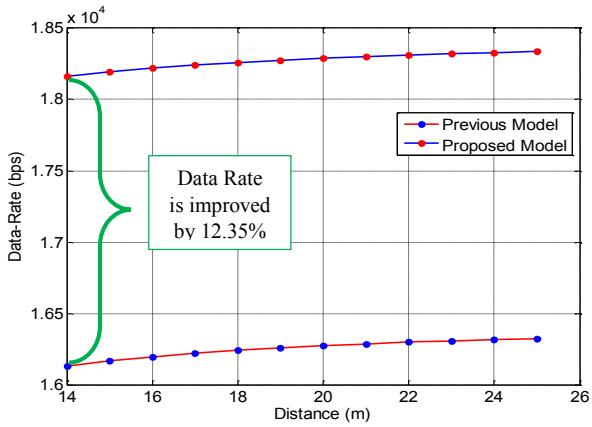

Fig. 7: Data Rate Improvement graph for a Reference Femtocell

From Figure 8, it is showed that firstly the values of SINR for a layer-1 femtocell with respect to other's layer-1 femtocell are less than 15dB, on the other hand after applying the proposed model the values of SINR has shifted above 15dB. From this result, we can say that channel quality has improved.

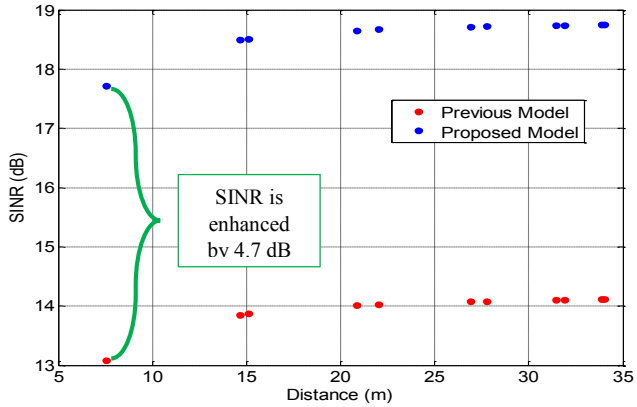

Fig. 8: SINR Improvement graph for a Layer-1 Femtocell

IV. CONCLUSION

In this paper, we have been worked to mitigate co-layer interference by using our proposed power control algorithm. Interference issue is one of the main concern for femtocell network because of its unplanned deployment in macrocell network. After using this scheme, we have developed the channel quality and data rate for communication channel. In first phase, we succeed almost 2.6dB SINR improvement in communication channel for a reference femtocell. This scheme improves the data rate around 12.35% for reference femtocell. Simulation results determine the usefulness of our model for achieving threshold SINR and data rate in communication channel. It reflects that we have effectively reduced co-layer interference in femtocell network by achieving optimum SINR and increased throughput.

Braille Thermometer: Thermometer for Deaf-blinds

Design and Implementation of Braille Thermometer and Its Performance Comparison with Clinical Thermometer

Abstract— **This paper introduces a new clinical thermometer named as 'Braille Thermometer' which will be used for measuring the body temperature of patients who are blind and also have hearing problem (deaf-blind). It is actually a microcontroller based device which collects temperature through a temperature sensor and indicates this temperature in a dial which is marked in Braille numbers. In this paper, the temperature readings of the Braille thermometer are also crosschecked with the readings of a clinical thermometer where input temperature was taken from the same source.**

***Index Terms*—Braille numbers, thermometer, deaf-blind, microcontroller, temperature sensor, stepper motor.**

INTRODUCTION

Clinical/ medical thermometer is available in the market. But these things are of no use to the blind people. Modern science has created audible thermometers too, which will tell the temperature aloud. Number of those people is not negligible who is blind and also have hearing problem at the same time. Considering people who have such condition, known as deaf-blinds, Braille thermometer is a great attempt. Patient can know their body temperature with the help of Braille numbers. This thermometer can indicate temperature from 98°F to 108°F (only integer temperatures, not fractions). At the end of this paper, the temperature input and corresponding indication is plotted with the help of MATLAB.

RESEARCH METHODOLOGY

In this Braille thermometer, human body temperature is measured in Fahrenheit. But the temperature sensor used here, calculates everything in Celsius. So, the following formula has been used to convert the temperature from degree Celsius to degree Fahrenheit [1]:

$$T_C = \frac{5}{9}(T_F - 32)$$

This temperature sensor has the following relation between input temperature and output voltage:
For 1°C input temperature, the output voltage will be 10 mV; which is discussed in the Modeling & Design section.
In order to get the desired output, corresponding to a specific input signal, the microcontroller used here needs to convert analog signal into digital signal. The conversion result can be formulated as follows [2]:

$$ADC = \frac{V_{IN} \times 1024}{V_{REF}} \quad (1)$$

Where V_{IN} is the input voltage and V_{REF} is the selected reference voltage.

MODELING & DESIGN

The model of the Braille thermometer is constructed with six major components. These components are:

1. 5V fixed DC supply.
2. Temperature sensor.
3. Microcontroller.
4. Motor driver.
5. Stepper motor.
6. Braille dial.

These major sections and their interconnections are illustrated in Fig. 1:

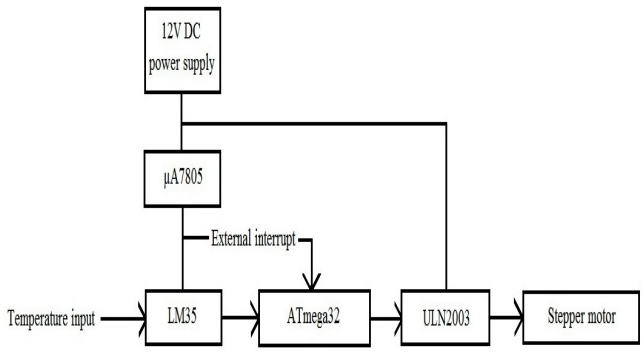

Fig. 1 Block diagram of the Braille thermometer.

In this Modeling and Design section, the entire component's power supply, input and output connections are described. Also the signal transferring between two segments is explained sequentially.

Fixed 5V DC Supply

For both ATmega32 microcontroller and temperature sensor LM35 to operate, a constant 5V DC supply is required. This is done with the help of µA7805 IC. If an input DC voltage greater than 5V is given between pin 1 and pin 2 (ground), with the following circuit arrangement, then a constant output of 5V is found between pin 3 and pin 2 of µA7805 IC [3]:

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

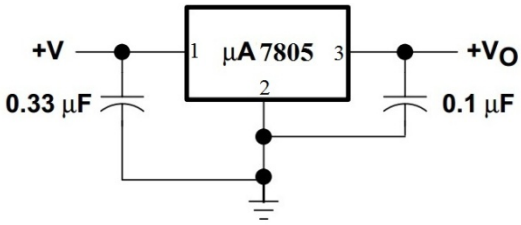

Fig. 2 Fixed 5V DC output regulator using µA7805 IC.

Temperature Sensor

LM35 IC is used as the temperature sensor for Braille thermometer which can detect temperature from -55°C to 150°C [4]. Here temperature is being measured from 98°F to 108°F, in Celsius scale 36.67°C to 42.22°C, which is quite within the range of the temperature sensor.

The constant 5V which acts as the supply voltage for this IC, is connected between pin 1 and pin 3 (ground). LM35 is an analog sensor which converts the surrounding temperature to a proportional analog voltage [5]. Now an output voltage corresponding to room temperature can be found between pin 2 and pin 3. If anyone holds the LM35 IC with his hand, output voltage will change according to his/her body temperature. From LM35 datasheet, few input temperature and output voltage relationships can be found like below [4]:

TABLE I
FEW TEMPWRATURE INPUTS AND THEIR COORESPONDING OUTPUT VOLTAGES FOR LM35 TEMPERATURE SENSOR.

Input temperature (°C)	Output voltage (mV)
-55	-550
25	250
150	1500

Microcontroller

Taking an input signal and converting this signal into an desired output signal, microcontroller is required. ATmega32 microcontroller is chosen for that purpose, considering its connection and coding simplicity.

Now, the output voltage of the LM35 temperature sensor will act as an input signal to the ATmega32 microcontroller's Analog-to-Digital Converter. For this microcontroller, Port A (pin 33 to 40) is the ADC [2]. Pin 40 is selected as the input pin of the microcontroller. The operating principle of the ADC is illustrated in equation (1). 5V fixed DC supply is selected as the reference voltage of the Analog-to-Digital Converter, which is connected to the pin 32 [2] of ATmega32. When the microcontroller gets an external interrupt signal, it will give output signal to its selected output port (Port C chosen here). Pin 16 (INT0) of ATmega32 microcontroller is used here to accomplish that job [2], where with the help of a push button an external interrupt is given whenever the output of the microcontroller is required. The microcontroller code was written and converted to HEX file with AVR studio software. The HEX file was loaded in the microcontroller with the help of PonyProg software, while the microcontroller was connected to a computer's parallel port with a DB 25 connector [6]. The necessary hardware required to load the program in ATmega32 microcontroller is shown in Fig. 3.

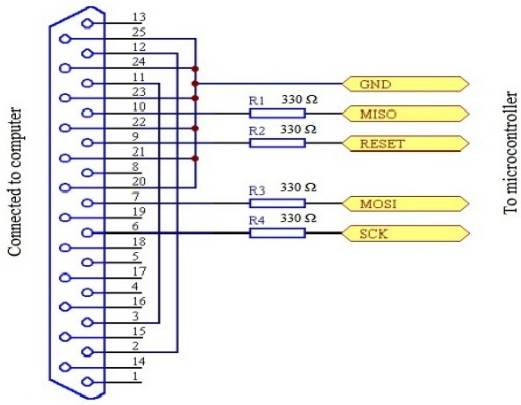

Fig. 3 Hardware used to load program in ATmega32.

The output of the microcontroller is connected to the motor driver.

Motor Driver

ULN2003 motor controller is a Darlington array IC which is generally used for interfacing between low level logic circuitry and power loads. Motor driver is necessary here, because stepper motor cannot be directly operated from a microcontroller. In order to drive a stepper motor, high current is required, which is supplied by that IC. This particular IC has seven drivers. ULN2003 IC's Pin 9 is provided a fixed 12V DC supply and pin 8 of is connected to ground [7].

Stepper Motor

It will be a convenient and feasible design if a stepper motor of 30° step angle is used here. If the step angle is a factor of 30, then it will work too. Stepping motor M42SP-6NPK is used here whose step angle is 7.5° [8]. So, in order to give a 30° rotation, the motor will have to move 4 steps.

Stepper motor M42SP-6NPK has four wires of color Red, Orange, Blue and Yellow. If a square pulse is given between the Red and the Orange wire, then the motor will rotate in clockwise direction. Whereas a square pulse between the Blue and the Yellow wire will rotate the motor in counter clockwise direction.

Braille Dial

The whole motor, indicator setup is mounted on a dial where temperature is written in Braille numbers from 98°F to 108°F.

The temperature indicating Braille dial has 12 sections. These sections are:

98°F	99°F	100°F	101°F	102°F	103°F
104°F	105°F	106°F	107°F	108°F	START

Their corresponding Braille numbers are as follows [9]:

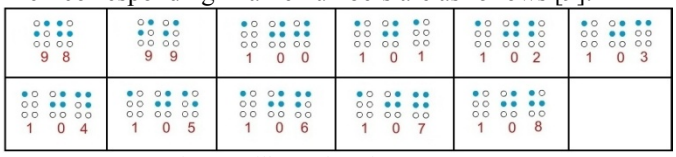

Fig. 4 Braille numbers from 98 to 108.

The Braille thermometer with its power supply and the program loader is shown in Fig. 5:

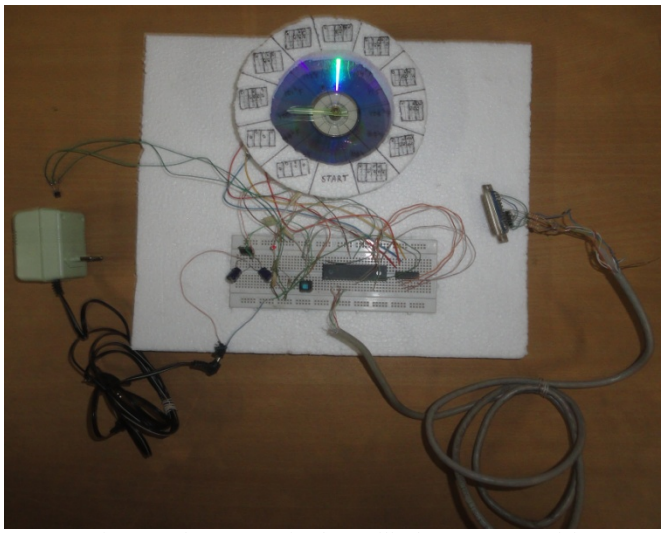

Fig. 5 Hardware setup for the Braille thermometer model.

OPERATING PRINCIPLE

Firstly, the overall circuit will have to be powered up with a 12V DC power supply. From here a fixed 5V DC supply will be generated. In this setup, the temperature sensor and the microcontroller will require 5V fixed DC supply and the motor driver needs 12V DC voltage. Then, when a person holds the temperature sensor, it gives the output voltage corresponding to the input temperature as discussed in the Research Methodology section. Human body temperature is an analog signal and corresponding output voltage of LM35 is also an analog signal. So, the output signal of LM35 will have to be converted to digital signal, since microcontroller deals only with digital signals in its algorithm part. That's why output of the LM35 temperature sensor is connected to the ADC (Analog to Digital Converter) of ATmega32. When the microcontroller's ADC gets an analog input voltage, it converts the analog signal into digital signal as mentioned in equation (1). With an appropriate microcontroller code, ATmega32 can produce desired output voltage at selected output pins corresponding to a particular input. The coding part describes the relation between input temperature and the corresponding number of pulses generated in the output pins to rotate the stepper motor specific degrees. By connecting the bidirectional stepper motor to the microcontroller's output port, the stepper motor can be rotated from 0° to 360° both clockwise and anticlockwise. The stepper motor will have an indicator needle connected to its rotor. Patient will have to follow the indicator with hand and read the corresponding temperature by touching the Braille numbers on the dial.

But, as mentioned earlier, stepper motor cannot be directly operated from microcontroller. In order to do that stepper motor should be connected with microcontroller through a Darlington array IC like ULN2003.

Initially, the stepper motor's indicator will be fixed at a position named as 'START'. Now according to the temperature sensor's input the stepper motor will rotate clockwise few degrees, stay there for 30 seconds and again rotate anticlockwise those particular degrees. That means after waiting 30 seconds, the indicator will return to its initial position. The complete algorithm of Braille thermometer's operation is chronologically explained through a flowchart:

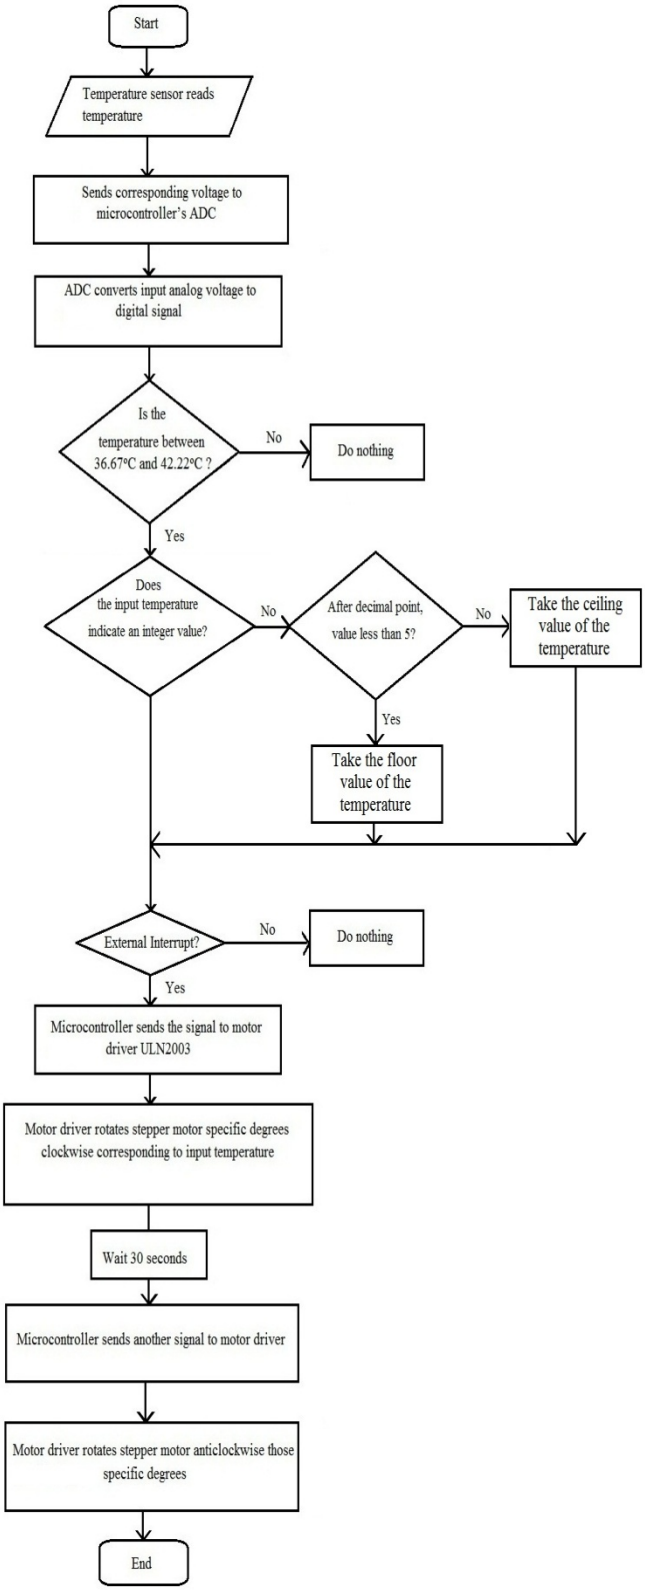

Fig. 6 Flowchart for the operating principle of Braille thermometer.

RESULTS & DISCUSSIONS

In order to check the Braille thermometer's performance, its temperature sensor was heated from 98°F to 108°F with a temperature variable heater. For a particular temperature, Braille thermometer's reading was taken. At the same time, the heater's temperature was also measured by a clinical thermometer. From this comparison it was observed that, for an integer temperature, the reading of the Braille thermometer and the reading of the clinical thermometer was same. Fig. 7 shows how Braille thermometer and clinical thermometer are reading temperature of a heater at the same time.

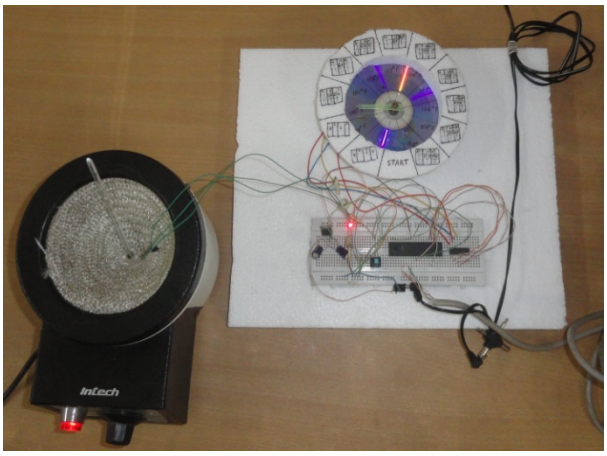

Fig. 7 Temperature reading comparison between Braille thermometer and clinical thermometer.

For 98°F to 108°F temperature, the Braille thermometer's stepper motor rotation was recorded and a temperature versus rotation graph was plotted using MATLAB.

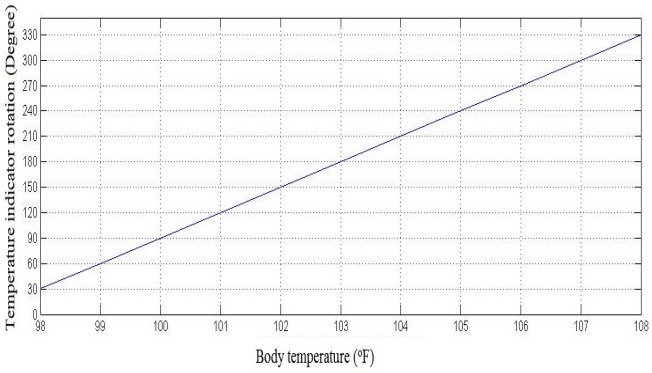

Fig. 8 Graph between temperature and corresponding motor rotation.

Here only integer temperature has been used for calibrating the Braille thermometer. Whenever a fractional temperature is given as input, the microcontroller follows a simple algorithm to convert the fractional temperature into an integer one. If, after the decimal point, the temperature is less than 5, the microcontroller will consider its floor value (e.g. for 100.25°F it will consider it as 100°F). But after the decimal point, if the temperature is equal or greater than 5, the microcontroller will convert it into the ceiling value (e.g. 100.5°F will be interpreted as 101°F).

CONCLUSION & FUTURE WORK

From the previous comparisons and observations it can be concluded that, this Braille thermometer model is only perfect for integer values of body temperature. This is not completely a practical expectation, because, for many medical applications, a little bit temperature change may hold a large significance. Considering this single limitation, Braille thermometer can be an excellent device to measure a deaf-blind patient's body temperature by himself/herself.

For future work/research, Braille thermometer can be constructed in such a way that it will indicate fractional temperatures (e.g. one digit after decimal point) too. But on a single dial, accommodating so many (101 values, if all the values between 98°F to 108°F is show) Braille numbers is not easy to manage. On the other hand, for a deaf-blind patient, it will be very difficult to pinpoint his/her temperature. The idea of solving this problem is: for fractional temperatures, the patient will read the integer part of the temperature from the Braille dial as this model does. And for measuring the fractional part, there will be another vibrating motor, which will vibrate according to the value of the fractional temperature (e.g. for 0.5°F the vibrating motor will vibrate 5 times). In this research work, the circuitry was powered by an adapter. Light weight rechargeable battery can be used to reduce the weight, which will be convenient for carrying too. For professional construction, instead of breadboard; veroboard or Printed Circuit Board (PCB) can be used for wire connections. Finally, the motor used (M42SP-6NPK) has a weight of 96 grams. This can be replaced by a motor of small size and weight (e.g. stepper motor PN 16305. Its weight is around 9 grams and has a 30° step angle [10]). Thus Braille thermometer can be made more accurate, compact, portable and easy to use.

***Abstract*—Biopotential measurements for clinical diagnostics and brain-machine interface are usually carried out by placing multiple electrodes to the target areas. Due to the non-invasiveness, ease of deployment, and relatively simpler manufacturing, surface electrodes have found immense number of applications. This work presents a field-referenced surface electrode for the measurement of surface potentials. Each electrode can be addressed by applying a constant reference signal on the field plate and the corresponding induced potential is measured from the sensing plate. The reference-biased field plate shields the sensing plate from tangential field lines and interference from the neighboring electrodes. Due to the presence of the reference signal, the electric field originating from a biological source crowds towards the referenced-field plate and impacts the induced potential in the sensing plate. Simulation results indicate the better selectivity performance of the proposed structure.**

***Index Terms*—Biosignal, surface electrode, selectivity.**

I. Introduction

The use of high-resolution neural recordings from the cortical surface for basic research and clinical medicine has been shown for a wide range of applications. To localize the seizure focus, neurosurgeons apply surface electrodes to measure the EEG or ECoG signals during the epileptic event. However, the subdural electrodes in use clinically, for the diagnosis and treatment of epilepsy, are much larger ($\sim 3\ mm$ in diameter) and have large interspacing ($\sim 10\ mm$) because of the clinical need to record from large areas of the brain surface ($80\ mm \times 80\ mm$) for the localization of seizure-originating brain regions [1]. Spatial spectral analysis of electrocorticograms from the superior temporal gyrus and motor cortex has revealed that electrode spacing should be 1.25 mm or closer in humans to sufficiently capture the rich spatial information that is available [2]. Motor control signals [3] and spoken words [4] can be decoded with substantially improved performance using electrodes spaced 1 mm apart or less. Therefore, for high-resolution brain mapping, a dense electrode array with high spatial-resolution is inevitable.

Much of the existing research in electrode technology has focused on penetrating electrode arrays, such as the Utah array [5], which can provide a high-resolution interface to a small area of cortex [6]. However, the penetrating microelectrodes suffer from reduced lifetime [7] (6-12 months) and may cause hemorrhage and inflammatory tissue responses from the immediate insertion [8],[9] or over long periods of time, because of the inability of the rigid penetrating electrodes to flex and move as the brain pulses, swells and contracts [10].

Conventional disc electrodes are currently being used for surface potential measurements for EEG, EMG and ECG signal acquisitions. The recorded signals have reference electrode problems as idealized references are not available. Surface Laplacian mapping has been shown to enhance the high spatial frequency components and spatial selectivity of the electrical activity located close to the point of interest. These unique characteristics can be derived as the surface Laplacian being the second spatial derivative of the surface potentials. To increase the spatial selectivity, researchers introduced a bipolar electrode configuration and calculated the induced potential using a five-point finite difference method (FPM). Others applied a quasi-bipolar tri-polar with two elements shorted concentric electrode configuration. To further increase the spatial resolution, a tri-polar concentric electrode configuration for approximating the analytical Laplacian based on a nine-point finite difference method (NPM) has been reported [11]. High-resolution surface electrodes over a large brain area had also been impractical owing to the complexity of connecting thousands of wires in the small intracranial space. Recently a 360-channel active electrode array capable of sampling a five-fold larger region of brain ($10\ mm \times 9\ mm$) than the previous methods with high spatial resolution ($\sim$500 μm spacing) and high temporal resolution ($>$ 10 kS/sec) and with reduced number of interconnecting wires has been reported [1].

Our work reports a field-referenced passive electrode for the measurement of surface potentials. The proposed electrode manifests a field plate around a sensing plate separated by a dielectric layer. Due to the presence of a reference signal on the field plate, the source electric field crowds towards the electrode and affects the induced potential on the sensing plate. The higher the field crowding the closer is the signal source proximity. The reference signal biased field-plate also provides measured signal robustness to interferences and results in better signal selectivity.

The description of our work is as follows: In section II, we have discussed our proposed electrode structure. Section III describes the electrode model for the finite element simulation setup and Section IV shows the simulation results for the electric field distribution and the induced potentials on the electrodes . A comparative study of induced Laplacian potentials has been shown between the proposed electrode and the conventional disc electrode with the changes of the position of an electrostatic source. Section VI summarizes the advantages of our proposed electrode structure and the future work.

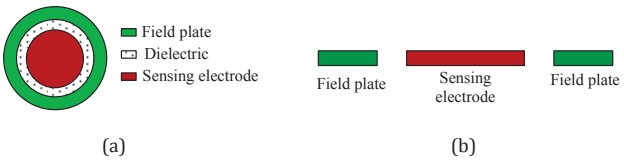

Fig. 1. Schematic view of the proposed electrode. (a) Top view where the field plate encircles the sensing plate separated by a dielectric layer, and (b) Side view of the electrode.

II. Proposed Field-Referenced Electrode

Fig. 1(a) shows the schematic view of a field-addressable electrode. It manifests a center sensing plate and an annular field plate. The proposed electrode is similar to a bipolar electrode; however, unlike the bipolar electrode the field plate in the proposed electrode acts as a reference line to pull the electric field towards the respective sensing plate. The field plate and the sensing plate are isolated by a dielectric layer. Fig. 1(b) shows the side view of the proposed electrode. In this arrangement, measurement of induced potential from the sensing plate is carried out when there is a reference signal in the field plate. The field plate provides not only reference signal location but also electrical shielding from crosstalk and interference. The electric field crowding occurs due to the presence of reference signal and enhances the induced potential of the sensing plate.

III. Finite Element Simulation

The proposed electrode structure has been simulated using Maxwell 2D simulator in electrostatic mode. The simulation has been carried out using adaptive mesh analysis with percentage refinement per pass of 15, percentage error of 0.1, and number of passes of 10. The model and the corresponding simulation results are depicted below:

A. Simulation Model

A nine electrode linear array system as shown in Fig. 2 is simulated using finite element analysis software, Maxwell of Ansoft. Each electrode consists of an inner disc to sense the potential and an outer ring to connect with the reference signal. In 2D, each electrode is represented by three rectangular segments. The inner segment is $4\ mm \times 1\ mm$ and the reference segments are $2\ mm \times 1\ mm$ each. The spacing between the electrodes is $4\ mm$. A constant positive charge is placed $10\ mm$ beneath the array. We notice maximum electric field crowding towards a reference electrode when the electric source is closest to that electrode. As we move the source position along the array, the crowding decreases and less potential is induced on the control electrode. The proximity of the source can be identified from the induced potential profile of the array. Au metal electrodes and dielectric

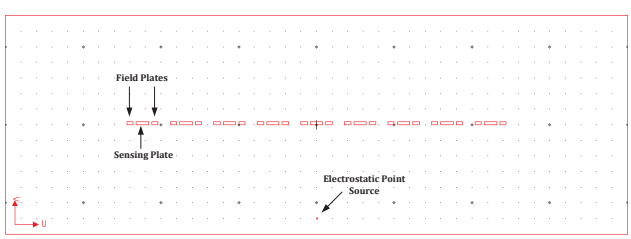

Fig. 2. Simulation of a 9 electrode linear array system using Maxwell 2D.

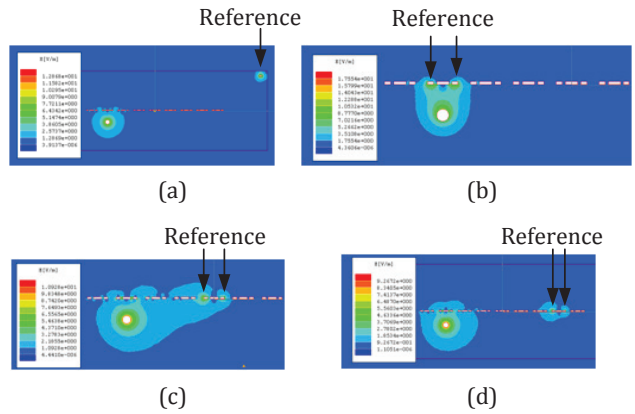

Fig. 3. Electric field distribution as the reference signal is applied to different electrodes along with a distant reference signal at the top right corner. (a) No reference at the electrodes, (b) Reference at the 2nd electrode (c) Reference at the 5th electrode, and (d) Reference at the 8th electrode.

medium are used for simulating the field propagation from a 1 pC of electrostatic source.

IV. Simulation Results

At a time, the plates of a single electrode are ground referenced while the field plates of rest of the electrodes are left floating. A 1 pC floating charge is used as a source and simulation is performed under electrostatic mode. The electric field crowding and the corresponding electric potential is measured from the sensing plates of all the electrodes. The reference location is then shifted to the next electrode and electric potentials on all the center sensing plates are measured. The process is continued for all the reference locations. Fig. 3 shows the electric field distribution for different locations of the reference signals. In Fig. 3(a) conventional disc electrode setup is considered where the reference electrode is far away (top right corner) from the electrode setup. The biosignal source is placed beneath the 2nd electrode. In this case, the electric field spreads in a uniform manner and more than one electrode receives almost equal field strength that reduces the selectivity of the electrode regarding the source location. In Figs 3(b), 3(c) and 3(d), the proposed electrode setup is considered with reference location on the field plates of the electrodes 2nd, 5th, and 8th, respectively. As seen in Fig 3(b) all the electric field is linked to the second electrode due to the close proximity of the source (source is beneath the 2nd electrode) and the reference location (reference is on the field plates of the 2nd electrode). This electric field crowding due to the presence of reference signal provides better selectivity compared to the conventional disc electrode setup with reference location far-away from the electrodes. For the identical source location (beneath the 2nd electrode) Figs 3c and 3(d) show the field crowding with the reference locations on the 5th and 8th electrodes, respectively. The relative strength of the electric field crowding and the corresponding induced potential in the sensing plate indicate the proximity of the biosignal source from that particular field-referenced electrode.

Figs 4 and 5 show comparison of induced potentials between the proposed electrode array and the conventional disc electrode array. In the first case (Fig. 4) the source is kept close to the 5th electrode ($0.6\ mm$ beneath the 5th electrode). For the disc electrode array, induced potentials are measured at the center of each electrode. For the proposed structure, the

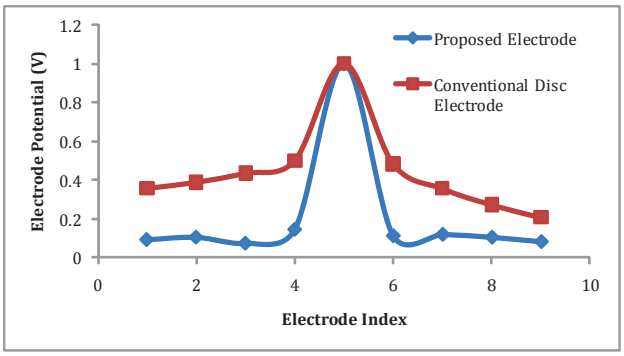

Fig. 4. Induced electrode potential with source position 0.6 mm down the 5th electrode.

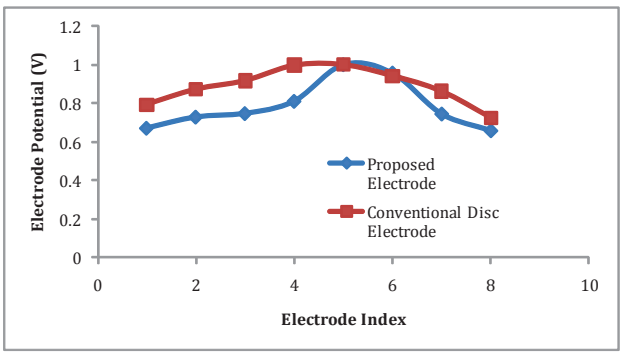

Fig. 5. Induced electrode potential with source position 3 cm down the 5th electrode.

reference is applied on the field plate of a single electrode at a time and corresponding center disc potential is measured. Since the source is closest to the 5th electrode, potential on the 5th disc has the highest value compared to the potentials on the other electrodes for both the structures (conventional and proposed), which can be seen from Fig. 4. However, the proposed structure demonstrates the higher selectivity to determine the location of the electrostatic source. In the second case, we move the source 3 cm down the 5th electrode. Fig. 5 shows that the induced potential curves for both the structure flatten because of the larger distance of the source from the electrode array. As we move the source from the closest to the farthest of the 5th electrode, the proposed electrode structure shows greater selectivity compared to the traditional one. For the comparison of selectivity, normalized induced potential values are used where the induced potential of each electrode is divided by the maximum of the induced potentials for that particular electrode setup. From Figs 4 and 5, the relatively smaller width of the induced potential curve for the proposed electrode indicates the superior selectivity feature.

V. Electrode Array Fabricated on PCB

A prototype electrode-array is fabricated on a printed circuit board and tested using a bench-top test setup. Fig. 6(a) shows a conventional electrode array used as the source electrode and Fig. 6(b) depicts the 4-by-4 field-addressable electrode array. For each electrode, the diameter of the center sensing disc is 3 mm and the annular field plate is 1 mm in width and 1 mm apart from the disc. The sensing discs are connected as row wise forming 4 sense lines and the annular rings of the electrodes are connected column wise forming 4 control

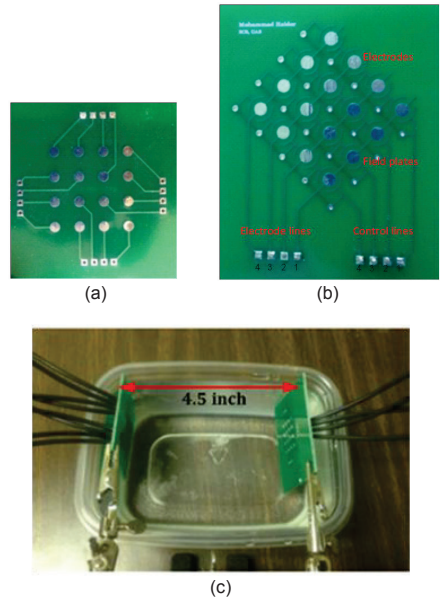

Fig. 6. Test setup (a) source electrode array, (b) proposed field-addressable electrode array, and (c) test setup where source and proposed electrode arrays are immersed in saline water and potentials are measured to determine the proximity of the source point.

lines as depicted in Fig 6(b). Fig. 6(c) shows the test setup. A single control line is activated at a time and potentials are measured along all the sense lines (1, 2, 3, and 4) and this process is repeated for all the control lines (1, 2, 3, and 4). Fig. 7 shows variation of measured electric potentials on different electrode sense lines (1, 2, and 3) with the variation of activating different control lines (1, 2, and 3). The measured results indicate the proximity of the sensing electrodes to the signal source. A zero potential is used as the control field and the induced surface potential is the lowest along the control field line. From Fig. 7, electrode with index 33 is the closest to the source. Measurement results show that the electrode array can be properly addressed by the control/reference electric field lines and the induced electric potential relates to the

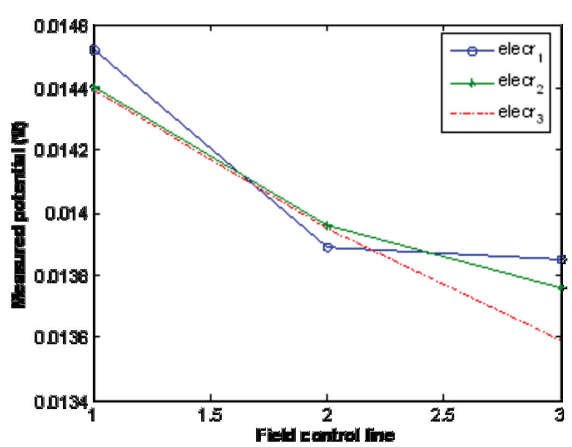

Fig. 7. Variation of measured electric potentials on different electrode sense lines with the variation of activating different control lines. Since the control voltage used is zero potential, the lower the induced potential the better is proximity towards the source electrode. Here electrode with index 33 is closest to the source.

proximity of the source.

VI. Conclusion

We propose a voltage referenced electrode structure for the determination of the proximity of an electrostatic source. The proposed electrode structure manifests a sensing plate and a field plate separated by a dielectric layer. The field plate is utilized to apply the reference bias to the electrode. The proposed electrode works based on the electric field crowding due to the presence of the reference signal. The relative strength of the electric field crowding indicates the proximity of the electrostatic source. The higher the electric field crowding the closer is the proximity of the biosignal source. The proposed structure has been simulated using a 2D finite Element simulation software package. Simulation results indicate the variation of electric field crowding with the variations of reference locations. The proposed structure has been compared with the conventional disc electrode structure and simulation results indicate the better selectivity of the proposed electrode structure under varying depths of the source locations. A prototype electrode array has been fabricated on PCB and the measured results validate the field-addressable feature of the proposed electrode array.

Development of a Novel Prepaid Gas Metering System

Mohammad Imam Hasan Bin Asad,* Md. Liakot Ali, and Md. Saiful Islam

Institute of Information and Communication Technology (IICT)
Bangladesh University of Engineering and Technology (BUET), Dhaka-1000, Bangladesh
*ihasan@iict.buet.ac.bd

Abstract—**Energy saving by mitigating the waste of energy and save the world from global warming is a very common concern of this day. This paper presents the design and implementation of a prototype novel contactless smartcard based prepaid metering system for domestic purpose that technologically forces the customers to stop the misuses of natural gas. The proposed metering system addresses all the drawbacks of our previously developed and deployed 4500 meters in a pilot site at Dhaka. The functionality of the meter has been tested in the laboratory and demonstrated to the utility company (KGDCL). The proposed meter is more efficient in terms of power consumption, more secured and more user friendly in terms of vending the smart card and top-up the meter than those of its earlier version.**

Index Terms—**Prepaid metering system, Contactless smart card, NFC.**

I. Introduction

To minimize the waste of energy is a very common concern of this day all over the world since the wasted energy in turn produces carbon di oxide (CO_2) and sulphur di oxide (SO_2) and creates global warming [1-2]. One of the main resources of world's energy supply is natural gas. This is more accurate for Bangladesh where it is the most found natural resource. Gas is widely used in industrial, commercial, power, transportation and domestic sector. In most cases where consumption is higher gas meters are implemented in customer premises. But some times for domestic customers are not given any gas meter and fixed monthly rate is used for them. In this case customer pays a fixed amount for whatever the amount of gas he uses. Hence there is a high probability of misuses of gas. In most cases customers pay very little attention for the proper use of gas like many of them use gas for drying clothes, keeping room warm, using inefficient appliances etc. Again there are some dishonest customers who indulge in gas pilferage. And as for this system there is no way to know the actual uses for a particular customer, it would not be possible for the utility company to know whether there is any system loss in the customer end. Though the consumption of an individual is not high but as there are many customers in this sector. If wastage and misuse of gas can be prevented then a considerable amount of gas can be saved for future use. Again in the traditional meter and postpaid billing system utility company has to allocate manpower for meter reading and sending the bills. Prepaid gas metering system may be an effective solution for the problems mentioned above. In this case as the customer has to pay only for the amount he uses, he would be more concern of wastage of gas. The proposed system includes a 2-way dataflow system. Through this system utility companies can check the vending profile of customers along with the consumption pattern to identify any irregularity or problem at the meter end take necessary actions.

Some works have been done on smart meter and prepaid metering system [3-14]. In [8] consumption measurement is done optically which is not power efficient. Along with this the valve control system also consumes a considerable amount of power. These problems were solved any another work [9]. In 2010 smart card based prepaid metering system was designed and developed by IICT, BUET for TITAS Gas Transmission and Distribution Limited, one of the famous gas distribution company in Bangladesh. In most cases the meters were setup outside of house, hence, they were vulnerable to the weather. In that design contact smart card was used for setup and recharging the meter module. As the meter couldn't be sealed perfectly due to the card slot through which contact card was inserted, water and dust may enter easily to the meter. This may degrade the performance and damage the electrical module or part of it. The meter was run by four AA size battery so the power consumption was little bit higher. There were some other limitations also at the software end like each customer was assigned to a zone and he can only buy credit from a specific place or office of that zone. This restricts the flexibility of the customer. All these limitations are analysed and solved in the proposed design. Earlier version of this paper was presented in the conference 'Industrial Engineering, Operation and Maintenance (IEOM 2014)' [16]. Since the audiences of the conference were related to the industry and manufacturing, the different attractive features of the system and its potentiality in commercialization were highlighted there. So it is worth to explore the hardware and software aspects of the proposed prepaid metering system for another group of audiences who are related to electrical, electronic and computer engineering. The next sections of the paper describes the overall design architecture, hardware design, firmware design, software design, test results and conclusion.

II. Design Architecture

The prepaid metering system includes a 2-way dataflow process via contactless smart card. Fig. 1 depicts the block diagram of prepaid gas metering system.

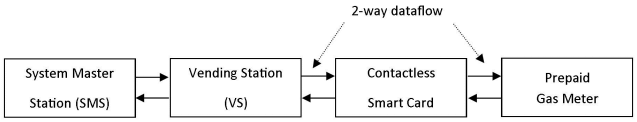

Fig. 1 Contactless smart card based prepaid metering system

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

According to the design the prepaid meters will be installed in customer premises, there will be necessary authorized vending stations all over the service area and the server will be installed in a secure place provided by the utility company. Vending Station (VS) is simply laptop or desktop computer with internet connection. Customers can purchase credit from vending stations. System Master Station (SMS) is the central application server along with database server and other necessary equipment necessary for security purpose where all information is processed.

Whenever a new customer requests gas line from a utility company, first a meter is assigned, set up and installed in his house. Then he is assigned a contactless customer card. With that card he can purchase credit from authorized vending stations and also recharge the meter whenever necessary. When the customer purchases credit, the credit information is written in the card. After that when he recharges the meter with the card, first the meter validates the card and then update the credit information and take action if necessary. Then the meter writes some important information about the meter to the card like consumption, max consumption rate and other health parameters. When the customer goes to the vending station for another purchase, the information stored in the card is uploaded to the central server. In this way utility company can monitor the consumption trend, health of the meter, check whether there is any fault at the meter end take necessary action.

III. HARDWARE DESIGN

For the overall design a G1.6 gas meter is used as base meter with protection of IP65 and our designed electronic board is attached to the meter. In the previous design IP56 base meter was used. The new meter is more suitable for the local weather condition. Fig. 2 shows the block diagram of the hardware design. For design and debugging purpose the overall design is divided in several modules. They are described in following sections.

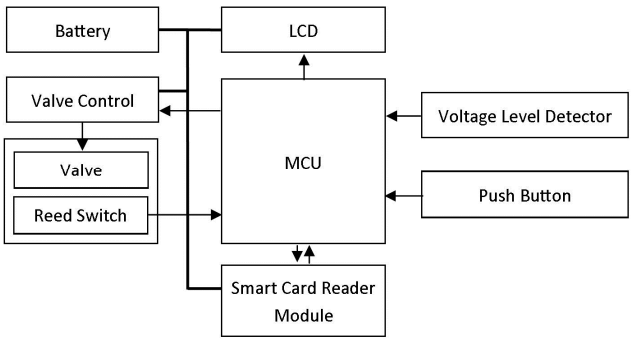

Fig 2. Block diagram of hardware design

A. MCU

The control unit of the design is the MCU module. For the design we use ATMEGA64A, a high-performance, low-power Atmel 8-bit AVR RISC-based microcontroller combines 64KB ISP flash memory with read-while-write capabilities, 2KB EEPROM, 4KB SRAM [15]. It has 53 general purpose I/O lines, 32 general purpose working registers, a real time counter, four flexible timer/counters with compare modes and PWM, two USARTs, a byte-oriented 2-wire serial interface, an 8-channel/10-bit A/D converter. It is a low power microcontroller which consumes low power both in active and sleep mode. This device can operate 2.2 - 5 V. We have designed out electronic module to be run on 3.5 V. In the previous design ATMEGA88 was used and the electronic board was designed for 5 V. Hence, the power requirement reduces for the proposed system.

B. Pulse sense module

The base meter is a gas meter with 8 mechanical wheels that shows the usage among which 3 wheels are for fractional digits. Along with the mechanical wheels it includes a pulse generating system with magnetically working reed switches. On the rightmost wheel a magnetic contact is fixed. Two other magnetic contacts are placed on the two sides of the wheel and connected to the reed switches. Whenever the wheel rotates and the magnetic contact comes near to any of magnetic contact of reed switches, an electronic pulse is generated with the corresponding reed switch. Those two switches are connected to the MCU with two interrupts. For each rotation of the rightmost wheel two electronic pulses are generated alternatively. The consumption is calculated from the received pulses.

C. Valve control module

The base meter also includes a DC brush motor to control its valve. The brush motor is connected to the MCU through a motor control module. To control the motor an H-Bridge driver IC Sanyo LB1836M is used [16]. MCU sends signal to the LB1836 for rotating the motor to the desired direction to control the gas flow.

D. Display module

A display module with SED1335 is used for displaying necessary information like consumption, remaining balance, recharge information, running condition, error etc. To minimize power requirement in normal condition the display module is kept off. Whenever customer press a button mounted on the board it is turned on for a short period of time and it slides necessary information for customer. It also includes icon for valve whether it is closed or open, battery condition and other operational information. If customer doesn't press the button again within a predefined time it is turned off again. It also shows recharge or setup information while recharging or setting up the meter for confirmation of the corresponding processes.

E. Smart card reader module

A smart card reader module is used to communicate with the contactless smart card. The module uses UART protocol to communicate with the MCU. The prepaid system is designed with Near Field Communication (NFC) standard to communicate with the card from meter and vending station [17]. It is based on Radio Frequency Identification (RFID) standards including ISO/IEC 14443. In the design Mifare 1k card is used with the range of 6 inches [18]. It uses contactless transmission for data and energy and no battery is required for that. Each card has a unique serial number and uses mutual three pass authentication (ISO/IEC DIS9798-2). Unlike the display module the smart card or NFC module is kept off for saving power. When the push button is pressed the module becomes active and searches for valid NFC card along with displaying information. If the module finds a valid card then it stops searching and the MCU performs the operation defined in the card. In case of customer card it only updates the credit and billing rate. Some other card types are also defined to set up or to change meter parameter. Previously contact smart card was used and as the insertion

point of the card in the meter, it was vulnerable to the weather. By using contactless smart card we can eliminate the probability and the security of the card is also stronger than the previous one.

F. Voltage level detector module

A voltage level indicator is included in the design. It detects the voltage level and whenever the voltage goes below a tolerable range, MCU saves all information to the EEPROM, lose the valve and shut down normal operation. This module serves another important operation in case of sudden power down i.e. battery is removed from the electronic board.

G. Power module

The whole circuit is designed to run with 3.5 V. To achieve that 3 AA size batteries are used in the batter module which are available anywhere all over the world.

IV. FIRMWARE DESIGN

The firmware is designed and implemented in two layers. The bottom layer is the hardware layer which consists all individual module drivers. The upper layer is the main firmware layer where operational algorithm is implemented. Fig. 3 shows the simplified firmware design.

At the startup MCU loads necessary information from the EEPROM and initializes the meter and peripherals. Then it goes to SLEEP mode to reduce the power consumption. It discontinues its SLEEP mode if any interrupt occurs. Three interrupt types are defined in the hardware: pulse interrupt, push button interrupt and low voltage interrupt. Whenever MCU gets an interrupt it goes to ACTIVE mode and take necessary action depending upon the interrupt and then goes back to the SLEEP mode again.

When customer uses gas the wheel of the meter rotates and MCU gets pulse to its interrupts. For each rotation of the rightmost wheel MCU gets two interrupts. Sometime reed switches may miss one or two pulses. An algorithm is implemented to calculate the usage from the alternate pulses considering the misses. Again sometime reed switch becomes faulty and in that case it is discarded from calculation. After detecting pulse MCU counts usage and deducts credit depending upon the active gas rate. Then it updates the valve status. If balance goes down below a certain level MCU shuts down the valve. In normal condition after getting one pulse if MCU doesn't get any pulse within a certain period of time, it goes to the SLEEP mode.

If the push button is pressed MCU goes to the ACTIVE mode. It activates the display module and slides necessary information like consumption, remaining balance, active billing rate and displays operational icons for a certain period of time. In the meantime MCU searches for valid NFC card. If MCU gets any valid NFC card, it shows a CARD BUSY icon. MCU checks the card type and takes certain action depending upon the card type like recharging credit or changing parameter. Then MCU uploads necessary information like gas usage, health condition. MCU also displays corresponding information in the display module. After successful operation of the card MCU shows REMOVE CARD to indicate that the customer can remove the card. . If MCU doesn't get any valid card or customer doesn't press the button within predefined time, MCU goes back to the SLEEP mode again.

If any low voltage is detected either by battery dying out or sudden removal of battery the MCU wakes up from SLEEP mode, saves all information to the EEPROM, shuts down the valve and stops all normal operation. The MCU includes two LEDs for notification purpose. Most common usage will be for balance condition. Multiple level of balances are defined in the design. If the credit goes down below a certain level then an indicator LED will be blinking to notify the customer. Another important feature in the design is the negative credit. In this case the meter can run even in the negative balance up to a negative balance threshold set by the utility company. This feature is very useful if the credit runs out after office hour or in holidays when customer can't buy credit from vending stations. The meter will run until the balance reaches the negative balance then it will shut down the valve and restrict the gas flow. In case of balance run out or any error like reed switch fault or memory fault the LED indicators are used to notify the customer.

V. SOFTWARE DESIGN

The software of the prepaid system consists two parts: 1. SMS which runs an application that communicates with the vending stations and the database 2. Vending station where customer purchases credit. For redundancy a backup database is also included which automatically syncs with the main database. The vending stations may also run in offline mode i.e. without internet connection. This feature is introduced because sometimes the internet connection becomes unstable due to optical fiber cut or other reasons. In that case whenever the vending station goes online all offline transaction are uploaded to the main database. The application server is a windows server and the central and the backup databases are MySQL on linux machines. Fig. 3 shows the vending window of the vending software running on windows platform.

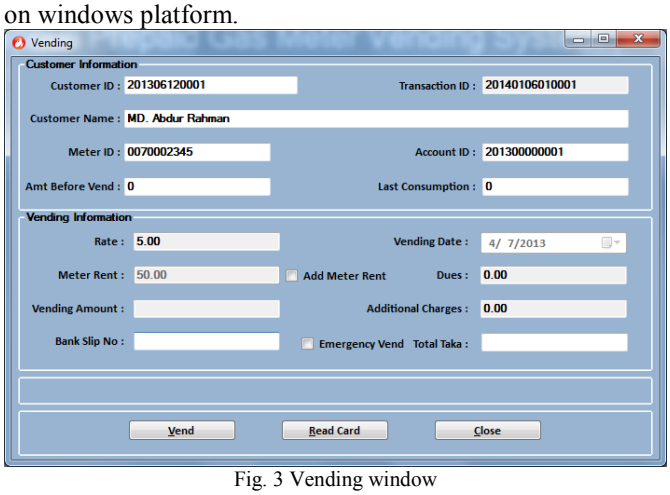

Fig. 3 Vending window

VI. TEST RESULTS OF THE METER

We have implemented our design in our laboratory. We have chosen a gas meter from many which is suitable for our environment and pressure condition of the local utility companies. We have attached out designed board to the meter. The software part was implemented with a central server with backup facility and multiple vending stations. We tested our gas meter and software with all necessary operations regarding prepaid metering system like setting up a meter, card assignment, buying credit from vending station, recharging the card and lastly uploading meter information to

the SMS through contactless smart card. Fig. 4 shows the designed board.

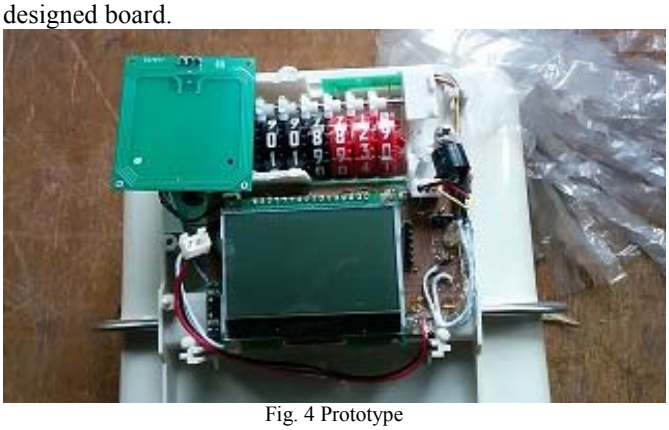

Fig. 4 Prototype

VII. CONCLUSION

In this paper a novel prepaid gas metering system is presented. The concept and design of the metering system is briefly discussed. The design was implemented and the prototype was tested successfully. A demonstration was given in KGDCL regarding the metering system with its different features from which both company and customers may be benefitted. After demonstration KGDCL showed interest to install our designed meter for 20000 domestic customers. There are some places where we can do some improvement. In the next step we will introduce a simple portable vending machine based on embedded system. This will replace the costly laptop or desktop. In that case along with the cost issue utility company and customers may enjoy more flexibility. As nowadays NFC is becoming more popular in the cell phones, we can build smart phone application though which customer may buy credit and also recharge the meter. This will make the system more flexible.

ACKNOWLEDGMENT

The authors gratefully acknowledge to Bangladesh University of Engineering and Technology (BUET) for allowing us to conduct the proposed research using all the facilities in the Centre of Embedded System, Institute of Information and Communication Technology (IICT). We are also grateful to Karnaphuli Gas Distribution Company Limited (KGDCL) for funding 4 lakh taka to develop the system.

Matching of Artificial Limb with Residual Human Limb by Capacitance Measurement Technique

Ashraful Haque*, Sheikh Jawad Ilham, Q. Ahsan

***Abstract*—Prosthetic amputee rehabilitation is a very common phenomenon in medical science. Artificial limb used as a substitution of a missing body part to restore its function is generally known as prosthesis. The most rudimentary requirement is to design the artificial limb such that it appears as natural as the missing body part in terms of functionality and comfort. A method of designing artificial limb is proposed after a detailed analysis of the existing prosthesis mechanisms, their evolution and drawbacks. The proposed technique presents a prosthetic replacement essentially with a complete negative impression of the residual limb and an exact matching customarily at the contact surface. The technique exploits the capability of measuring the capacitance in the range of picofarad (10^{-12} Farad) to acquire varying surface data of the residual limb for its exact matching with the artificial part. A micro-controller based capacitance measuring equipment is developed and it is applied to measure the unevenness of a surface. The accuracy is validated through image processing.**

***Index Terms*—Artificial human limb, Micro-controller based capacitance meter, Image processing.**

I. Introduction

Lower extremity amputation is a widespread problem prevailing at regions with higher rate of road accidents, natural disasters like earthquakes, cyclones and by wars. Amputee rehabilitation can be accomplished by an artificial limb fitted with the residual part to achieve cosmetic and functional capabilities to the prior level. Major concerns of rehabilitation process are to ensure that, the prosthetic limb appears as natural as missing body part irrespective of upper or lower extremity amputation and at the same time restitution of functionality with proper attachment to the residual limb.

A socket holds the prosthetic limb in place with the residual limb. The socket is considered as a major element of a artificial human limb. Socket must be carefully designed to fit the unique geometry of the residual limb. Existing technologies use different kinds of sockets to hold the artificial human limb in place with the residual body part. Existing technologies include: Patellar Tendon Bearing (PTB) Socket, Total Surface Bearing (TSB) Socket, and Hydro-static Weight Bearing (HWB) Socket. Fist two of them are shown in Fig. 1.

The residual limb can take any random shape after amputation illustrated at Fig. 2. On the other hand almost constant shapes of existing sockets result into mismatch of socket with the residual limb. The drawbacks of the existing technologies mainly arise from two phenomena with a common root of mismatch of a socket with the residual limb.

Again amputee using conventional passive prosthesis generates problems during locomotion. While walking, there is an angle between knee and toe [1], [2]. If the socket is not exactly matched it will create pressure on the contact surface. L. E. Pezzin et. al. [3] shows that nearly one third of the person using prosthetic limb devices expresses dissatisfaction with the comfort of their prosthetic limb. They are not comfortable with the fitting of limb with their body part while walking or standing. If the contact surface of the prosthetic limb does not exactly matches with the residual limb it creates pressure on the residual body part and creates discomfort. As pressure increases discomfort increases and this pressure can also cause serious damage to the soft tissues of residual body part [4]. The paper propounds a method for acquiring 3-D image of the negative impression of the residual limb and that can be incorporated as the top surface of the socket to the residual limb to eliminate almost all the problems arisen from gaps. By

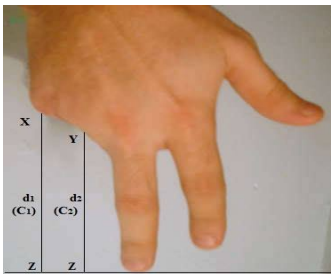

Fig. 3. Translation of Capacitance into Distance.

knowing the accurate force profile the exactly matched contact surface can be synthesized with localized pressure zoning system to be commensurate with force carrying capabilities of the stump for the removal of non uniform pressure related problems.

Traditionally, design of these sockets is done manually and plaster of Paris is used to capture the geometry of residual limb. Early in the 1970, VAPC knee caliper was used for anterior-to-posterior knee measurement and after placing socket in place, heat was used to modify the socket for better adjustment of contact area of artificial limb and residual limb [5]. But this process has serious error because of manual measurement and because of use of heat for exact matching of limb. Excessive heat can damage the socket and cause mismatch in the contact surface. Sand casting techniques were later introduced for designing of sockets [6]. In this technique residual limb is dressed with socks and inserted into liquidized silica with vacuum applied. After limb is totally inserted into the silica and taken out, vacuum is released and a mold of residual limb is thus formed. This mold is then used to design the sockets. However, if the surface area of the limb is considerably high then this technique will be unable to provide satisfactory result, as it could not provide accurate geometry of the uneven surface. It requires a complete new mold to be made every time there is a mismatch of socket and body part. Recent technologies include the use of Rapid Prototyping (RP) technology that creates physical models directly from three-dimensional data received from the computer [7], [8]. This technology is also known as 3-D printing [7]. But it requires the use of a 3-D printer which is still quite expensive and as a result the pricing of sockets increases. The consistency of these sockets is yet to be studied [7].

This paper proposes the designing of an artificial limb based on the capacitance measurement technique for matching of the artificial human limb with the residual body part. Proposed method does not require any manual measurement and also it eliminates the use of mold and plaster of Paris for making sockets. This paper also proposes a method for error checking while designing artificial human limb through image processing. Therefore, it eliminates the necessity of developing more than one socket for final matching of an artificial limb.

II. Methodology

Body part where artificial human limb is needed to be attached is, generally, an uneven surface. If a reference line is picked, each point of the surface has different distance from that. Fig. 3 shows the difference of only two points of the surface of the body part from a certain reference line as an example. Similarly, each point on the surface has different distance from the reference line.

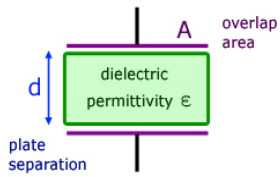

Fig. 4. Parallel Plate Capacitor.

Precise calculation is needed to measure these d_1, d_2 distances. As the difference between these points is not too large, conventional methods for measuring d_1, d_2 is not applicable here. More precise calculation is required for this measurement. The capacitance of a parallel-plate capacitor of Fig. 4 constructed of two parallel plates both of area A separated by a distance d may be expressed as,

$$C = \frac{\epsilon_0 \times \epsilon_r \times A}{d} \tag{1}$$

Where,
C = Capacitance in farads
A = Area of overlap of the two plates
ϵ_r = Dielectric constant of the material between the plates
ϵ_0 = Dielectric constant of vacuum
d = Separation between the two plates in meters.

Capacitance is proportional to the area of overlap and inversely proportional to the separation between conducting sheets. The closer the sheets are, the greater the capacitance. By rearranging (1) it can be written as,

$$d = \frac{\epsilon_0 \times \epsilon_r \times A}{C} \tag{2}$$

Now if the one plate at X and one plate at Z are placed it results C_1 and for one plate at Y and one plate at Z the resulting capacitance is C_2. From (2), d_1 and d_2 are obtained.

Similarly by placing one plate at different points on the limb and one plate on the reference line different capacitance values can be measured and in turn the distance of each point of the residual body part from a reference line, may be obtained.

This methodology can also be applied to a 3-D object where XY plane will be taken as reference plane and distances of different points of the surface will be calculated in a similar way.If the 3-D surface pattern of the residual body part is as Fig. 5 then through capacitance sensing method the distances d_1, d_2, d_3 etc. can be measured to reconstruct the 3-D negative impression of the residual body part.

Since, the distance of each point along the surface of the residual body part varies very slightly, it is very difficult to calculate the distance of each point through conventional measurement technique. Equation (1) shows that there is an inverse relation between capacitance and distance between parallel plates. So even if the difference of distance from one point to the next point is very small the change of the value of capacitance will be easily distinguishable. This is the main advantage of proposed technique that is, accurately measured capacitance even in the range of picofarad can easily be translated into distance of each point of residual body part from a reference point. These distances can be then used to generate an accurate negative image of the residual body part. This negative image will then be used to make exactly matched artificial body parts.

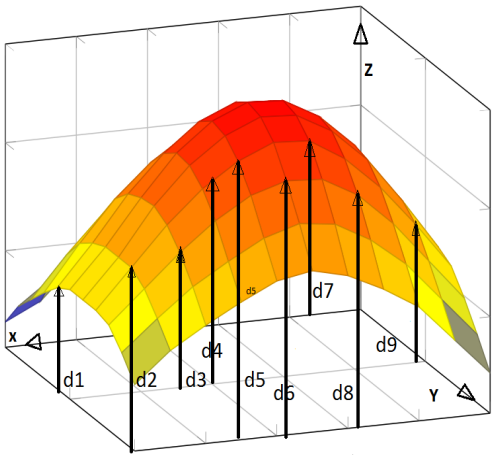

Fig. 5. 3-D Image Construction.

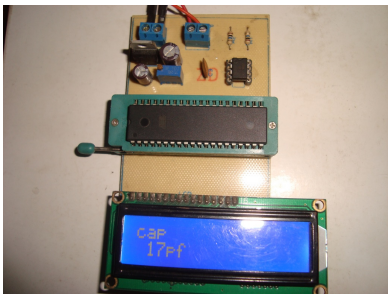

Fig. 6. Developed Capacitance Sensing Device.

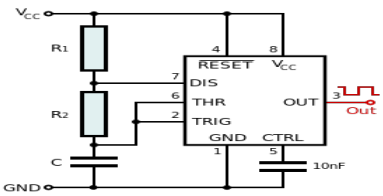

Fig. 7. Astable Multivibrator Circuit.

III. Sensor Design

Existing capacitance meter uses charging and discharging principle of capacitor to measure capacitance [9]. But charging-discharging technique can not distinguish between small amount of capacitance change. A prototype capacitance meter is developed, shown at Fig. 6.

For the capacitance meter 555 timer IC, ATmega16 microcontroller, LCD display, 7805 IC for providing power to microcontroller and LCD display are used. If the capacitance formed by different points of surface of the body is connected to the 555 timer IC in the following manner it forms an astable multivibrator shown at Fig. 7.

The output is a pulse whose frequency is F.

$$F = \frac{1}{ln(2) \times C \times (R_1 + 2 \times R_2)} \tag{3}$$

Here, C is the capacitance that is formed by placing one plate at a reference point and one plate at the surface of the body part.

This output pulse is fed to the microprocessor. Microprocessor determines the capacitance and translates these values to distances.

TABLE I
Error Percentage Calculation of Distances Measured By the Device with Distances Acquired from Image Processing

Reading No.	C_Standard (pF)	C_Measured (pF)	Error (%)
1	15	15	0
2	22	21	4.5
3	30	29	3.33
4	45	43	4.4
5	47	45	4.25
6	60	58	3.34
7	100	98	2
8	120	117	2.5
9	150	147	2

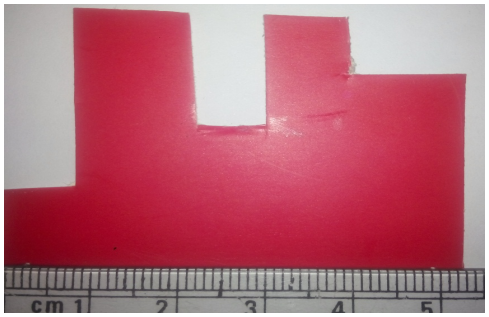

Fig. 8. Captured Image with Centimeter Scale

IV. Data Collection

Readings of different valued standard capacitors were taken using the developed capacitance meter. Table I shows the actual capacitance, measured capacitance and error. The table clearly shows that the error is within 5 percent of the standard value.

V. Result

Distances at different points corresponding to a reference point are determined using the developed capacitance meter. Validation of these measured values are done by image processing in several steps.

- First the image of the object is taken with a centimeter scale lying on the same plane with the intended surface of the object illustrated at Fig. 8.
- The image is cropped properly to get real distance per pixel of the image of that particular surface. The image is then read and coded into grey scale using MATLAB built-in function. Then the edge of that edge detected image is acquired using several MATLAB built-in functions and the best suited one is taken from them to be read into a matrix as white dots in black background with elements either 1 or 0 illustrated at Fig. 9 with inverted color.
- Then from the reference row the index of the last white dot of each individual column is read and plotted which gives the exact pixel distance of that particular point from the reference line illustrated at Fig.10.
- By using real distance per pixel constant obtained earlier, the scale of that plot is changed into real distance. Thus the real distance is measured from the image of the object shown at Fig. 11.

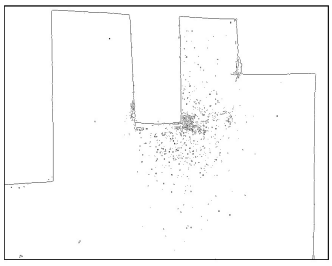

Fig. 9. Edge Detected Image by Prewitt Method.

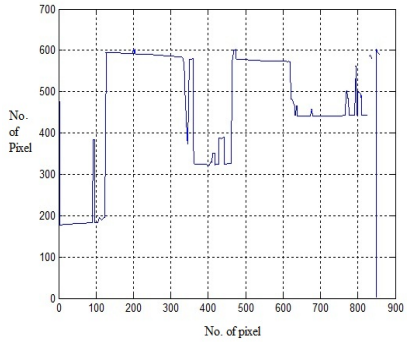

Fig. 10. Reconstructed Image in Pixel Distance.

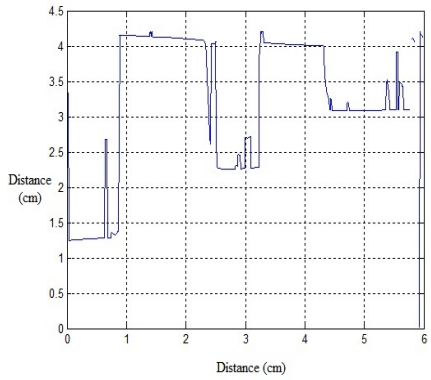

Fig. 11. Reconstructed Image in Real Distance.

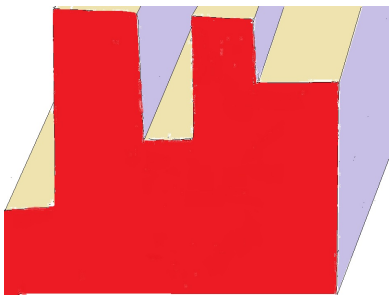

Fig. 12. 3-D view of Sample Object.

- This validation process can also be implemented in case of a 3-D object illustrated at Fig. 12, where individual images of different surfaces with same arrangement, stated earlier, are recorded.

TABLE II
ERROR PERCENTAGE CALCULATION OF DISTANCES MEASURED BY THE DEVICE WITH DISTANCES ACQUIRED FROM IMAGE PROCESSING

Reading No.	d_Actual (cm)	d_Measured (cm)	Error (%)
1	1.2	1.05	5
2	3.7	3.8	2.7
3	2.2	2.25	2.3
4	3.8	4	5.3
5	2.5	2.6	4

The actual distances of the edges are compared with the actual data from the image processing in Table II. The table clearly shows that the difference is not significant.

VI. CONCLUSIONS

Prosthetic amputee rehabilitation success depends profoundly on proper designing of contact surface which is the fundamental part of an artificial limb having a direct contact with the residual limb. Without proper fitting, overall function of the prosthesis as well as comfort to the patient is hampered. Thus it is imperative that, technique used here, to produce limb sockets is accurate, repeatable, and cost-effective and has high patient satisfaction. The unevenness of surface can vary from picometers to several inches. Therefore, precise determination is needed. Exactly matched surface with proper force profile is the perquisite for restoring cosmetic and functional purposes of an artificial human limb. By taking into consideration, all the limitations and drawbacks of existing technologies, this paper proposes a capacitance measurement technique along with the validation through image processing for error checking for matching of artificial human limb.

***Abstract*— Oil filled transformers are widely used to step up or step down voltages in power transmission and distribution systems. A periodic maintenance of the transformers includes checking oil level, chemical analysis and dielectric strength (break down voltage) test taking oil sample and sending it to laboratory. Sometimes it becomes impossible to check the oil level without opening the transformer. In this paper the method of sweep frequency response analysis (SFRA) has been proposed for on-site and instant test of oil condition without requiring the transformer to be opened and sending oil sample to a remote laboratory. Notably SFRA has long been used to diagnose transformer winding faults such as mechanically displaced and shorted or open turns. So this paper proposes application of SFRA for the first time ever for spot monitoring of certain conditions such as oil level and contamination in emergency situations. The experimental results obtained from SFRA of a healthy transformer and two transformers having oil related problems were compared. In this way a guideline regarding the frequency range where a deviation from the response of the healthy transformer may suggest oil related problem, has been formulated. The conclusion has also been supported through a PSpice simulation.**

***Index Terms*—Frequency response, Transformer oil, On site oil monitoring**

I. INTRODUCTION

Basically in sweep frequency response analysis (SFRA) a frequency sweep of sinusoidal signals with low amplitude (less than 10V) and commonly in the range of 50 Hz to 1 MHz is injected [1] to a transformer's terminals. For each frequency the injected signal is measured and the output response is measured at another terminal. Then the response is plotted against the entire frequency range in terms of 20 $\log_{10}(V_{out}/V_{in})$ dB (decibels) along the Y-axis and frequency in Hz (Hertz) along the X-axis (in logarithmic scale). The plot is compared with that for a healthy transformer and the results are interpreted [1-3] depending upon the range of frequencies where the deviation occurs.

However, it appears that while the guidelines [1-3] for interpreting the mechanical deformations and electrical faults in windings using SFRA have been reported, no application of SFRA for monitoring the oil conditions such as reduced oil level and oil contamination has ever been reported. Till now oil level and contaminations are cheeked respectively through physical inspection (if a conservator is provided) and dielectric test of collected sample. Sometimes it becomes impossible to check the oil level without opening the transformer.

In this paper a new application of SFRA has been proposed for onsite monitoring of oil level and contamination without collecting oil sample and sending it to a laboratory. For this three 11/0.4 kV oil type transformers respectively a 250 kVA healthy one, another 250 kVA transformer with almost empty tank and a 500 kVA transformer containing moisture contaminated oil were subjected to SFR analysis. In this way a guideline has been formulated regarding the frequency range where a deviation from the response of the healthy transformer may suggest oil related problem. An attempt has also been made for PSpice simulation to support the findings.

II. CONNECTION FOR OIL TEST BY SFR

SFR test can be applied in various ways depending upon the purposes. For winding related faults the connection [1-3] is as in Fig.1.

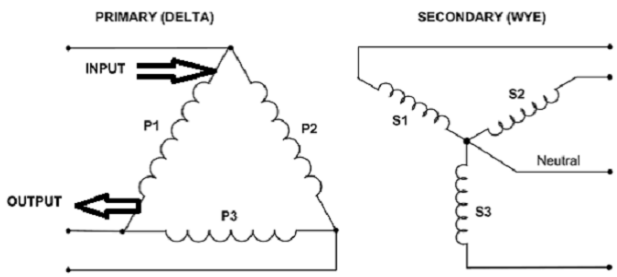

Fig. 1 End to end connection for winding related fault diagnosis

But for SFR test of oil that exists in between the high voltage and low voltage windings, the connection in Fig. 2 has been used in this work. Here for a Δ-Y transformer the input voltage is applied between a high voltage (HV) winding and the neutral of the low voltage (LV) windings and the output voltage is measured between corresponding LV winding and the neutral of LV windings.

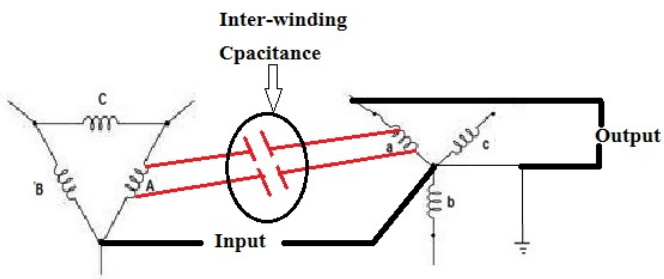

Fig. 2 End to neutral connection for proposed oil related fault diagnosis

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

III. Comparison between Healthy Transformer and a Transformer with Reduced Oil Level

SFR test was done in the range of 100 Hz to 1 MHz using the connection shown in Fig. 2 for the phase 'A' winding and its corresponding LV winding for a 250kVA transformer which was known to have its tank empty of oil. The same was done for another healthy transformer of 250 kVA size. The SFR plots for the two are compared in Fig. 3. The analysis of the plots shows that the deviation from the healthy one's response due to reduced (empty) oil level is confined mostly within the 60 kHz to 300 kHz range.

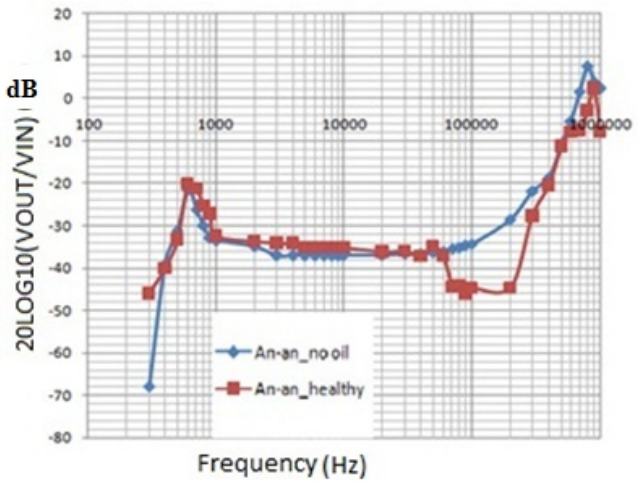

Fig.3 Comparison of SFR plots for two 250 kVA transformers (one healthy and the other with empty tank) using end to neutral connection

Since it was known that both transformers are free from winding related faults so to support the Fig. 3 response due to reduced oil level, the same two transformers were subjected to SFR test using end to end connection setup of Fig.1. The response plots are shown in Fig. 4 which clearly shows that the deviation between the two responses is uniform throughout the frequency spectrum and thus excludes the possibility of winding faults. This end to end test was repeated for every other winding of the two transformers and the responses were found to be similar as in Fig. 4.

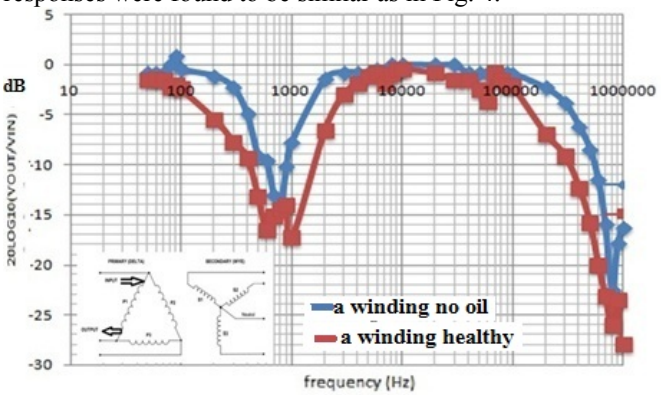

Fig.4 Comparison of SFR plots for the two 250 kVA transformers (one healthy and the other with empty tank) using end to end connection

IV. Comparison BETWEEN HEALTHY transformer and a Transformer with Contaminated Oil

SFR test was done in the range of 100 Hz to 1 MHz using the connection shown in Fig. 2 for the phase 'B' winding and its corresponding LV winding for a 500 kVA transformer which was known to have its oil contaminated by moisture. The same was done for the healthy transformer of 250 kVA size. The SFR plots for the two are compared in Fig. 5. The analysis of the plots shows that the deviation from the healthy one's response due to oil contamination is confined also within the 60 kHz to 300 kHz range.

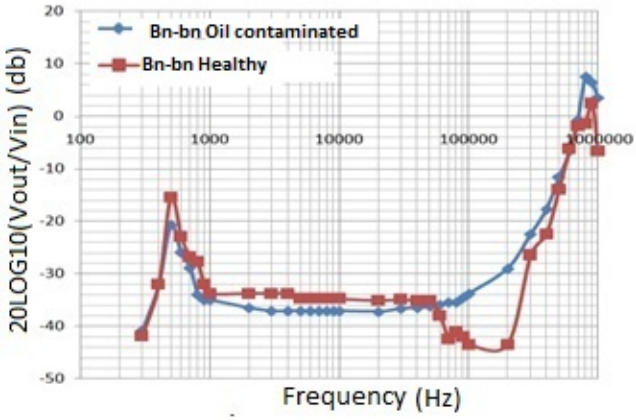

Fig.5: Comparison of SFR plots for a 250 kVA healthy transformer and a 500 kVA transformer with contaminated oil using end to neutral connection

As before the SFR test was also done for these transformers using end to end connection and the responses plotted in Fig. 6 which shows a uniform deviation throughout thre frequency spectrum excluding the possibilities of winding related problems.

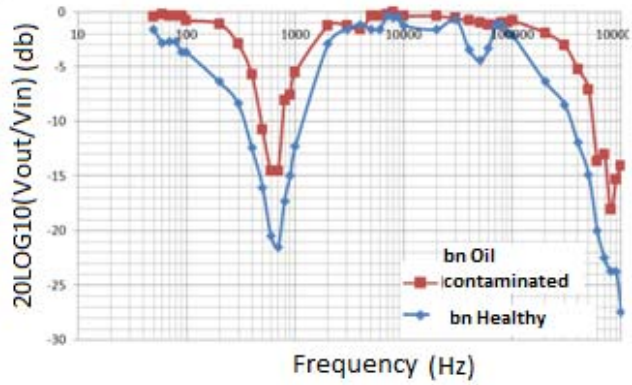

Fig.6 Comparison of SFR plots for the 250 kVA healthy and the 500 kVA transformer with contaminated oil using end to end connection

It should be noted that when transformer oil is contaminated, or the oil level is reduced the capacitance between two sides (HV and LV) reduces. This is because $C = \varepsilon A/d$ so that with the reduced oil level or contamination in oil the permittivity ε as well as the capacitance decreases. Consequently the ratio of output to input voltage increases and the SFR curves move upward relative to the healthy transformer response curves in the range 60 kHz and above as observed in Figs. 3 and 5.

V. PSpice Circuit Simulation

The equivalent circuit for a turn [3] of a transformer in the sweep frequency range has been used in this work to synthesize a circuit representing 10 turns in a winding of the Δ side while 5 turns in a winding of the Y side of a generic transformer. The inter-winding capacitances with typical

values have been added in the present work to represent oil conditions. Then a PSpice simulation was done for the input –output response of this circuit in 10 Hz to 1 MHz range considering end to neutral connection.

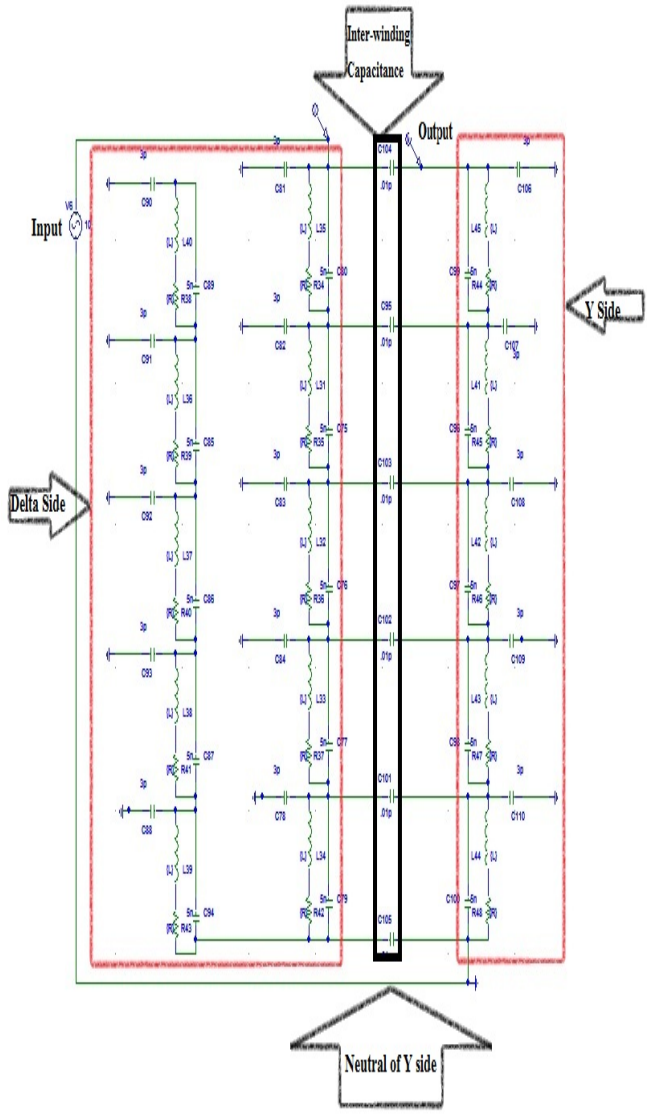

Fig.7 Equivalent circuit for PSpice simulation

Fig. 8 shows the SFR curves obtained from PSpice simulation for various oil conditions which clearly supports one of the the experimental finding that more the oil related problem more is the upward shift in the SFR. However, exact matching of simulation and experimental response curves is not expected. This is because it is difficult to synthesize an equivalent circuit considering actual number of turns in HV and LV windings and exact values of the circuit parameters.

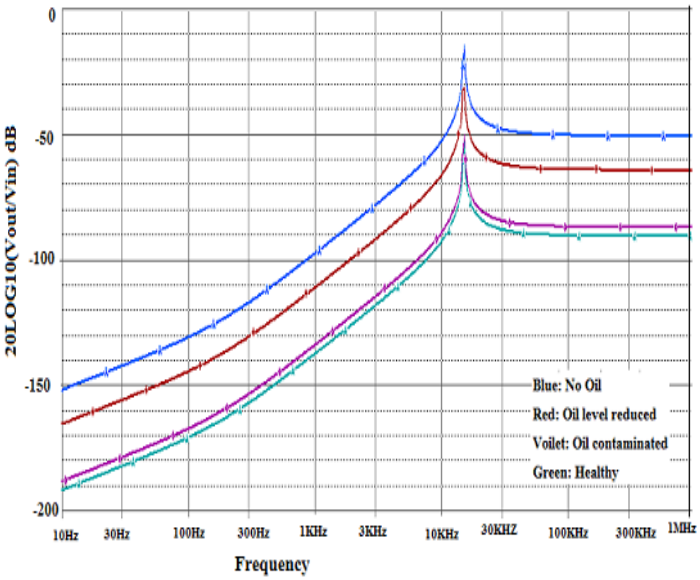

Fig.8 SFR responses from PSpice simulation

VI. Conclusion

Use of sweep frequency response (SFR) for on-site and instant test of oil level and oil contamination in power/distribution transformers during emergency situations has been proposed. For this an end to neutral connection set up is to be used. Based on the experiments conducted on a healthy transformer and two other transformers respectively with reduced oil level and degraded oil, it is suggested that the SFR curves due to oil related problems will shift above that for a healthy transformer usually in the 60 kHz to 300 KHz. A PSpice simulation of the equivalent circuit for the set up of a generic transformer with different oil conditions has also been done and this also supports the basic experimental observation.

Acknowledgments

This research was conducted at the CERS (Central Equipment and Repairing Shop), a unit of Bangladesh Power Development Board, located at Tongi, Gazipur, Bangladesh. All the personnel of CERS are thankfully acknowledged for their help and support.

Abstract—**Detection of unhygienic impurities in water is one of the major concerns of human society.The detection of impurity in water is not only important for drinking water but also for water in industrial use. The type of impurity to be detected varies with the variation of the use of water. A low cost parallel plate based capacitive sensor is designed and implemented for the experimental setup. The detection circuit proposed is a RC oscillator with a time constant proportional to the capacitance. The resulting time constant is measured by Arduino Uno microcontroller board. Simulations of the oscillator circuit are performed using Proteus. This paper investigates the impurities with different concentrations of Sodium Chloride (NaCl), Sugar($C_6H_{12}O6$) , Ferrous Sulphate ($FeSO_4$) and Copper Sulphate ($CuSO_4$). Empirical relationships are developed to identify the type of impurity and its concentration.**

Index Terms—**Distilled Water, Capacitance Measurement, Electrolyte Impurities.**

I. Introduction

Water is one of the most essential factors for sustaining the life of all living organisms. Apart from drinking water to survive, there are various industries and chemical and biological laboratories where highly purified water is essential. Besides this, the uses of impurity free water include- coolant in nuclear reactors, boilers, automotive cooling, cleansing of surgical apparatus.There has been a great deal of interest in the detection of impurities in distilled water.

It is very difficult to determine the total amount of impurity in a sample by direct chemical analysis. Moreover, it is impossible to produce reproducible results by evaporating the water sample to dryness and weighing the residue as some of the present minerals, mainly chloride is lost during final stages of heating [1]. Hence, the measurement of impurities, mainly saline has been done using both direct method and indirect methods [2]. Most of these measurement methods work on the basis of change of conductivity [3].

Modern conductivity sensors are basically of two types: contact type and noncontact type sensors. Contact type sensors let the solution under test flow through them and sense the conductivity by measuring the current flow through the circuit [4]. In spite of the simplicity of design, they suffer a few significant drawbacks. Since there is direct contact between the solution and probe, it risks corrosion and fouling effects. Space charge polarization effects are also pronounced since same probes are used, both for applying voltage and measuring the resultant current. Although these problems are minimized by using 4 probe sensors, the issue of fouling still exits.

Non-contact type sensors have no contact between the sensing device and the analyte. This gives them advantage over the contact type sensors. But long term stability is dictated by polarization and fouling .The measuring principal in non-contact type sensors is mainly inductive. It consists of two coils. The primary coil is a single coil whereas, the surrounding liquid forms the secondary liquid. An ac current of known frequency and amplitude drives the primary. When this coil is brought near water, transformer action ceases and a eddy current, directly proportional to the conducting ability of the medium, is generated. This kind of sensor has not yet been applied to the determination of impurity in water [5], but has been used in non-invasive electromagnetic conductivity sensing in biomedical research [6].

Non-contact, inductive conductivity sensors, specially double transformer based ones are widely used because of their inherent advantage of not being prone to fouling and polarizing [7],[8]. But, inductive sensors face problems from external fields. The measuring field being used for inductive sensing method is exposed to surrounding media. However, the whole of this media is not coupled inductively. The contributions of these external fields can be as much as up to 20% [9]. This leads to proximity errors. Even the anti-fouling coating can change the geometry of the sensor, resulting in errors. Another problem associated with this method, is its heavy dependence on temperature and pressure variation [5].

All these problems associated with the inductive sensing methods can be lessened to great extent using the capacitive methods for conduction sensing. This paper uses the parallel plate capacitive configuration because of its simplicity of design, inherent confinement of the measuring field between the two plates and easy detection of a small variation of capacitance even in the range of Pico farad (10^{-12}). Only a small field is exposed to the external medium which gives rise to fringing effects. The fringing effects were dealt with by the use of Kelvin guard rings [10].

Four of the most common salts dissolved in water have been used as sample impurities. They are - Sodium Chloride (NaCl), Sugar($C_6H_{12}O_6$) , Ferrous Sulphate ($FeSO_4$) and Copper Sulphate ($CuSO_4$).

II. Methodology

A. Sensor Design

The sensor consists of two parallel conducting (copper) plates. One of the plates has a dimension of 2inch×1inch and the other plate is built with slightly larger dimensions (2.1 inch×1.1 inch)for purposes of alignment. The sensor plates are constructed on copper clad substrate boards. Since our experiments were conducted on water and water conducts electricity, we insulated the copper plates by coating it with varnish oil. Contact wires were soldered out for connection purposes. The capacitance of a parallel plate capacitor is given by (1).

$$C = \frac{\varepsilon A}{d} \tag{1}$$

Where, ε is the permittivity of the dielectric medium between two plates. A is electrode area and d is the distance between electrodes. However, in practice, the measured capacitance of a capacitor is generally higher than the calculated capacitance if value of d is comparable to that of A. This increase is attributed to the fringing fields at the plate edges. It is difficult to calculate the fringe field. So, Kelvin guard electrodes (ring) have been used to minimize the fringing effect and also protection from external interference [12]. It is sufficient to use this ring around just one of the electrodes. A typical arrangement for Kelvin guard ring is as shown in Fig. 1

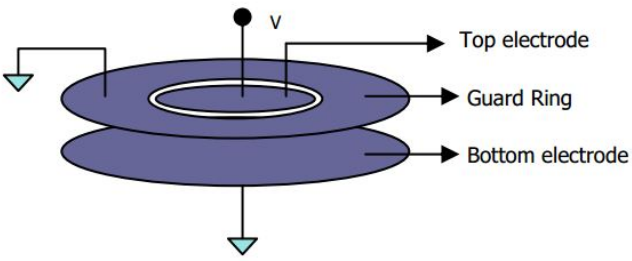

Fig.1 Capacitive Sensor with Kelvin Guard Ring

B. Detection Circuitry

The detection circuit used for this experiment used auto range detection schemes for two different ranges of capacitors. For small capacitors (1pF – 1nF), a voltage divider was formed between the test capacitor and a known capacitor (30pF) as shown in Fig. 2

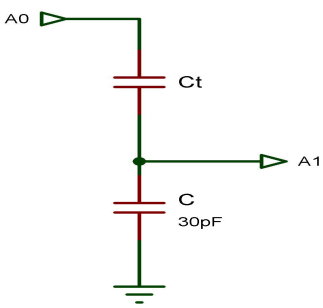

Fig.2 Sensor Circuitry for higher concentration of impurities

Initially, both capacitors are discharged with A0 at zero volts. Then a 5volt is applied at A0. The voltage at A1 will settle down to 1% of its final value within 30ns. The value of Ct is calculated from (2).

$$Ct = \frac{V_{A1}}{V_{A0} - V_{A1}} C \tag{2}$$

For the higher range of capacitors, RC circuit shown in Fig.3 was used.

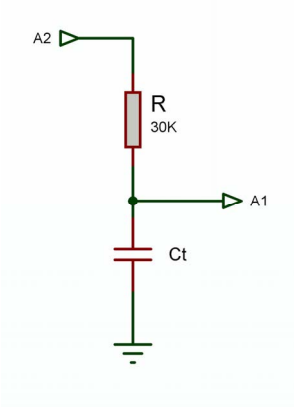

Fig.3 Sensor Circuitry for lower concentration of impurities.

The internal pull up resistance of the Arduino Uno board was used as the resistor of the RC network. It has a value of around 30kΩ. A 5volt was placed at A2 and the voltage at A1 was sampled along with the timestamps. Since, "Analog-Read" function takes longer response time, the "Digital Read" function was used to sense when the voltage at A1 was 2.5 volt. After that, "Analog-Read" was used. The value of test capacitance was calculated from (3).

$$Ct = \frac{-t}{R \ln\left(1 - \frac{V_{A1}}{V_{A2}}\right)} \tag{3}$$

C. Sample and Solution Preparation

The experiment was carried out on solutions with up to 20gm of impurity- Sodium Chloride (NaCl), Sugar ($C_6H_{12}O_6$) , Ferrous Sulphate ($FeSO_4$) and Copper Sulphate ($CuSo_4$) dissolved in 1 Litre of distilled water. A micro pipette was used to measure the volume of water. Proper analysis was carried out to ensure a decrement of 1gm of dissolved impurity for each iteration.

D. Measurement technique

At first the sample solution was prepared. The sensor circuit was immerged into the solution. The resulting capacitance was shown on the 16×2 alphanumeric display. 3 repetitions were done and the average was taken as the corresponding reading.

III. Results

A. Accuracy of the Sensor

Readings were taken for standard value capacitors and in each case the readings were within a tolerance limit of 6%. The reading of the sensor for various ranges of capacitors are listed below in Table 1.

TABLE I
ACCURACY OF SENSOR

Capacitor Model	Real Value	Sensor Output	Error
15J	15pF	15.461pF	3.07%
22J	22pF	23.103pF	5.01%
47J	47pF	48.532pF	3.26%
101J	100pF	102.000pF	2.00%
471K	470pF	478.776pF	1.87%
102K	1.000nF	1.053nF	5.30%
222K	2.22nF	2.34nF	5.40%
392K	3.92nF	3.853nF	-1.71%
472K	4.720nF	4.884nF	3.47%
103K	10nF	10.50nF	5.00%
104K	100nF	104.75nF	4.75%
105K	1uF	0.986uF	1.40%

As we can see, over the large range of capacitance values from 15pF to 1uF, the maximum error is below 6%,which is be accurate enough to serve our purpose.

B. Readings for different impurities

1) *Sodium Chloride(NaCl)* :When sodium chloride was added as the impurity, the measured capacitance was found to decrease with increasing concentration. The value of measured capacitance against the amount of dissolved impurities are plotted in Fig.4

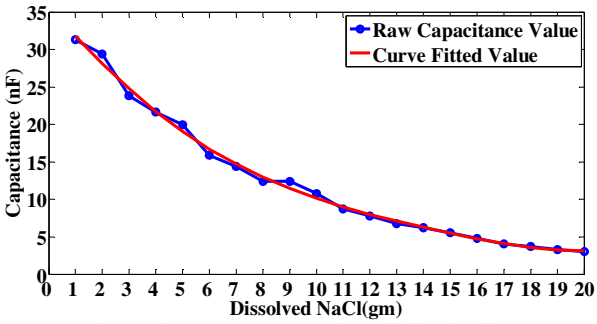

Fig.4 Measured Capacitance Vs Amount of NaCl dissolved in water

2) *Ferrous Sulphate($FeSO_4$):* The observed capacitance decreased for the$FeSO_4$ solution with increasing concentration of impurity .The graph is shown in Fig.5

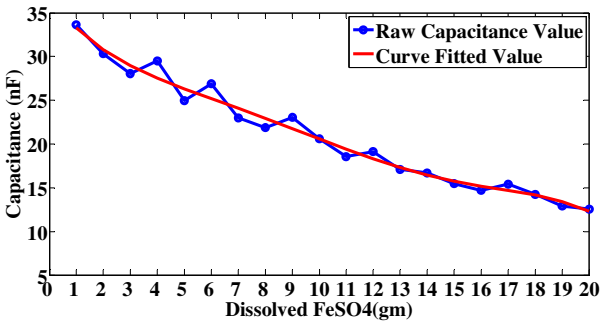

Fig.5 Measured Capacitance Vs Amount of $FeSO_4$ dissolved in water

3) *Copper Sulphate($CuSO_4$):* Similar to the previous two impurities, the capacitance decreases with increased amount of dissolved impurities. The graph for $CuSO_4$ is shown in Fig.6

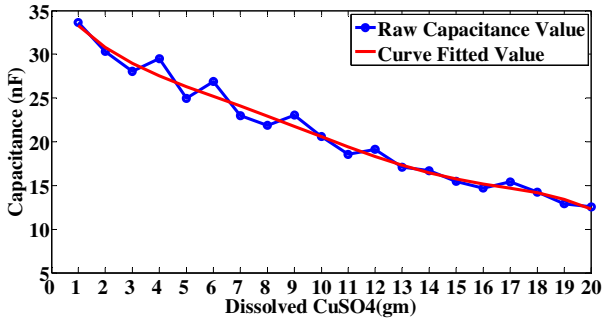

Fig.6 Measured Capacitance Vs Amount of $CuSO_4$ dissolved in water

4) *Sugar ($C_6H_{12}O_6$):* Similar to the previous two impurities, the capacitance decreases with increased amount of dissolved impurities. The graph for $CuSO_4$ is shown in Fig.7

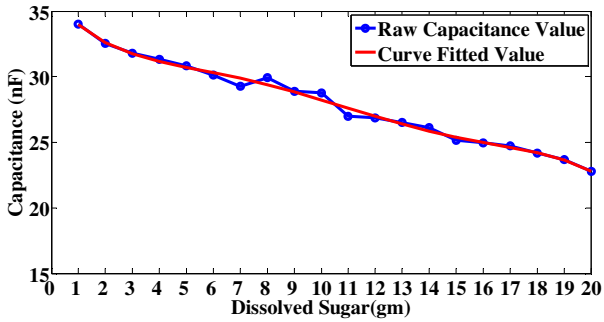

Fig.7 Measured Capacitance Vs Amount of Sugar dissolved in water

C. Data Analysis

If we compare the capacitance vs dissolved impurity graph for the different materials, as shown in Fig. 8, it is evident that for all the cases, the capacitance of distilled water decreases with increasing amount of dissolved impurity.

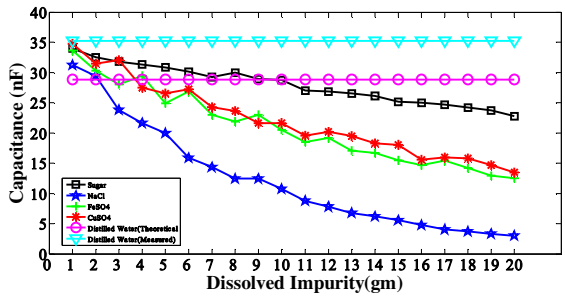

Fig. Comparison of capacitance vs dissolved impurity for different impurities.

This phenomenon can be well explained by *Electrolytic Dissociation Theory in Solutions*. Even a very small concentration of electrolyte usually causes a significant change in the conductivity of the liquid. The dielectric behaviour of liquid medium respond to dissolving of impurities in two probable ways. Firstly, association of ions

may result in generation of ion pairs or similar species. These species of appreciable dipole moment will be expected to make their own contribution to the dielectric polarization process and also the dispersion. Secondly, ions can influence the solvent's molecular interaction by its own strong localized field. A straight forward consequence would be imparting its own characteristics to the solution.

It is the second aspect, that is mostly responsible for the analysis of the dielectric property[13]. The electrostatic field in the immediate proximity of the dissolved impurity ions interact with the polar water molecules in such a way that appreciable number of water molecules are "frozen" around each of the solute ions. The hydrated salt ions are bulkier entity than a non-hydrated ion. Moreover, the hydrated sheath around the dipoles prevents them from orienting themselves with the external electric field. This is the principal cause of reduction in permittivity which results in reduction of capacitance due to addition of impurity.

Another observation from the comparison shown in Fig.8 is that although capacitance decreases for all the impurities, the rate of change of capacitance is not the same for all the impurities. Of the considered impurities, NaCl had the largest rate of decreasing of capacitance while Sugar had the least. NaCl is an ionic compound where as Sugar is a covalent compound where polarity arises due to the hydroxyl bonds (-OH) present. So, the contribution to the local field around the hydrated ions is much more for NaCl than for Sugar. That is why, change of capacitance is most for NaCl and least for Sugar. The total decrease in capacitance for the diffent materials are given.

IV. CONCLUSIONS

A parallel plate capacitive sensor was fabricated to detect the type and concentration of impurities in water by capacitance measurement. Data analysis is carried out to curve fit the acquired raw data in order to develop empirical relations among the variables. Experimental results show, specific trends of reduction of capacitance with the concentration of impurities. This approach could be extended to the detection of impurities in non-binary solutions, containing more than one kind of impurities.

A Two Dimensional Analytical Model of Drain to Source Current and Subthreshold Slope of a Triple Material Double Gate MOSFET

M. A. Mahmud and S. Subrina*, Member, *IEEE*

Department of Electrical and Electronic Engineering, Bangladesh University of Engineering and Technology
Dhaka-1000, Bangladesh

*samiasubrina@eee.buet.ac.bd

Abstract—**A two dimensional analytical model of drain to source current as well as subthreshold slope of a triple material double gate MOSFET has been developed in this work. Basic drift-diffusion equation has been used to derive the drain to source current model. An expression of pinch-off voltage has been derived for modeling drain current in saturation region. The current in the device has been studied as function of drain to source voltage and gate voltage as well. In the work, leakage current in zero gate bias condition has also been presented. Variations in subthreshold slope of the device owing to change in device parameters have been lifted up. Our model results have been verified with the simulation data obtained by using a professional numerical device simulator.**

Index Terms **— Drain to source current, gate engineering, leakage current, pinch off voltage, subthreshold slope.**

I. Introduction

Short channel effects (SCE) originating from downscaling of electronic devices need to be mitigated for optimum performance of the devices. Triple material double gate MOSFET is a potential candidate for microelectronic industry due to its ability of suppression of various short channel effects (SCE) compared to traditional single or double gate single material MOSFET structures. Double gate structure is advantageous over the traditional single gate structure because of its higher current drive capability, off-current reduction and better scaling and effective short channel effect handling capability [1]-[4]. In addition, as a form of gate engineering, both the upper and lower gate electrodes of this structure consist of three metals having different work functions. The metal close to the source having the highest work function while that close to drain having the lowest. It gives a two-step surface potential profile that suppresses Drain induced barrier lowering (DIBL) effectively. This gate engineering also allows to have the same threshold voltage for the device with a reduced doping concentration in the channel region. This results in better immunity against mobility degradation and higher transconductance. Some theoretical and experimental works on the TM gates have already been published [5]-[6]. Tiwari *et al*. presented a two dimensional analytical model of surface potential and threshold voltage of a triple material device [6]. But no model for drain to source current and subthreshold slope of this structure was reported in the literature.

In this work, a two dimensional analytical model of drain to source current and subthreshold slope of the aforesaid structure along with results from a commercially available 2D device simulator is presented. All the analytical model results show good agreement with the results obtained from 2D device simulator that justify the validity of our model.

II. Analytical Modeling

This section presents the modeling of two dimensional drain to source current and subthreshold slope of a triple material dual gate MOSFET (TMDG MOSFET). A schematic structure of the device is shown in Fig. 1. The x- and y- axes of the 2D device structure are considered to be along the front oxide-semiconductor interface and the source terminal-channel interface, respectively. The total channel length, L is divided into 3 regions. The front and the back gate electrodes of the device are symmetric and composed of three different materials having work functions of Φ_{m1}, Φ_{m2} and Φ_{m3} ($\Phi_{m1} > \Phi_{m2} > \Phi_{m3}$) deposited over lengths L_1, L_2 and L_3, respectively. The front and the back gate terminals are shorted to a fixed potential, V_{GS}. The drain bias is V_{DS} and the source terminal is grounded. A layer of SiO_2 has been used with both front and back gate terminals.

A. Drain to Source Current Model

For modeling of drain to source current, mid-channel potential, Φ_{cj} has been considered instead of surface potential in basic drift and diffusion current equation, because considering surface potential in this case assumes punch-through current to flow only at surface, which is invalid for double gate fully depleted SOI MOSFET [7, 8]. Drain to source current can be expressed as a combination of drift and

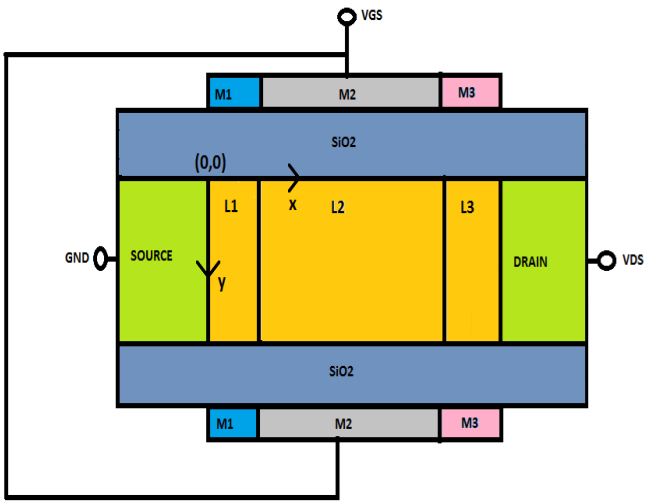

Fig. 1. Schematic diagram of triple material double gate MOSFET

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

diffusion current [9] for all the regions which can be given as:

$$I_{DRIFT_j} = W \cdot \mu_j(x) \cdot Q_{Ij}(x) \frac{d\Phi_{cj}(x)}{dx} \quad (1)$$

$$I_{DIFF_j} = W \cdot \mu_j(x) \cdot V_T \frac{dQ_{Ij}(x)}{dx} \quad (2)$$

where, $W, V_T, \mu_j(x)$ and $Q_{Ij}(x)$ are channel width, thermal voltage, carrier mobility and inversion layer charge, respectively for j=1,2,3 and are given by:

$$\mu_j(x) = \frac{\mu_0}{\sqrt{\left[1+\left\{\frac{E_j(x)}{E_c}\right\}^2\right]}} \quad (3)$$

$$Q_{Ij}(x) = 2\{Q_{sj}(x) - Q_{Dj}\} \quad (4)$$

where, μ_0, $E_j(x)$, E_c, $Q_{sj}(x)$ and Q_{Dj} are low carrier mobility, electric field, critical electric field, surface charge and depletion layer charge, respectively [10]-[11] and are given by:

$$E_j(x) = \frac{C_{ox}\left[\Phi_{cj}(x) - V_{GS} + V_{fbj}\right]}{\in_{si}} \quad (5)$$

$$E_c = 6.01\times10^2 \cdot T^{\frac{3}{2}} \quad (6)$$

$$Q_{sj}(x) = -C_{ox}\left[V_{GS} - V_{fbj} - \Phi_{cj}(x)\right] \quad (7)$$

$$Q_{Dj} = C_{ox}\left(\varphi_F - V_{th} + V_{fbj}\right) \quad (8)$$

where $C_{ox} = \frac{\in_{sio2}}{t_{ox}}$ is oxide capacitance, $\in_{si}$ and $\in_{sio2}$ are permittivities of Si and SiO_2 respectively , $\varphi_F = V_T \ln\left(\frac{N_A}{n_i}\right)$ is Fermi potential, N_A is acceptor doping concentration in all the three regions of the channel and n_i is the intrinsic carrier concentration of silicon. V_{th}, V_{fbj} and Φ_{cj} are threshold voltage, flatband voltage and mid-channel potential, respectively and are given by Tiwari *et al*. [6].

Now, integrating both sides of the Eq. 1 and using Eqs. 3-4 and 7-8,

$$\int_{L^*_{j-1}}^{L^*_j} I_{DRIFT_j}\,dx = \int_{\Psi_{cj-1}}^{\Psi_{cj}} \frac{W\mu_0\left[-2C_{ox}\left\{V_{GS} - \Phi_{cj}(x) + \varphi_F - V_{th}\right\}\right]}{\sqrt{\left[1+\left\{\frac{E_j(x)}{E_c}\right\}^2\right]}} d\Phi_{cj} \quad (9)$$

where,

$$\begin{cases} L^*_0 = 0, \\ L^*_1 = L_1, \\ L^*_2 = L_1 + L_2, \\ L^*_3 = L_1 + L_2 + L_3, \end{cases}$$

and

$$\begin{cases} \Psi_{c0} = \Psi_{cj}(x)\big|_{x=L^*_0} \\ \Psi_{c1} = \Psi_{cj}(x)\big|_{x=L^*_1} \\ \Psi_{c2} = \Psi_{cj}(x)\big|_{x=L^*_2} \\ \Psi_{c3} = \Psi_{cj}(x)\big|_{x=L^*_3} \end{cases}$$

and j=1,2,3

From Eqs. 5, 7 and 9, we get,

$$I_{DRIFT_j} = \frac{S_4}{L_j - L_{j-1}}\left[(S_1 + S_3)\ln\left\{\frac{\left(S_3 + \Phi_{cj}\right) + \sqrt{S_2^2 + \left(S_3 + \Phi_{cj}\right)^2}}{\left(S_3 + \Phi_{cj-1}\right) + \sqrt{S_2^2 + \left(S_3 + \Phi_{cj-1}\right)^2}}\right\} - \left\{\sqrt{S_2^2 + \left(S_3 + \Phi_{cj}\right)^2} - \sqrt{S_2^2 + \left(S_3 + \Phi_{cj-1}\right)^2}\right\}\right] \quad (10)$$

where,

$$S_1 = V_{GS} + \varphi_F - V_{th} \quad (11)$$

$$S_2 = \frac{\in_{si} E_c}{C_{ox}} \quad (12)$$

$$S_3 = V_{fbj} - V_{GS} \quad (13)$$

$$S_4 = -2\in_{si} \mu_0 W E_c \quad (14)$$

Now, integrating both sides of the Eq. 2 and using Eqs. 3-6,

$$\int_{L^*_{j-1}}^{L^*_j} I_{DIFF_j}\,dx = \int_{Q_{Ij-1}}^{Q_{Ij}} \frac{W\mu_0 V_T}{\sqrt{\left[1+\left\{\frac{E_j(x)}{E_c}\right\}^2\right]}} dQ_{Ij} \quad (15)$$

where,

$$\begin{cases} Q_{I0} = Q_{Ij}(x)\big|_{x=L^*_0} \\ Q_{I1} = Q_{Ij}(x)\big|_{x=L^*_1} \\ Q_{I2} = Q_{Ij}(x)\big|_{x=L^*_2} \\ Q_{I3} = Q_{Ij}(x)\big|_{x=L^*_3} \end{cases}$$

and j=1,2,3

From Eqs. 4-6 and 15, we get,

$$I_{DIFF_j} = \frac{S_7}{L_j - L_{j-1}}\left[\ln\left\{\frac{\left(S_5 + Q_{Ij}\right) + \sqrt{S_6^2 + \left(S_5 + Q_{Ij}\right)^2}}{\left(S_5 + Q_{Ij-1}\right) + \sqrt{S_6^2 + \left(S_5 + Q_{Ij-1}\right)^2}}\right\}\right] \quad (16)$$

where,

$$S_5 = 2C_{ox}\left[V_{fbj} + \varphi_F - V_{th}\right] \quad (17)$$

$$S_6 = 2\in_{si} E_c \quad (18)$$

$$S_7 = S_6 W V_T \mu_0 \quad (19)$$

So, the drain to source current can be expressed as,

$$I_{DS} = \sum_{j=1}^{3}\left[I_{DRIFT_j} + I_{DIFF_j}\right] \quad (20)$$

Now, the expression in Eq. 20 is valid for all values of drain to source voltage below pinch off i.e. where the inversion layer charge becomes zero. With the gradual increase of drain to source voltage $V_{DS,}$ at certain value, pinch off occurs at drain end of the channel and this voltage is called Pinch off voltage, V_{DP}. Above V_{DP}, the drain to source current remains constant. Now, the expression of V_{DP} can be obtained by equating inversion layer charge in Eq. 4 at L^*_3 to zero and using Φ_{cj} and Eqs., 4, 7- 8 and 11:

$$V_{DP} = V_{GS} - V_{th} + \varphi_F + \frac{\beta_3}{\eta^2} - A^*_3 e^{\eta L^*_3} - B^*_3 e^{-\eta L^*_3} \quad (21)$$

where, β_3 and η are constants and A^*_3 and B^*_3 are values of

constants A_3 and B_3 [6] at $V_{GS} = V_{th}$ and can be given by a common expression:

$$A^*_j = A_j - \frac{V_{DP}}{2\sinh(\eta L)} \tag{22}$$

$$B^*_j = B_j + \frac{V_{DP}}{2\sinh(\eta L)} \tag{23}$$

So, for $V_{DS} \geq V_{DP}$, drift current component,

$$I^*_{DRIFT_j} = \frac{S_4}{L_j - L_{j-1}}[(\Phi_{c3} + S_3)\ln\left\{\frac{(S_3 + \Phi^*_{cj}) + \sqrt{S_2^2 + (S_3 + \Phi^*_{cj})^2}}{(S_3 + \Phi^*_{cj-1}) + \sqrt{S_2^2 + (S_3 + \Phi^*_{cj-1})^2}}\right\}$$

$$-\left\{\sqrt{S_2^2 + (S_3 + \Phi^*_{cj})^2} - \sqrt{S_2^2 + (S_3 + \Phi^*_{cj-1})^2}\right\}] \tag{24}$$

where,

$$\Phi^*_{cj} = A^*_j e^{\eta L^*_j} + B^*_j e^{-\eta L^*_j} - \frac{\beta_j}{\eta^2} + V_{DP} \tag{25}$$

$$\Phi^*_{cj-1} = A^*_j e^{\eta L^*_{j-1}} + B^*_j e^{-\eta L^*_{j-1}} - \frac{\beta_j}{\eta^2} + V_{DP} \tag{26}$$

Also, for for $V_{DS} \geq V_{DP}$, diffusion current component,

$$I^*_{DIFF_j} = \begin{cases} \frac{S_7}{L_j - L_{j-1}}\left[\ln\left\{\frac{(S_5 + Q^*_{Ij}) + \sqrt{S_6^2 + (S_5 + Q^*_{Ij})^2}}{(S_5 + Q^*_{Ij-1}) + \sqrt{S_6^2 + (S_5 + Q^*_{Ij-1})^2}}\right\}\right]; j=1,2 \\ \frac{S_7}{L_j - L_{j-1}}\left[\ln\left\{\frac{S_5 + \sqrt{S_6^2 + S_5^2}}{(S_5 + Q^*_{I2}) + \sqrt{S_6^2 + (S_5 + Q^*_{I2})^2}}\right\}\right]; j=3 \end{cases} \tag{27}$$

where,

$$Q^*_{Ij} = -2C_{ox}(S_1 - \Phi^*_{cj}) \tag{28}$$

$$Q^*_{Ij-1} = -2C_{ox}(S_1 - \Phi^*_{cj-1}) \tag{29}$$

So, for $V_{DS} \geq V_{DP}$, drain to source current can be expressed :

$$I^*_{DS} = \sum_{j=1}^{3}\left[I^*_{DRIFT_j} + I^*_{DIFF_j}\right] \tag{30}$$

Finally, the drain to source current can be expressed as :

$$I_{DS,tot} = \begin{cases} I_{DS}; V_{DS} < V_{DP} \\ I^*_{DS}; V_{DS} \geq V_{DP} \end{cases} \tag{31}$$

B. Subthreshold Slope

Subthreshold slope can be obtained using the following equation :

$$SS = \frac{dV_{GS}}{d\log[I_{DS}]} \tag{32}$$

III. Results

In this section, the results obtained in the analytical modeling section have been represented graphically along with the results obtained from 2D device simulator for model validity. Work functions used in this analysis are φ_{m1} =4.8eV, φ_{m2} =4.6eV and φ_{m3} =4.4eV. Acceptor doping concentration, N_A of 10^{16} cm^{-3} in all the three regions of the channel and drain and source region (heavily doped with donor atoms) concentration of 10^{20} cm^{-3} have been used in our work. Total channel length, L of the device has been considered to be 120nm. Ratio of the length of the channel regions, $L_1 : L_2 : L_3$ has been kept 1:1:1. In our analysis, channel thickness, t_{si} has been considered 20 nm. Oxide thickness, t_{ox} is kept 3.5nm. It is reported in that the QME (Quantum Mechanical Effects) become negligible if the channel thickness, t_{si} is over 5nm

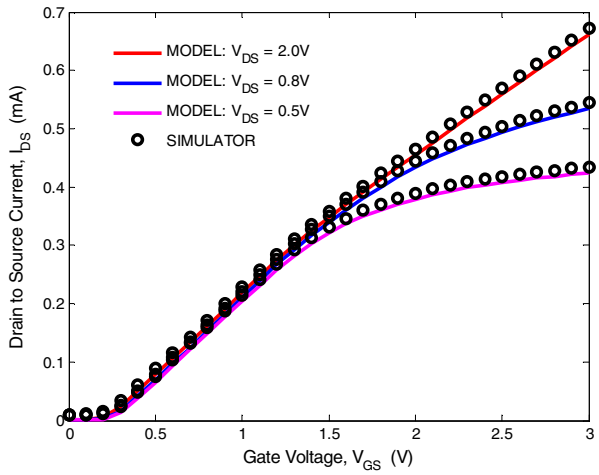

Fig. 2. Drain to source current as a function of gate voltage for different values of drain to source voltage (V_{DS}).

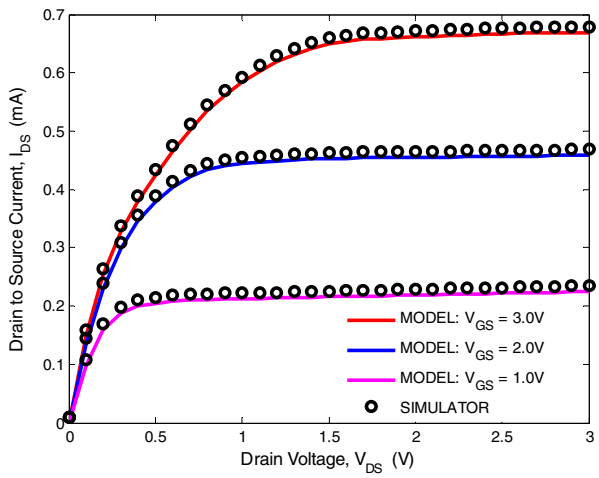

Fig. 3. Drain to source current variation against drain voltage for gate voltgae,V_{GS}= 3V, 2V and 1V

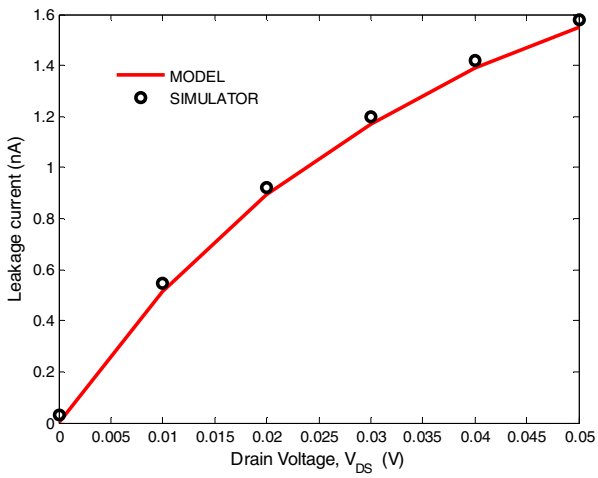

Fig. 4. Leakage current in the device as a function of drain voltage while V_{GS} = 0V

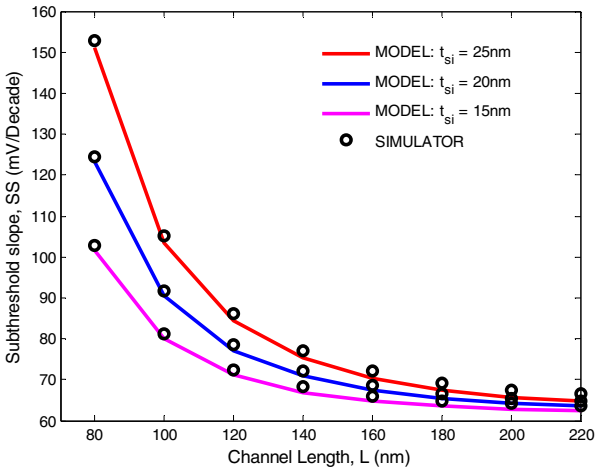

Fig. 5. Subthreshold slope variation with channel length for different values of Si-film thickness (t_{Si}) while V_{DS}=0.1V.

[12]. Since, channel thickness used in our analysis is above it, we have not included QME in our modeling.

Fig. 2 shows the drain to source current with varying gate voltages for three different drain voltages. In the subthreshold region, negligible leakage current flows through the channel. Once the threshold voltage is achieved, the device is turned on and drain to source current increases with increasing gate voltage and drain voltage as well. Fig. 3 presents the plot of drain current with drain voltage for three different values of gate voltage. It is obvious from the figure that, at a certain value of V_{DS} (pinch off voltage ,V_{DP}), pinch off occurs at the drain end and current remains constant with increasing drain voltage. Fig. 4 illustrates leakage current with low drain bias for V_{GS} =0V. Negligible leakage current (in nA) is observed under this condition. Fig. 5 lifts up the subthreshold slope of the device with varied channel length and Si film thickness. It is obvious from the figure that subthreshold slope is higher for device with thicker silicon channel thickness and shorter channel length. With the increase in silicon channel thickness, there is a rise in depletion layer capacitance in a fully depleted MOSFET. Since, subthreshold slope is proportional to the ratio of depletion layer capacitance to gate oxide capacitance [13], thicker channel MOSFETs exhibit higher subthreshold slope. The analytical model results show good agreement with the numerical results from the 2D device simulator.

IV. Conclusion

A two dimensional analytical model of drain to source current and subthreshold slope of triple material double gate MOSFET have been presented in this paper. Dependence of device subthreshold slope on device parameters like channel length and silicon channel thickness has also been explored. The model results have been verified with the simulation results as well.

Abstract— **The novel electronic properties of graphene nanoribbons (GNRs) including purely two-dimensional structure along with its tunable bandgap have led to intense research into possible applications of this material in nanoscale devices. However, as yet, dimensions of its possibilities in practical device levels have remained inconsistent. In this paper we propose a model for GNR-FET that is made from only Armchair GNRs. Our complete NEGF-based simulation reveals its potential for fast digital electronics with On/Off ratio up to 10^3, transconductance of 8.5×10^3 nS/nm which lead to a analog operational frequency up to 3.3THz. The effects of Stone-Wales defects and Edge Roughness in GNRs have been analysed here that shows switching and frequency performance degradation of such GNR-FETs.**

Index Terms—**Armchair GNR, Edge Roughness, GNR-FET, NEGF, Stone-Wales Defects.**

I. Introduction

Graphene, the 'miracle material' of the 21st century is a material with immense possibilities due to its excellent electrical, magnetic, thermal, optical and mechanical properties. These properties, along with the ballistic electronic transport and high carrier mobility [1] cause this material to be promising candidate for nanoelectronics applications. For graphene, energy dispersion relation is linear at Dirac-points [2], so electrons in graphene behave as massless fermions [3] and travel through the lattice with long mean free path, which ensures higher electron mobility. As graphene is a zero bandgap material it seems unsuitable for transistor applications. However energy gap can be opened up by means of lateral confinement [4], which is realized by etching the graphene sheet in narrow strips, called graphene nanoribbons (GNRs). GNRs have opened a prospect for GNR based FETs as their energy gap is inversely proportional to their width [5] and depending on this width they can be semiconducting or metallic. The ultrathin structure of GNRs leads to perfect electrostatic control of gate over channel which is a key advantage over conventional semiconductors. Extensive research is now going on for fabricating GNRs with narrow width and smooth edges. Patterned GNRs have been exhibited experimentally with ~10nm width [6]-[7]. However, due to the embryonic stage of this new field of research, state-of-the-art etching techniques are far from atomistic resolution, so edge roughness can play an important role on overall performance of the GNR-FET devices [8]. Computer simulations can be very useful to provide physical insights of such phenomena and determine performance of GNR-FETs with ultrathin width. GNR-FET has been simulated previously using scattering matrix approach based on effective mass Hamiltonian [9], which fails to incorporate scattering due to nonidealities in quantum regime. Whereas quantum simulations based on a tight-binding approach [10] have been used to evaluate GNR-FET characteristics incorporating such nonideal phenomena.

In this paper, *I-V* characteristics of GNR-FET made from only Armchair GNRs are studied in order to establish its switching and frequency performance that can be expected if technological challenges are met. The electronic transport is analyzed using non-equilibrium Green's function (NEGF) formalism [11]. Different types of nonidealities have been investigated. In particular, we have studied the effect of Stone-Wales (SW) defects in the channel and Edge Roughness on the switching and frequency performance of the device. Our simulation study reveals that performance of GNR-FET severely degrades due to such defects.

II. Device Configuration and Simulation

FET operation requires a gate controlled channel region and two electrode regions to serve as source and drain. Depending on the chirality of graphene nanoribbon it can be Armchair or Zig-zag. Armchair GNR (AGNR) and Zig-zag GNR (ZGNR) show semiconducting or metallic behaviour depending on the number of carbon atoms along its width [12]. GNR-FET can be made from one Zig-zag semiconducting GNR channel and two Armchair metallic GNR leads [13]. Taking the variation of bandgap with the width of Armchair GNR into consideration we propose a GNR-FET that can be made from only Armchair GNRs. In the channel region N=7 (E^g=1.35eV) semiconducting Armchair nanoribon of 3.5nm length is used, where N is the number of carbon atoms along the width of the GNR. This region is then connected with two N=8 ($E^g \approx 0$eV) metallic Armchair nanoribbons, considered as electrodes. Width of the device is ~0.74nm. The structure is shown in Fig. 1. In this device HfO_2 ($\kappa \approx 25$) is used as gate oxide and oxide thickness is 0.4nm. This structure provides excellent interface matching between channel and electrode regions, eliminating the possibility of interface defect. While a contact metal would introduce large contact resistance to the device [14], contact with the metallic Armchair GNR makes smoother metal-semiconductor interface with minimum contact resistance.

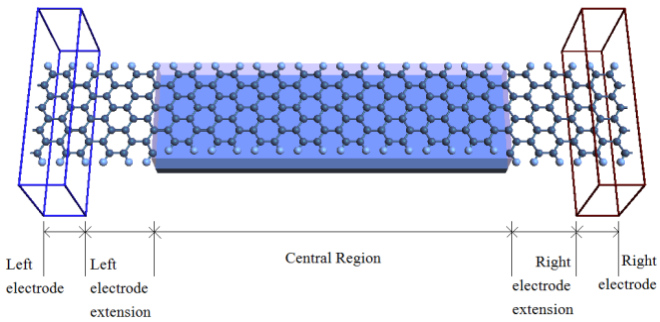

Fig. 1 Device configuration used for NEGF simulation.

In this paper we have used NEGF approach coupled with Poisson's equation to calculate electronic transport in GNR-FET. Here the NEGF formalism is based on tight binding P_Z orbital model which incorporates 3rd nearest neighborhood calibrated through a first-principle calculated *ab-initio* model [15]. The charge distribution described by NEGF is self-consistently coupled with Poisson's equation to incorporate the effect of self-consistent field and solved by multi-grid finite difference method. The edge atoms are considered as hydrogen passivated (σ bond).

III. Results and Discussion

A. Transmission Spectrum

As the first outcome of simulation we get the transmission spectrum of the central region of devices, when both gate and drain bias voltages are zero. Zero energy level is denoted by Fermi energy. Transmission coefficient above Fermi level is for electron and transmission coefficient below Fermi level is for holes. Within the bandgap energy (1.35eV) transmission coefficient is zero. Interesting finding is that, though in the above device channel-electrode interface was thought as perfect matching and the transmission spectrum should be smoothed at all energy level, we can see that transmission coefficient values degrade at some energy level as shown in Fig. 2. It is because interface atoms fail to keep electrons at all the energy levels what central region atom can, along with scattering effects at the interfaces.

B. I-V Characteristics

When a positive gate potential is induced, minimum energy for non-zero electron transmission coefficient comes closer to Fermi energy level, whereas a negative gate potential has opposite effect. So the charge carrier in a two dimensional channel can change from electrons for positive gate voltage to holes for negative gate voltage. But this phenomenon has less effect when we are using semiconducting GNR as channel.

Fig. 3 and Fig. 4 show I-V_{ds} and I-V_{gs} curve for the simulated device. With the increment of gate voltage, conductivity of the channel increases so current increases at constant drain to source voltage. The On/Off ratio is a key parameter to compare performances among different FETs. The Manchester research group demonstrated GFETs with On/Off ratio of ~30 at room temperature [2]. The first top-gated GFET with On/Off ratio < 2 was demonstrated by researchers of AMICA and RWTH Aachen University in 2007 [16]. Here On/Off current ratio for the above device is found to be ~10^3, which seems promising for FET operation.

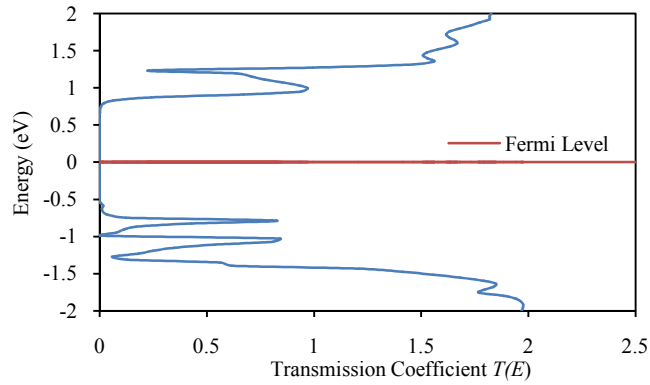

Fig. 2 Transmission spectrum of simulated device at zero gate bias.

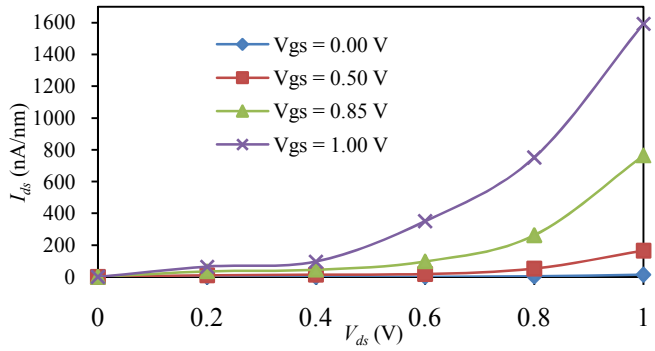

Fig. 3 I-V_{ds} curve at different gate voltages.

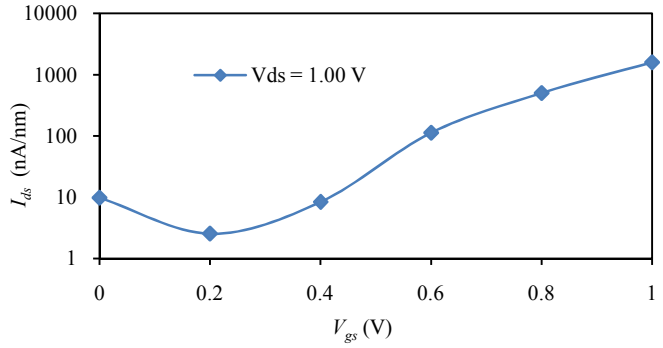

Fig. 4 I-V_{gs} curve at V_{ds}=1V.

C. Frequency Performance

Fig. 5 shows values of transconductance, g_m for different gate voltage at V_{ds}=1V. g_m starts to increase at V_{gs}=0.4V and become saturated after V_{gs}=1V. From this figure we can measure high frequency performance of our device. The cutoff frequency, f_T is related to g_m via the quasi-static approximation as

$$f_T = \frac{g_m}{2\pi C_g} \tag{1}$$

where C_g is the gate capacitance (for this device C_g= 4.1×10^{-10} F/m). Fig. 6 shows the values of f_T at different gate voltages. So for analog application, the device can operate up to 3.3THz. In [10] f_T up to ~4THz was found for defectless GNR-FET. Compared to RF frequency electronics, wider bandwidths, component compactness and improved spatial resolution are possible by GNR-FET, which may open up opportunities for faster electronics.

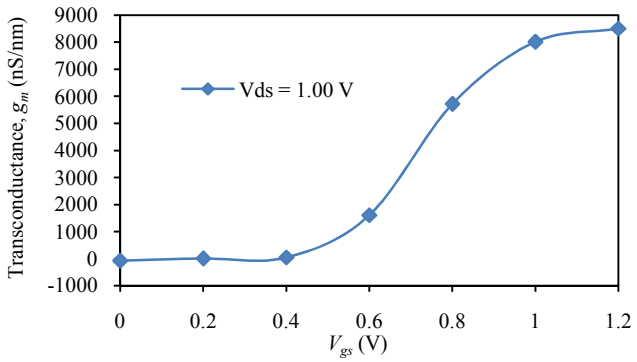

Fig. 5 Transconductance, g_m at different gate voltages for the device.

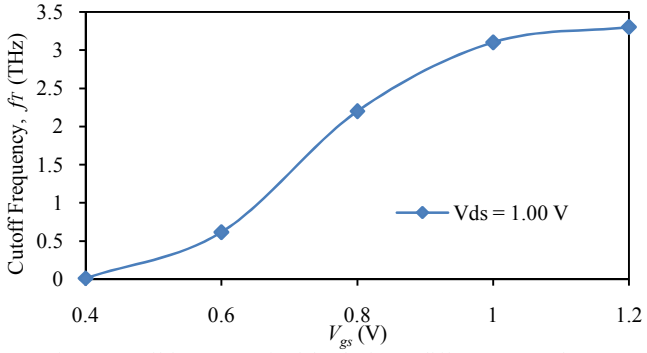

Fig. 6 Cutoff frequency, f_T of the device at different gate voltages.

IV. Defect Analysis In GNR-FET

Fabrication process of graphene nanoribbon may suffer from different types of defects in graphene sheet. Here we will discuss the effects of two such prominent defects on FET performances.

A. Stone-Wales Defects

Stone-Wales (SW) defects [17] are important topological defects in sp^2-bonded carbon materials, playing a central role in the formation, transformation, fracture, and embrittlement of carbon nanotubes, fullerenes, and other carbon nanostructures. SW defects have also been predicted to alter the electronic properties, band structure and density of states of graphene and is likely to impact upon its unique transport properties.

SW defects involve an in-plane 90° rotation of two carbon atoms with respect to the midpoint of the bond. In this transformation four hexagons are changed into two heptagons and two pentagons as shown in Fig. 7(a). Some researchers suggest that SW defects may enhance the tendency of graphene layers to transform into nonplanar nanostructures such as nanotubes and fullerenes and that SW defects may play a role in the intrinsic rumpling of graphene. For this reason we have considered the channel GNR with a single SW defect otherwise planner sheet may transform into nonplanar sheet.

B. Edge Roughness

The edge of the channel nanoribbon may distort if a number of atoms are missing in its edge as shown in Fig. 7(b). Edge roughness or distortion primarily occurs during fabrication process. In such cases the nanoribbon loses its chirality and show inconsistent bandgap behaviour along its length. Such defects can also alter the electronic properties, band structure and have an adverse impact upon its transport properties.

C. Effects of Defects on GNR-FET Performance

Fig. 8 shows the transmission spectrum for defected (Stone-Wales and Edge Roughness) and defectless GNR-FET. Comparing the results it is evident that transmission spectrum is strongly suppressed due to scattering by both types of distortion at higher energies. For edge-distorted ribbon, due to loss of chirality, transmission at bandgap energy range has been observed. From this transmission behaviour *I-V* characteristics of defected GNR-FET are computed (Fig. 9). Current in the device suffering from Stone-Wales defectdegrades significantly due to transmission spectrum suppression. In case of edge distorted GNR-FET higher valueof current is found at lower bias due to transmission at bandgap energy range.

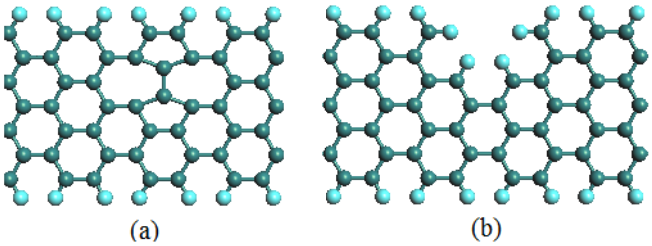

Fig. 7 (a) Stone-Wales defect (b) Edge Roughness.

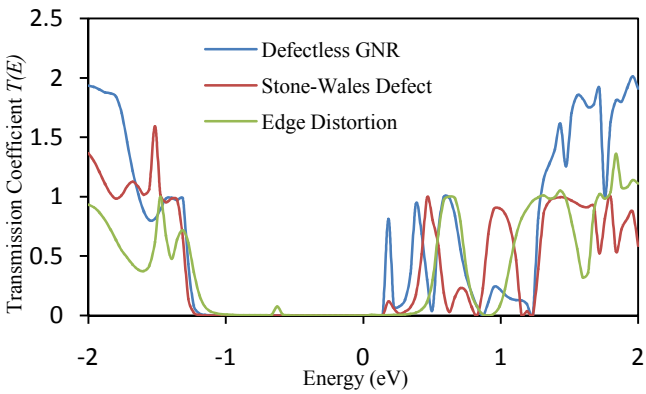

Fig. 8 Transmission spectrum for defected and defectless GNR.

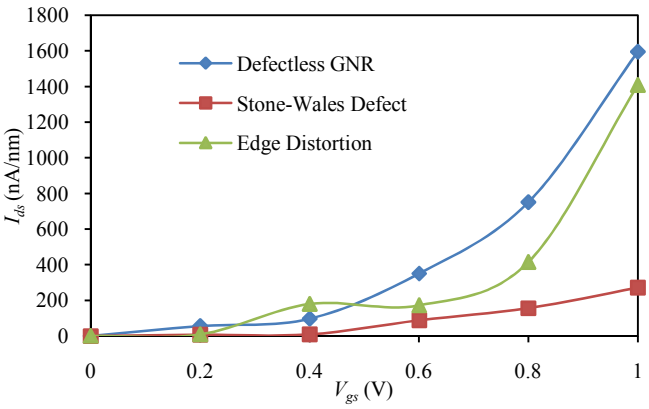

Fig. 9 I-V_{ds} curve of defected and defectless GNR (V_{gs}=1V).

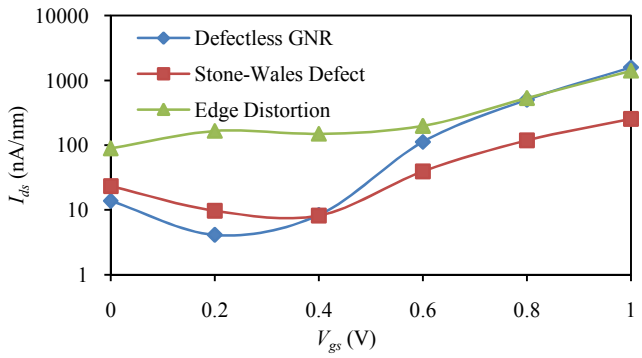

Fig.10 I_{ds}-V_{gs} curve of defected and defectless GNR (V_{ds}=1V).

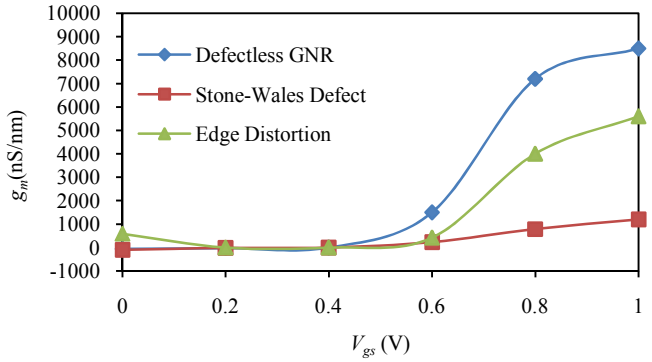

Fig.11 g_m-V_{gs} curve of defected and defectless GNR (V_{ds}=1V).

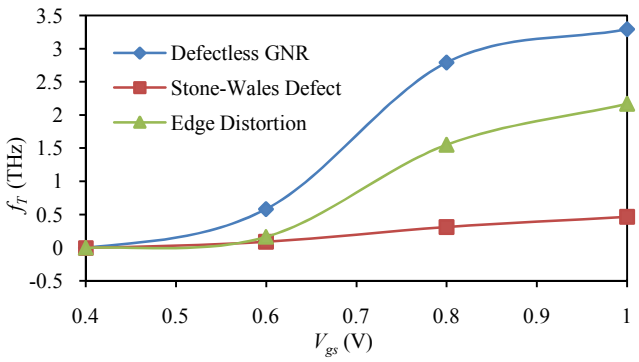

Fig. 12 f_T at different gate voltages for the device (V_{ds}=1V).

Switching performance of the GNR-FET suffering from defects can be determined from Fig. 10. On/Off ratio for SW defected FET and Edge Distorted FET is ~11 and ~16 respectively where for defectless device the ratio is ~10^3, which indicates significant switching performance degradation.

Frequency performance of the defected GNR-FETs can be analysed by first obtaining the transconductance, g_m of the device. Fig. 11 shows values of g_m for different gate voltages at V_{ds}=1V for both defected and defectless GNRs. From the figure it is evident that defect causes significant degradation of the gate voltage control over the channel region. As a result values of g_m reduce significantly for defected GNRs from its defectless case. Cutoff frequency of the device is then obtained using equation (1). Fig. 12 shows the values of f_T at different gate voltages. For analog circuit application, where the defectless device can operate up to 3.3THz, edge distortion limits the operational frequency to 2.2THz causing ~33% reduction in f_T. Stone-Wales defects show severe cutoff frequency degradation by limiting its value to 465GHz causing ~86% degradation. In conclusion we can say that, frequency performance of the GNR devices strongly depends on the fabrication process and introduction of defects causes significant alteration in the cutoff frequencies of the devices.

V. Conclusions

In this paper, we have performed NEGF simulation to demonstrate the intrinsic current-voltage characteristics of ultra-thin GNR-FETs. The FETs made from intrinsic semiconducting Armchair nanoribbons can exhibit very high levels of performance, with On/Off ratio up to ~10^3, transconductance of 8.5×10^3nS/nm which leads to a cutoff frequency up to 3.3THz. Then the effects of Stone-Wales defects and Edge Roughness is analysed. Simulation is performed to show that introduction of such defects during fabrication process may alter the switching performance of the GNR-FETs and degrade the overall frequency performance as well.

Abstract—**Since the fabrication of first III-V Gate-All-Around (GAA) MOSFET it is under extensive research, as it is one of the potential candidates to replace the state of art tri-gate FinFETs, to continue progressive scaling. In this work, transport characterization of experimentally demonstrated gate-all-around (GAA) $In_xGa_{1-x}As$ nanowire MOSFET in near-ballistic regime is performed using 3D self-consistent Schrödinger-Poisson solver based on Uncoupled Mode Space approach, taking wave function penetration and other quantum mechanical effects into account. The effects of channel length variation on transport characteristics are also examined.**

Index Terms—**Ballistic Transport; Mode Space Approach; Gate-all-around MOSFET; $In_xGa_{1-x}As$ Nanowire; III-V Channel Material.**

I. Introduction

ITRS road map suggests that, to maintain progressive scaling of transistors, extensive research should be done on improving Multi-gate devices and alternate channel structures such as nanowires [1]. Although, 22nm technology Trigate FinFETs are commercially available from 2012, to conform Moore's law transistors must be scaled further to sub-10nm very soon where aggressive short channel effects (SCEs) are prominent. Gate-all-around (GAA) structure with Si nanowire channel has proven most resistant to SCEs [2]-[6] implying that it can be a feasible solution for reaching that goal. Apart from the structure of the device, ITRS roadmap also suggests involvement of III-V materials in the channel for further research [1]. III-V FinFETs [7]-[8] and multi-gate quantum-well FETs [9] provide performance improvements over si-FinFETs in deep submicron regime offering better speed and higher ON/OFF current ratio. Taking the advantages of both GAA architecture and III-V nanowire channel, Gate-all-around $In_xGa_{1-x}As$ nanowire MOSFET with ALD Al_2O_3 as gate dielectric has been experimentally demonstrated by Gu et al. [10] in recent past where better performance than existing FinFETs has been reported. Although, TCAD modeling of transport characteristics is available for this device [11], theoretical transport modeling that concurs with the experimentally reported result is yet to appear in the literature. In this work, rigorous transport characterization of that experimental Gate-all-around $In_xGa_{1-x}As$ nanowire MOSFET is done in ballistic regime and effects of channel length variation is studied using 3D self-consistent simulator based on Uncoupled Mode Space (UMS) approach with a step-like transmission co-efficient.

II. Device Structure

The device used in this study is an $In_{0.53}Ga_{0.47}As$ nanowire FET identical to the experimental demonstration by Gu et al. [10]. It is a gate-all-around device comprising four gates connected together on all four sides of an oxide (Al_2O_3) - $In_{0.53}Ga_{0.47}As$ structure having square-shaped cross-section. The channel material is $In_{0.53}Ga_{0.47}As$ and 10nm thick Al_2O_3 serves as the gate dielectric. The source and drain regions are formed with n+ $In_{0.53}Ga_{0.47}As$. The substrate is 30nm×30nm p+ InP. The doping for p- $In_{0.53}Ga_{0.47}As$ channel is Na=2 × 10^{16} cm^{-3} (Fig. 1).

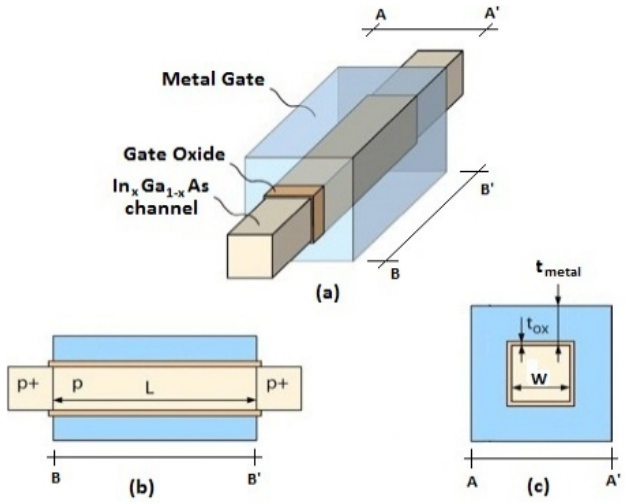

Fig. 1 (a) Schematic 3D view of an inversion-mode GAA n-channel $In_{0.53}Ga_{0.47}As$ (2×10^{16} cm^{-3}) MOSFET with ALD 10nm Al_2O_3/20nm WN gate stacks, a heavily doped wide bandgap InP lies underneath the bottom gate [10]. (b) Lateral cross section showing channel L_{ch}=50nm. (c) Vertical cross section of GAA device under simulation showing fin-width W=30nm, oxide thickness t_{ox}=10nm and metal gate width t_{metal}=20nm.

III. Modeling Approach

A. Self-Consistent Schrödinger- Poisson Solver

The developed self-consistent simulator involves numerical solution of two partial differential equations in a coupled manner, namely Poisson's equation and Schrödinger's equation along with numerical integration. Finite Element Method is used to solve the Partial differential equations (PDE). COMSOL Multiphysics is used as the PDE solver tool which is invoked from MATLAB by using the scripting language of COMSOL. In case of solving Poisson's equation, at the external boundaries of the gates Dirichlet i.e. fixed

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

voltage boundary condition is used and Neumann i.e. continuous electric flux boundary condition is used at all internal boundaries. For Schrödinger's equation, all boundaries are kept as open boundaries to allow wave function penetration.

In the oxide region, charge density (ρ) is zero. For channel region, charge density is obtained from to the following expression.

$$\rho(y, z) = q\sum_i \int_{Ei}^{\infty} D(E)\, f(E)\, |\psi_i\,(y,z)|^2\, dE \qquad (1)$$

Here, i is the number of sub-band, *D(E)* is 1-D density of states and *f(E)* is Fermi-Dirac distribution function with respect to source/drain Fermi level. E_i and ψ_i are Eigen energies and corresponding normalized wave functions obtained from 2D Schrödinger's equation. Ten Eigen energies are considered in charge calculation.

Starting with zero initial charge profile, Poisson's and Schrödinger's equations are solved using mixing coefficient (α) of 0.04 until self-consistency between charge and potential profile is achieved. The potential profile is updated after every iteration using the following expression.

$$V_{final} = V_{new} \times \alpha + V_{old} \times (1-\alpha) \qquad (2)$$

Once the solution converges, the charge distribution inside the device can be determined.

B. Mode Space Approach

A nanowire transistor has a three-dimensional (3D) distribution of electron density and electrostatic potential. As a result, a 3D simulator is required for the simulation of nanowire transistors. The calculation involves a self-consistent solution of a 3D Poisson's equation and a 3D Schrödinger equation with open boundary conditions. Using the finite element method, we solve the 3D Poisson equation to obtain the electrostatic potential. At the same time, we solve the 3D Schrödinger by Uncoupled Mode Space (UMS) approach which provides both computational efficiency and high accuracy as compared with direct real space calculations [12]-[13]. In UMS instead of solving Schrödinger equation for entire device, multiple 2D cross sections are solved and the resultant Eigen energy and wave functions are combined to get the solution for 3D structure [13]. Once self-consistency is achieved, the simulator provides the Eigen energies of different modes and the current is computed by,

$$I_{SD} = \frac{2e}{h}\int_{-\infty}^{+\infty} T(E)(f(\mu_S, E) - f(\mu_D, E))dE \qquad (3)$$

Where, $f(\mu_S, E)$ and $f(\mu_D, E)$ are Fermi-Dirac distribution functions at source and drain end respectively.

For the calculation of electron current, the total transmission coefficient can be written as a summation of the transmission coefficient, $T_m(E)$ for each mode m,

$$T(E) = \sum_{m=1}^{M} T_m\,(E) \qquad (4)$$

The Transmission co-efficient, T(E) can be computed using NEGF formalism and introducing Buttiker Probes the effect of scattering can be calculated[14]-[15]. To avoid computational complexity in this work, only ballistic transport is considered assuming a step-like [16] transmission probability curve.

IV. Results and Discussion

Fig. 2(a) and 2(b) show the 3D potential profile of the device for on and near-threshold conditions respectively. On the other hand, Fig. 3(a) and 3(b) respectively show the electron concentration throughout the channel for those bias conditions. These figures demonstrate the channel formation of the device under study. Since, the cross section of the device is fairly large (30nm x 30nm) the channel is formed near the oxide interface indicating surface inversion, as expected [17].

Fig. 4 depicts, the transfer characteristics and trans-conductance of the device for different bias conditions. From Fig. 5(a) sub-threshold swing (SS) is found to be 285 mV/dec which is greater than the experimentally reported value, 168 mV/dec [10]. On the other hand, threshold voltage is extracted from Fig. 5(b) as -0.7V, which matches with the experimental threshold of -0.68V [10].

Fig. 6(a) shows the output characteristics of the device, revealing DIBL of 64.57mV/V for 50nm channel length. Finally, Fig. 6(b) displays the output characteristics for different channel length, showing sharp increase in DIBL effect with decrease in channel length, as expected. It is to be noted that, the drain current calculated here, is more than twice of the experimental current reported by Gu et al. [10], which is quite reasonable since no scattering is considered in the developed transport model.

V. Conclusions

Using 3D simulation technique, the transport properties of $In_xGa_{1-x}As$ GAAFET is characterized in ballistic regime. Uncoupled Mode Space approach adopted with step-like transmission profile shows consistent results for studying ballistic transport properties of $In_xGa_{1-x}As$ GAAFET. The channel length variation is also performed showing that the decrease in channel length results in lower current but increased DIBL. The result is coherent with the trend of reported experimental data.

Abstract—**Self-heating is a severe problem in electronic devices since local heat generation and temperature rise limit the application of the devices. Here we demonstrate that thermal management of Field Effect Transistor (FET) devices can be substantially improved by introducing alternative heat-escaping channels implemented with graphene. Graphene is a good candidate for heat removal owing to its extremely high thermal conductivity. We simulated heat propagation in different GaAs FET circuits, namely metal oxide semiconductor field effect transistor (MOSFET), metal semiconductor field effect transistor (MESFET) and heterostructure field effect transistor (HFET), without and with graphene lateral heat spreaders. We also simulated the devices with other heat spreaders and compared their performance with that of grapheme. Numerical solutions of the heat propagation equations were obtained using the finite element method. It was found that the incorporation of graphene or few-layer graphene (FLG) layers with proper heat sinks can substantially lower the temperature of the localized hot spots. The maximum temperature in the FETs was studied as function of graphene's thermal conductivity and the thickness of FLG. The developed model and obtained results are important to solve the thermal issues in FET devices.**

Index Terms—**FET devices, graphene, heat conduction, heat spreaders, thermal management.**

I. Introduction

Continuous miniaturization of electronic devices and circuits, increased speed and integration densities resulted in problems with thermal management. As the electronic industry moves toward nanometer designs, one of the most important challenges is growing chip power consumption as well as the issue of self-heating. When we scale the device using constant voltage scaling, there has been a significant increase of drain current as a result of short channel length. It leads to an increased power density which in turn increases the device temperature substantially. As a result, temperature rise in devices can lead to performance degradation and early thermal breakdowns [1]–[3]. So, efficient thermal management plays a significant role in device design for long-term reliability and optimum performance [4]. Since the performance of ULSI circuits depends on temperature, even a small increase in temperature results in reduction of the device lifetime. A possible approach for solving the thermal problem is to find a material with extremely high thermal conductivity. Conventional materials such as Cu or Al used for heat removal has lower thermal conductivity. Hence for efficient heat management an alternative material named graphene, the latest of the discovered allotropes of carbon with extremely high intrinsic thermal conductivity, is a potential candidate. The room temperature thermal conductivity of the suspended graphene is determined to be ranging from 3080 – 5300 W/mK [5]–[6]. Thermal conductivity of graphene revealed strong flake size dependence [6]–[8]. Many studies demonstrated that quality graphene has very high electron mobility (~$2\times10^5 cm^2V^{-1}s^{-1}$), low resistivity (~$10^{-8}$Ohm-m) and very low thermal boundary resistance (~$3.7\times10^{-9}m^2KW^{-1}$) [9]–[12]. The unique properties of graphene make it a promising material for the electronic devices, electrical interconnects and thermal management [5] – [8], [13]. In this work we carry out the feasibility study graphene heat spreader and compare its performance with that of conventional heat spreader for thermal management of FET family.

II. Model of Heat Conduction

To study the feasibility of the use of graphene heat spreader with a view thermal management of FET devices, we simulate heat propagation in GaAs MOSFET, GaAs MESFET and GaAs/AlGaAs HFET with and without graphene heat spreader. The thicknesses of SiC substrateand epitaxial GaAs film are assigned to be 100 μm and 0.2 μm while their thermal conductivities are 490 W/mK and 46 W/mK, respectively [14]. The thickness and thermal conductivity of AlGaAs in HFET is 8 nm and 46 W/mk respectively. The gate oxide layer for MOSFET is of 10 nm thick and its thermal conductivity is 1.4 W/mK. A conventional heat sink is attached to the device structure at the bottom. A graphene heat spreader layer, when used, is connected to the drain region with a side heat sink forming the channel for heat escape as shown in Fig. 1. The heat spreader is insulated from the drain terminal by a thin SiO_2 layer. The arrangement of heat spreader and heat sink is common for MOSFET, MESFET and HFET as shown in the prototype device (Fig. 1).The simulations were carried out with the help of finite element analysis using COMSOL software [15].

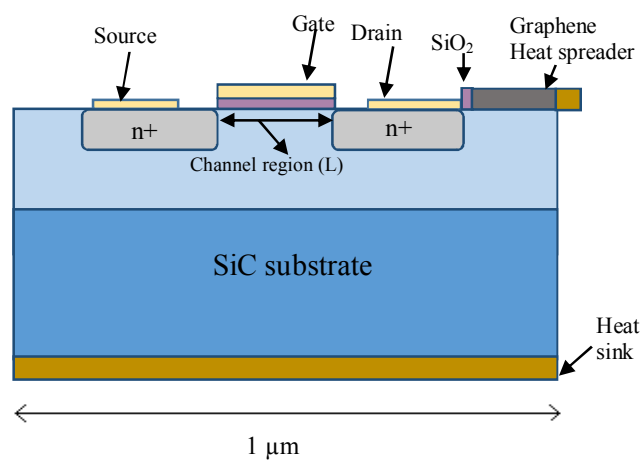

Fig. 1. Schematic view of a prototype FET device (MOSFET) with graphene heat spreader attached to the side heat sink and a main heat sink at the bottom.

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

We have modeled the self-heating by solving Joule heating numerically within the device since current in the device channel causes heat generation and the concerned equations can be expressed as

$$E = -\nabla V \quad (1)$$
$$J = \sigma E + J_e \quad (2)$$
$$\nabla . J = Q_j \quad (3)$$

where J is the current density, σ is electrical conductivity, V is the applied voltage and E is the corresponding electric field and Q is the generated heat within the device. The heat transport along graphene layers was assumed to be diffusive since the size of the layer is much larger than the phonon mean free path [6] – [8]. The heat propagation within the device was modeled by solving the Fourier's law of heat conduction.

$$-\nabla \cdot (k \nabla T) = Q \quad (4)$$

where Q is the heat source i.e. the heat energy generated within a unit volume per unit time, T is the absolute temperature and k is the thermal conductivity. The bottom surface of the substrate and the far end of the graphene heat spreader were kept at a constant temperature T = 300K. The external surfaces were modeled in such way that they are kept insulated from environment.

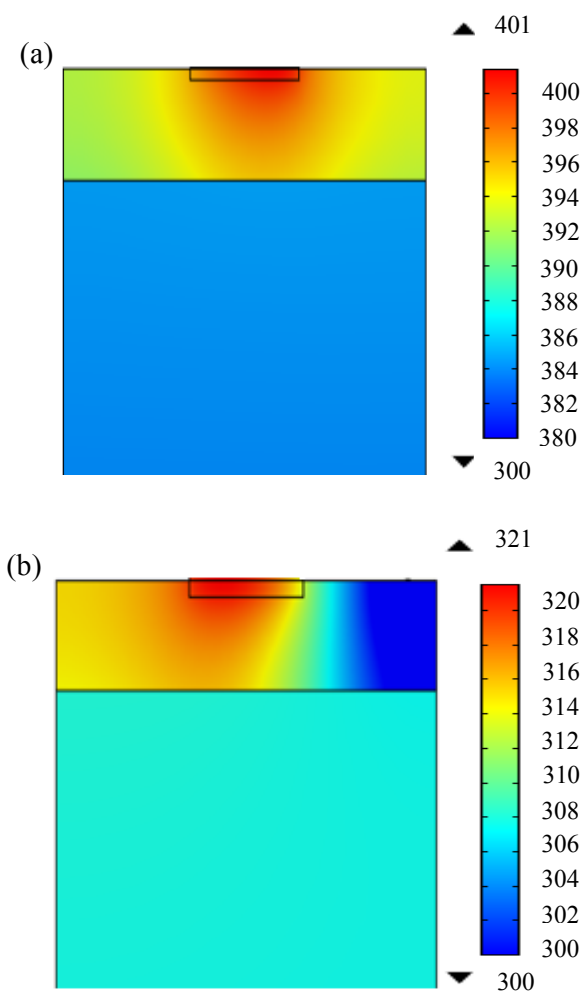

Fig. 2. Temperature profile for GaAs MOSFET (a) without heat spreader(b)with graphene heat spreader for drain voltage V_d=3V,gate voltage V_g=2V.

III. SIMULATION RESULTS

Fig. 2 shows the simulated temperature profiles for the MOSFET without and with the graphene lateral heat spreader. The maximum temperature of MOSFET decreases by 80 K when graphene layer is incorporated into the device for drain voltage of 3V and gate voltage of 2V. The thermal conductivity of single layer graphene (thickness ~ 0.35nm) is considered to be 5000 W/mK. The drop in temperature into the device structure with the heat spreader also depends on the device size and geometry, thickness of the substrate and dissipated power across device.

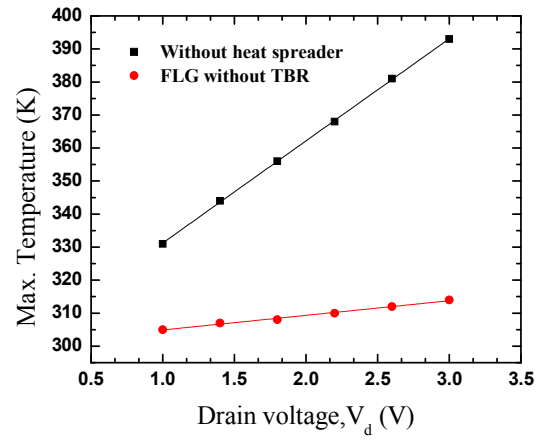

Fig. 3 Maximum temperature in MOSFET as a function of drain voltage without and with graphene heat spreader.

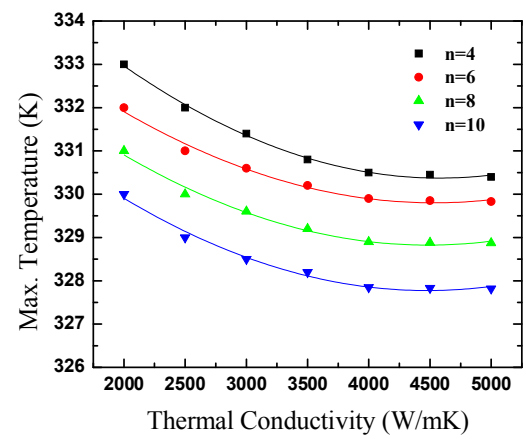

Fig. 4. Maximum temperature in MOSFET as a function of the thermal conductivity of the graphene heat spreader with different number of graphene layers.

Fig. 3 shows the reduced temperature rise as a function of drain voltage while graphene heat spreader is attached to the MOSFET. It shows that at higher drain voltage, higher current causes higher temperature rise. Maximum temperature increases almost linearly with the increase of drain voltage. And the drop in temperature with graphene is higher at higher drain voltage.

Fig. 4 represents the effect of variation of thermal conductivity as well as the thickness of graphene layer on maximum temperature of MOSFET. The maximum temperature is decreased with the increase of thermal conductivity for a given number of graphene atomic layers. So we simulated the device for different no. of graphene layers.

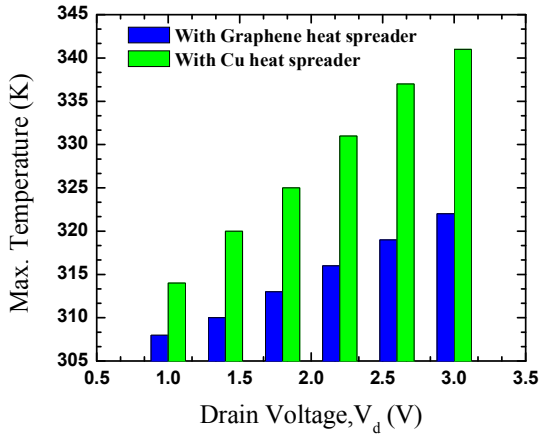

Fig. 5. Performance comparison between the MOSFETs with graphene and copper heat spreaders.

For a given thermal conductivity maximum temperature is reduced significantly with the increase of number of atomic layers of graphene. This improvement occurs at constant thermal conductivity since the higher the number of atomic layers of graphene, the larger the surface area for heat removal. In literature, it is reported that thermal conductivity of FLG decreases with the increase of number of atomic layers [5].In the simulations, the thermal conductivity of FLG was assumed to be ranging from 1000 W/mK to 5000 W/mK.

Fig 5 shows a comparison between the performances of graphene heat spreader with that of Cu. Graphene heat spreader gives the larger temperature reduction compared to conventional heat spreader like Cu heat spreader i.e. Cu shows the least improvement as heat spreader. Based on the dispersion calculations in graphitic materials, the phonon group velocity in graphene is higher than that in Cu, which leads to larger k which in turn causes better the thermal improvement. The thermal conductivity of Cu is reported to be 401W/m.K [16].

Fig. 6 and Fig. 7 indicate the temperature improvement using graphene heat spreader in MESFET and HFET, respectively. The temperature improvement is due to the superior thermal conductivity of graphene.

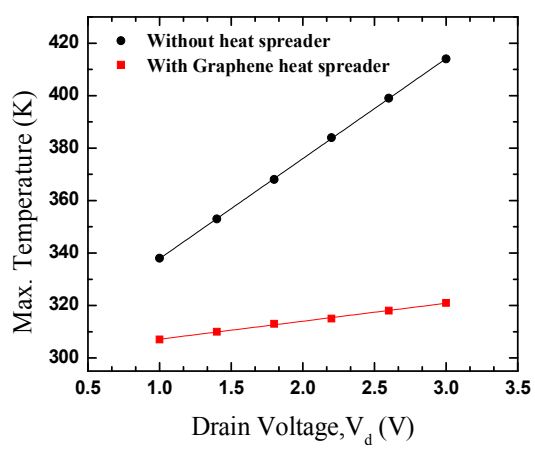

Fig. 6. Maximum temperature in MESFET as a function of drain voltage without and with graphene heat spreader.

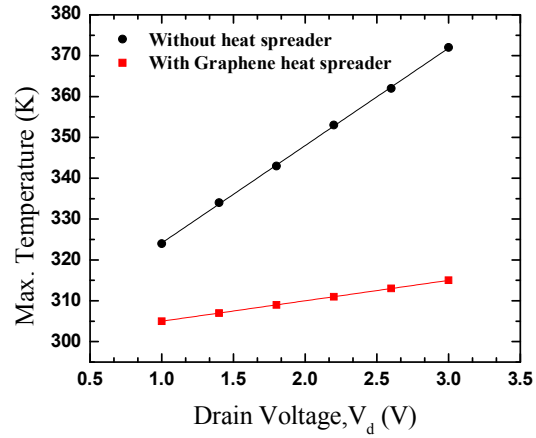

Fig. 7. Maximum temperature in HFET as a function of drain voltage without and with graphene heat spreader.

In Fig. 8 and Fig. 9 we show a comparison between graphene and Cu heat spreader for MESFET and HFET, respectively. In either case graphene outperforms the commonly used copper as heat spreading materials and gives the best result for thermal improvement.

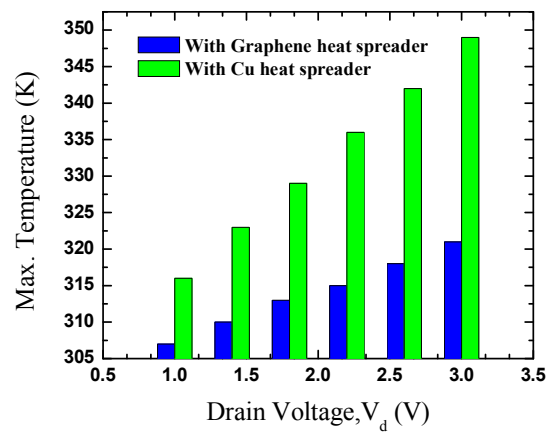

Fig. 8. Performance comparison between the MESFETs with graphene and copper heat spreaders.

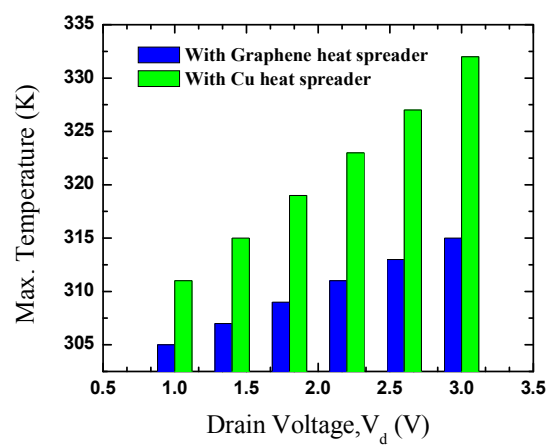

Fig. 9. Performance comparison between the HFETs with graphene and copper heat spreaders.

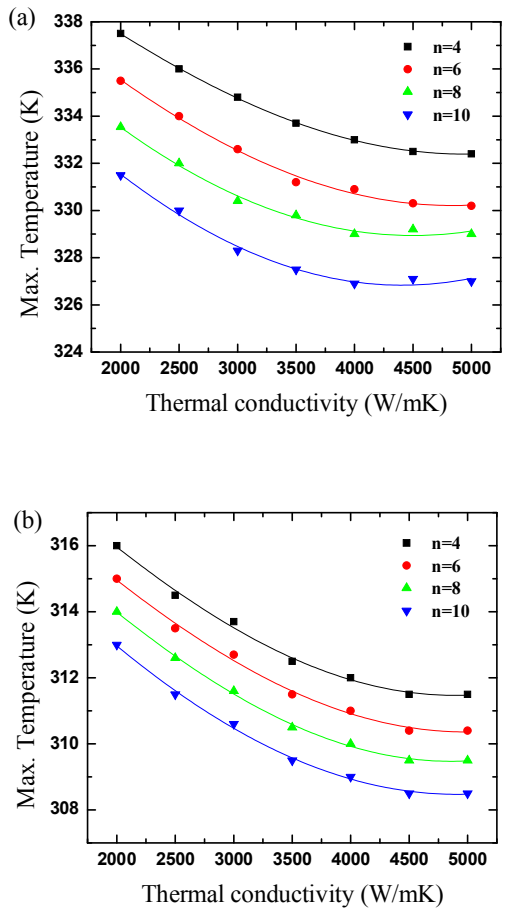

Fig.10. Maximum temperature in (a) MESFET and (b) HFET as a function of the thermal conductivity of the graphene heat spreader with different number of graphene layers.

Fig. 10 represents the effect of variation of thermal conductivity of graphene on maximum temperature of MESFET and HFET. Maximum temperature reduces by a great extent withthe increasing thermal conductivity and thickness of the spreader because it gives larger the surface area for heat removal. The application of few layer graphene is expected to be encouraging since it allows for greater flexibility with fabrication. On the contrary, the thermal conductivity of FLG is lower than that of graphene approaching that of bulk graphite along the basal plane (~2000 W/mK at room temperature). So it requires an optimization in order to achieve the best throughput. The heat generation and its mitigation in the FET family with different heat spreaders for a specific drain voltage, V_d =3V and gate voltage, V_g= 2V, is illustrated in TABLE I.

TABLE I
HEAT MITIGATION IN FET DEVICES WITH DIFFERENT HEAT SPREADERS

Heat spreader	MOSFET Max Temperature (K)	MESFET Max Temperature (K)	HFET Max Temperature (K)
Without heat spreader	401	414	372
Graphene heat spreader	321	323	314
Cu heat spreader	341	348	332

The above table illustrates the thermal improvement for different heat spreaders. Graphene provides the thermal improvement by 20K, 25K and 18K compared to conventional Cu heat spreader in MOSFET, MESFET and HFET, respectively. Since a small thermal improvement increases device lifetime, hence using graphene heat spreader also improves the device reliability. So graphene heat spreader gives an outstanding thermal improvement in FET devices in compare to other conventional heat spreaders.

IV. CONCLUSIONS

Graphene is demonstrated to be a promising heat spreader material for heat dissipation of hot spots with high heat flux. Our results show that the incorporation of graphene heat spreader can cause substantial reduction in temperature of the hot spots compared to other heat spreader i.e. copper. We also illustrate the incorporation of FLG heat spreaders which might be technologically more feasible than single layer graphene. The obtained results would be useful for thermal management of FET as well as electronic devices.

Surface Potential Modeling of Junctionless Double Gate MOSFETs using Gradual Depletion Approximation

Shuvro Chowdhury,* Md. Ziaur Rahman Khan
[1]Department of Electrical and Electronic Engineering, Bangladesh University of Engineering and Technology
Dhaka-1000, Bangladesh
*schowdhury@eee.buet.ac.bd

***Abstract*—A new model for long channel Junctionless Double Gate (JL DG) MOSFETs based on gradual depletion inside the channel is presented. This new model uses a regional approach to determine surface potential of JL DG MOSFETs. Because of the gradual depletion approximation surface potential characteristics are found to have smooth transition between fully depleted region and partially depleted region. This smoothness may prove useful for modeling with SPICE like programs. The proposed model shows improved performance over the previous models based on abrupt depletion. Dependences of surface potential on various device and process parameters have also been studied. The validity of the proposed model has been checked with numerical simulations and TCAD tool. Upon comparison, it has been found that the results obtained from proposed model matches quite perfectly with those provided by numerical simulations and TCAD tool.**

***Index Terms*—Junctionless, Double-Gate, Surface potential, Abrupt depletion, Gradual depletion**

I. Introduction

In recent literature, junctionless (JL) double-gate (DG) field effect transistors (JL DGFET) have been reported [1], [2], [3] as promising candidates for future technology nodes. Proper operation of this device requires the device to be fabricated with a high content of the same impurity concentration within the channel and source/drain (S/D) regions. Hence these devices are junctionless. Junctionless FETs exhibit many advantages [4], [5], [6], [7], such as simple and flexible fabrication process, nearly ideal subthreshold slope (SS $\approx$ 60 mV/dec), high ON-OFF current ratio ($I_{\mathrm{ON}}/I_{\mathrm{OFF}} > 10^7$), low S/D series resistance, and small drain-induced barrier lowering. Moreover, the JL transistor shows some peculiar characteristics, like conductance oscillations at low temperature [8] and high temperature behavior [9].

Because of its excellent electrostatic performance, JL DG MOSFET has drawn attention for developing an accurate model to investigate its theoretical foundations, to better understand the behavior of this device, and to elucidate its strengths and weaknesses. Duarte et al. [10] first proposed a simple bulk current model relying on depletion approximation for the JL DGFET but neglected the accumulation condition. Then, Sallese et al. [11] carried out a space-charge-based model for the JL DG MOSFET to calculate the charge density and drain current, but it may cause convergence problems. Subsequently, Duarte et al. [12] proposed a non-piecewise model for the JL DG MOSFET based on parabolic potential approximation by a uniform charge-potential relationship. However, few studies have been carried out to develop a surface-potential-based compact model for the JL DG MOSFET valid in all regions, which includes a more physical and accurate description of the transistor behavior and is commonly accepted in compact modeling applications. Chen et al. [13] has proposed a surface potential based drain current model for JL DG MOSFET. This model is based on abrupt depletion between depleted and neutral regions and shows discontinuities in surface potential and drain current characteristics.

Here in this paper, a *gradual depletion approximation* has been used to determine the surface potential of JL DG MOSFETs. This approximation has made it posible to obtain a *continuous* surface potenatial-gate voltage characteristics. Significant improvement in surface potential modeling has also been achieved through this approximation which has been verified from comparison with numerical simulations.

II. Device description

The n-channel symmetric JL DG MOSFET structure used in this work has been shown in Figure 1. The device has a channel length L, device width W, and, channel thickness of t_{Si}. Gate oxide thickness is t_{ox} for both top and bottom gate oxides. A uniform donor doping concentration N_D within the channel, source and drain regions has been used. The dielectric constants of gate oxide material and channel are ϵ_{ox} and ϵ_{Si} respectively.

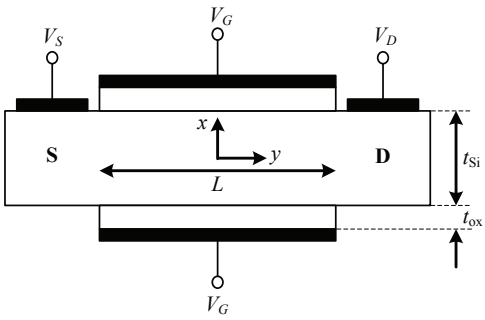

Fig. 1. JL DG MOSFET structure

Using the basic MOS capacitor equation it can be written that

$$V_G = V_{FB} + \phi_{ox} + \phi_s = \phi_{MS} - \frac{Q_{SC}(\phi_s)}{C_{ox}} + \phi_s \quad (1)$$

Here, V_G, ϕ_s, V_{FB}, ϕ_{ox} and ϕ_{MS} are applied gate voltage, surface potential, flatband voltage, voltage drop across oxide and metal-semiconductor workfunction difference respectively. The absence of parasitic oxide charge and interface trap charge density has been implicitly assumed in (1). Q_{SC} is defined as

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

the *space charge density per unit area* and $C_{ox} = \epsilon_{ox}/t_{ox}$ is the *oxide capacitance per unit area*. From hereon, the specification *per unit area* will be omitted when referred to space charge densities and oxide capacitance values.

III. Formulation of working equation

A working equation has been obtained from the Poisson's equation in conjugation with Boltzmann carrier statistics. In an n-type doped channel acceptor doping concentration, $N_A = 0$. For the sake of simplicity it has also been assumed that the hole concentration, $p = 0$. In terms of Boltzmann carrier statistics, electron concentration, n is written as,

$$n = n_0 \exp\left[\frac{\phi - V}{V_T}\right] \tag{2}$$

where, V is known as *quasi Fermi potential*, $V_T = k_B T/q$ is the *thermal voltage*, k_B is Boltzmann's constant, T is the absolute temperature and q is electronic charge. n_0 is the electron concentration at flatband condition where, $\phi = V$. For a heavily doped semiconductor $n_0 \simeq N_D$. With these, normalized Poisson's equation in rectangular coordinates can be written as

$$\frac{d^2u}{dp^2} = \exp(u - v) - 1 \tag{3}$$

where $u = \phi/V_T$ and $v = V/V_T$ are termed as *normalized* electrostatic potential and *normalized* quasi Fermi potential and $p = x/\lambda_D$ with

$$\frac{1}{\lambda_D} = \sqrt{\frac{qN_D}{\epsilon_{si} v_T}} \tag{4}$$

Here, λ_D is known as *Debye length*. (3) is to be solved with appropriate boundary conditions which are given by

$$\left.\frac{du}{dp}\right|_{p=0} = 0 \tag{5}$$

$$\text{and} \qquad u(\pm P) = u_s \tag{6}$$

where $P = \dfrac{t_{si}}{2\lambda_D}$ is the normalized half-channel width. The first boundary condition is due to the symmetry of the device and the second one is due to the presence of Dirichlet boundary at the gate terminals.

IV. Approximate solutions of the working equation

Although (3) has a very simple appearance but it does provide any closed-form solution. This is due to the presence of the -1 term on the right hand side. Numerical techniques can be employed to obtain the exact solution but an approximate closed-form solution may prove very helpful in modeling JL DG MOSFET behavior. That is why in this section, appropriate assumptions have been made to obtain approximate solutions of the working equation stated in (3).

A. Electric field intensity and surface charge

Normalized electric field intensity, $E_n(p)$ is defined as

$$E = -\frac{d\phi}{dp}\frac{dp}{dx} = -\frac{v_T}{\lambda_D}\frac{du}{dp} = -\frac{v_T}{\lambda_D} E_n \tag{7}$$

An expression for $E_n(p)$ can be obtained by integrating (3) with respect to p as

$$E_n(p) = \left(2\left\{e^{[u-v]} - e^{[u(0)-v]} - u + u(0)\right\}\right)^{1/2} \tag{8}$$

Normalized surface electric field intensity, E_{ns} can be found by setting $p = P$ into (8),

$$E_{ns} = \left(2\left\{e^{[u_s-v]} - e^{[u(0)-v]} - u_s + u(0)\right\}\right)^{1/2} \tag{9}$$

$u(0)$ in (8) and (9) is the normalized potential at the center of the channel. Further integration of (8) does not yield any closed-form expression. Therefore approximations are mandatory to obtain any analytical solution.

Surface charge density, Q_{SC} can be expressed as

$$Q_{SC} = -2\epsilon_{Si}\left.\frac{d\phi}{dx}\right|_{x=\frac{t_{Si}}{2}} = -2\left(\frac{\epsilon_{Si} v_T}{\lambda_D}\right) E_{ns} \tag{10}$$

B. Surface potential at accumulation

The proposed model deals only with the solution in depletion region of operation. Therefore it incorporates the solution provided in [13] for accumulation region of operation without further modification. Here the expressions for electric field and surface potential under accumulation is just restated in terms of normalized variables

$$E_{ns} \approx \frac{V_T}{\lambda_D}\sqrt{2\left[\exp(u_s - v) - 1\right]} \tag{11}$$

and

$$\beta v_T\left[\exp(u_s - v) - 1\right] = \left(V_G - V_{FB} - u_s v_T\right)^2 \tag{12}$$

where β is defined as

$$\beta = \frac{2q\epsilon_{Si} N_D}{C_{ox}^2} \tag{13}$$

C. Surface potential at depletion

When the device is biased in depletion or subthreshold conditions i.e., $u_s < v$, the exponential term present on the right hand side of (3) is *linearized* by setting

$$u = u_c + \delta u \tag{14}$$

where u_c is regarded as the potential at the symmetry axis of the device. Assumption of this type is regarded as *gradual depletion approximation* or *first-order approximation* to the exact carrier concentration and has already been applied for JL nanowire FETs [14]. With this approximation (3) is modified as

$$\frac{d^2\delta u}{dp^2} - \exp(u_c - v)\,\delta u = \exp(u_c - v) - 1 \tag{15}$$

which is valid for $0 \le p \le p_0$. The point p_0 is defined as the point where

$$\delta u(p_0) = -1 \tag{16}$$

Let $\alpha = \exp(u_c - v)$ and using this definition (15) can be modified as

$$\frac{d^2\delta u}{dp^2} - \alpha\delta u = \alpha - 1 \tag{17}$$

(17) is to be solved with the following initial conditions

$$\delta u(0) = 0 \tag{18}$$

$$\text{and} \qquad \frac{d\delta u}{dp}(0) = 0 \tag{19}$$

The solution of (17) can be found as

$$\delta u(p) = \frac{\alpha - 1}{\alpha}\left[\cosh\left(\sqrt{\alpha}\,p\right) - 1\right]; \qquad 0 \le p \le p_0 \tag{20}$$

From (16) and (20), the value of p_0 can be determined, i.e.,

$$p_0 = \frac{1}{\sqrt{\alpha}} \cosh^{-1}\left(\frac{1}{1-\alpha}\right) \tag{21}$$

For the region $p_0 < p < P$, the depletion approximation is used instead of (17) i.e.,

$$\frac{d^2\delta u}{dp^2} = -1 \tag{22}$$

The first initial condition required to solve (22) has already been mentioned in (16). The second initial condition can be written as

$$\left.\frac{d\delta u}{dp}(p_0)\right|_{0<p<p_0} = \left.\frac{d\delta u}{dp}(p_0)\right|_{p>p_0} \tag{23}$$

The final solution of (22) can then be obtained as

$$\begin{aligned}\delta u(p) &= -1 - \frac{p^2 - p_0^2}{2} \\ &+ \left[p_0 + \frac{\alpha-1}{\sqrt{\alpha}}\sinh\left(\sqrt{\alpha}\,p_0\right)\right](p - p_0)\end{aligned} \tag{24}$$

which is valid for the region $p_0 < p < P$. Since surface potential, $u_s = u(P)$, expressions for u_s under depletion mode of operation can be obtained by setting $p = P$ into (20) and (24).

$$u_s = u_c + \frac{\alpha-1}{\alpha}\left[\cosh\left(\sqrt{\alpha}P\right) - 1\right] \tag{25}$$

for $p_0 > P$, and

$$\begin{aligned}u_s = u_c &- 1 - \frac{P^2 - p_0^2}{2} \\ &+ \left[p_0 + \frac{\alpha-1}{\sqrt{\alpha}}\sinh\left(\sqrt{\alpha}p_0\right)\right](P - p_0)\end{aligned} \tag{26}$$

for $p_0 < P$.

Finally Q_{SC} can be determined as

$$Q_{SC} = -\frac{\epsilon_{si} v_T}{\lambda_D}\left[\frac{\alpha-1}{\sqrt{\alpha}}\sinh\left(\sqrt{\alpha}P\right)\right] \tag{27}$$

for $p_0 > P$, or

$$Q_{SC} = \frac{\epsilon_{si} v_T}{\lambda_D}\left[P - p_0 + \frac{1-\alpha}{\sqrt{\alpha}}\sinh\left(\sqrt{\alpha}p_0\right)\right] \tag{28}$$

for $p_0 < P$.

V. Results and Discussion

The symmetric device structure shown in Fig. 1 has been simulated with the proposed model and the results have been verified against the results obtained from numerial simualtions using MATLAB and SILVACO ATLAS TCAD tool [15]. The results have also been compared with the abrupt model proposed in [13]. For simulation purpose, the device has been assumed to have $L = 1$ μm, $W = 1$ μm, $t_{ox} = 8$ nm, $t_{Si} = 10$ nm, $N_D = 10^{19}$ cm^{-3} and $\phi_{MS} = 1.12$ eV. Silicon ($\epsilon_{Si} = 11.7$) and SiO_2 ($\epsilon_{ox} = 3.9$) have been used as channel and oxide material respectively.

Fig. 2 demonstrates the validity of the proposed model by comparing the results with those from ATLAS and MATLAB simulation. This figure shows that the proposed model provides better performance for the whole range of gate voltage from deep depletion to strong accumulation. Surface potential obtained from abrupt depletion approximation based model fails to match with numerical solutions in partial depletion region where it simply deviates from the actual solution. In abrupt-depletion approximation based model *discontinuity in transition* from deep depletion to partial depletion around the threshold voltage is readily observable from the figure.

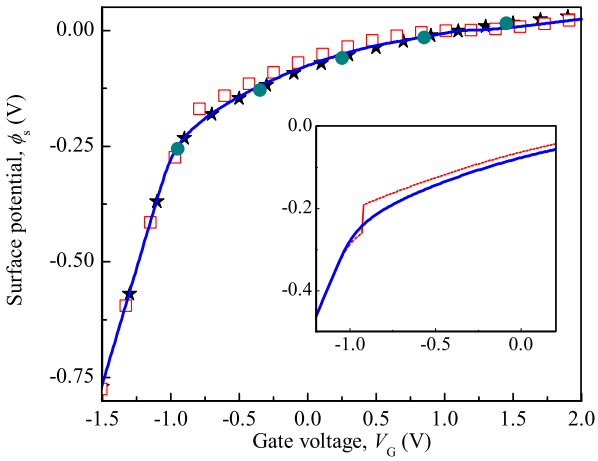

Fig. 2. Surface potential of the JL DG MOSFET plotted against the gate voltage. (Stars) SILVACO ATLAS simulation. (Squares) Abrupt model. (Circles) MATLAB simulation. (Line) First-order model. (Inset) Expanded view of transition from full depletion to partial depletion - solid line corresponds to gradual depletion model and dashed line represents abrupt depletion model.

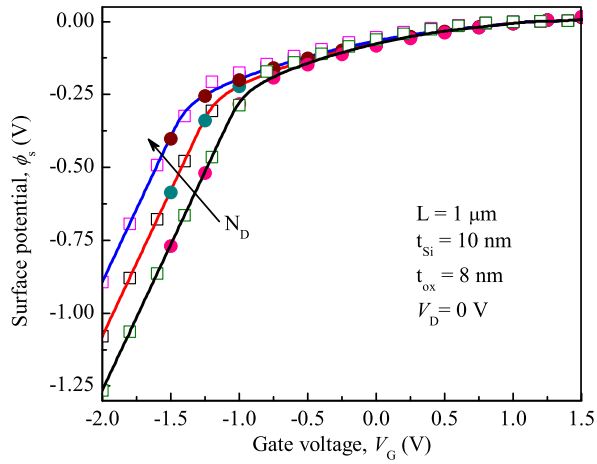

Fig. 3. Surface potential of the JL DG MOSFET plotted against the gate voltage for N_D ranging from 10^{19} cm^{-3} to 1.2×10^{19} cm^{-3} in steps of 1×10^{18} cm^{-3}. (Solid symbols) MATLAB simulation. (Hollow symbols) Abrupt model. (Lines) Gradual depletion model.

The effects of device and process parameters on surface potential characteristics have been illustrated in Fig. 3 to 6. It is readily evident that the variation in gate oxide thickness, channel thickness, doping concentration and quasi-Fermi potential affects the surface potential-gate voltage characteristics significantly.

With the increase in doping concentration surface potential increases in the subthreshoold region and it saturates to a constant value in the accumulation region as evident from Fig. 3. This is because denisty of free electrons increases with the increase in doping concentration.

From Fig. 4 it can be observed that increasing gate oxide thickness shifts the subthreshold region of the characteristics towards left which means an increase in surface potential. The surface potential in accumulation also slowly reduces with increasing oxide thickness. As gate oxide thickness continues to increase, more gate voltage drops across the gate oxide and less potential drops inside the channel.

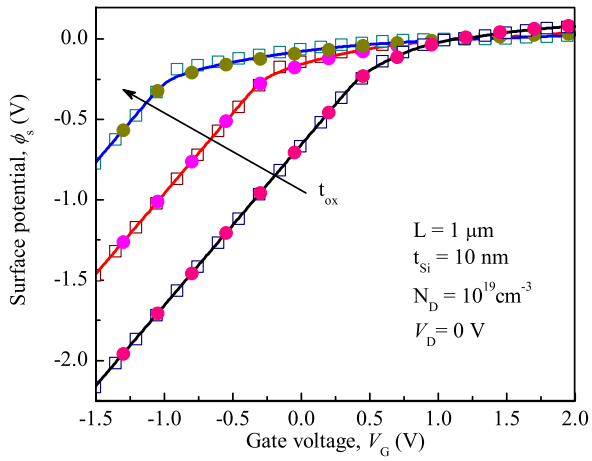

Fig. 4. Surface potential of the JL DG MOSFET plotted against the gate voltage for t_{ox} ranging from 2 nm to 8 nm in steps of 3 nm. (Solid symbols) MATLAB simulation. (Hollow symbols) Abrupt model. (Lines) Gradual depletion model.

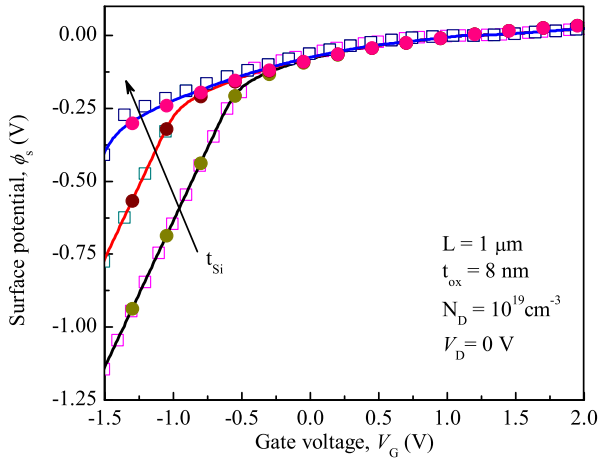

Fig. 5. Surface potential of the JL DG MOSFET plotted against the gate voltage for t_{Si} ranging from 8 nm to 12 nm in steps of 2 nm. (Solid symbols) MATLAB simulation. (Hollow symbols) Abrupt model. (Lines) Gradual depletion model.

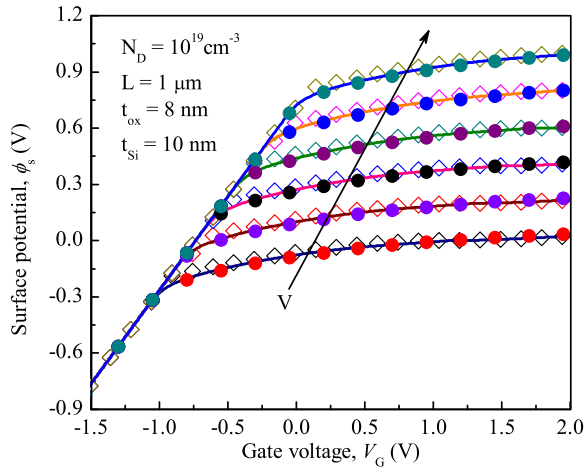

Fig. 6. Surface potential of the JL DG MOSFET plotted against the gate voltage for V ranging from 0 V to 1 V in steps of 0.2 V. (Solid symbols) MATLAB simulation. (Hollow symbols) Abrupt model. (Lines) Gradual depletion model.

Fig. 5 shows that increasing channel thickness also increases surface potential. which is due to the fact that a thicker channel is populated with more free electrons than a thinner channel.

Increasing quasi-Fermi level does not affect the subthreshold region but increases the surface potential value in accumulation region which has been demonstrated in Fig. 6. In all the figures, the discrepancies between the abrupt-depletion based surface potential model and gradual-depletion based model can easily be identified.

VI. Conclusion

An improved analytical model has been proposed to determine the surface potential for a symmetric long-channel JL DG MOSFET. The model has been developed for long-channel devices and hence does not considers short-channel and quantum effects. Possion's equation for the device cannot provide any closed-form solution hence a regional approach has been used for the analysis. The proposed model is valid for all regions of device operation and provides continuous transition from one region to another. This continuity feature may prove very useful for simulation programs and make this model a better candidate in studying the device operation and other charateristics of JL DG MOSFETs.

Abstract—**This paper focuses on the design of an improved DFWHT (Discrete Fast Walsh Hadamard Transform) domain robust, blind digital image watermarking algorithm. Both encoding and extraction algorithm have been verified using MATLAB R2013a. Here both grayscale and binary watermarks are possible for embedding and extraction using the same designed algorithm and only grayscale cover image of maximum size(256 x 256) is used. The speciality of this algorithm attracts to the fact that there is no requirement for any other information other than the received watermarked image to extract the watermark at decoding, which makes it blind watermarking. The time complexity of the proposed algorithm is of the order of $O(n^2)$ and it is simple to implement in hardware.**

Index Terms **- Blind Digital Image Watermarking; DFWHT; Robust; time complexity; Binary and Grayscale watermark.**

I. INTRODUCTION

There are various ways by which digital watermarking [1] can be accomplished, such as image, text, video and audio for example. Several data embedding schemes are available for spatial [2] and transform domain (e.g. Discrete Fourier Transform[3], Discrete Cosine Transform[4], Discrete Wavelet Transform[5], Discrete Walsh Transform[6],[7]).Digital Watermark can be classified as visible and invisible watermark. In case of visible watermark the watermark is visible to normal eye such as company logo etc., but for invisible watermark the locations where the watermark is embedded is secret and known only to the authorized person. One of the important characteristics for watermarking is Robustness ,that is how good the watermark is to resist the common signal processing attacks such as Scaling, sharpening and geometrical transforms. The watermark which are not being able to resist the attacks are Fragile in nature, and watermark which can to some extent sustain the attacks are called Semi-fragile. Thus depending on the application for which the watermark is used, watermarking can be of several types. Modern day, to ensure Quality Of Service of a multimedia channel, digital watermarking is also used. For this purpose visible and fragile watermark can be used. For high security data transmission purpose invisible and robust watermark must be used.

For embedding the data, several watermarking techniques are used, but transform domain watermarking are most widely used due to high robustness of the watermark. Among them the most popular for watermarking JPEG and JPEG 2000 images are DCT and Wavelet transform. However, it is been found out that DCT domain transform are much more robust to JPEG but not so robust to JPEG 2000 images. Reverse are true for Wavelet domain transforms. So proper watermarking scheme must be used which shows similar robustness for both JPEG and JPEG 2000 images. It is been reported in [6] that Hadamard and Hartley transforms, due to small values of the standard deviation for the processing noise provide higher resiliency at low quality compression compared to DCT and Wavelet transforms.

In this paper, we have proposed the design of an improved invisible, blind and robust (with respect to sharpening and scaling) image watermarking algorithm in DFWHT [8] domain. The rest of the paper is organized as follows. Section II gives the basics of DFWHT. Section III describes the related works and motivation. Section IV states the proposed image watermark encoding and extraction algorithm in DFWHT domain. Section V focus on the detail description of the watermark encoding and decoding units. Section VI reports the analysis and experimental results. Section VII is the conclusion followed by the references.

II. DISCRETE FAST WALSH HADAMARD TRANSFORM PRELIMINARIES

Let [A] be the original image block and [H] be the Walsh transformation matrix then the Walsh transformed block can be viewed as

$$[Y]= ([H][A][H])/N. \quad (1)$$

Here N is the order of the Hadamard matrix; H is a (N x N) Hadamard matrix of which all element are either +1 or -1. The elements of the Walsh Hadamard Matrix are simple and real valued.

The inverse Walsh Hadamard transform is given by

$$[A]= ([H][Y][H])/N. \quad (2)$$

Here we use the (8x8) Hadamard matrix given by

$$\begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & -1 & 1 & -1 & 1 & -1 & 1 & -1 \\ 1 & 1 & -1 & -1 & 1 & 1 & -1 & -1 \\ 1 & -1 & -1 & 1 & 1 & -1 & -1 & 1 \\ 1 & 1 & 1 & 1 & -1 & -1 & -1 & -1 \\ 1 & -1 & 1 & -1 & -1 & 1 & -1 & 1 \\ 1 & 1 & -1 & -1 & -1 & -1 & 1 & 1 \\ 1 & -1 & -1 & 1 & -1 & 1 & 1 & -1 \end{bmatrix}$$

Fig. 1 Order 8 Hadamard matrix.

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

Here the first row and first column are DC values, and the rows in which the sign changes are AC values.

III. RELATED WORKS AND MOTIVATION OF PROPOSED WORK

Ho et.al.[6] proposed an algorithm in which the watermark image is transformed by Walsh Hadamard transformation. Then the cover image is partitioned into blocks of size (8 x 8) and the 16 watermark image coefficients values are inserted into cover image block by substituting the lower rows of the blocks which are the high frequency blocks. The scheme stated in [6] has left out the DC coefficient value (that is the first row and column values in the watermark image transformed block) while embedding other AC or high frequency values in a pseudo randomly selected blocks. Thus the disadvantage in [6] is that we have to separately send the DC values. It has been reported in [9] that processing noise increases drastically for high frequency DCT and Wavelet co-efficient. On the other hand the high frequency Hadamard coefficients are much more immune to processing noise. Thus it is quite possible to embed data to the higher frequency bands of the Walsh Hadamard Transformed blocks than to DCT or Wavelet high frequency bands.

Watermarking schemes using Walsh Hadamard Transform is also used in several works. In [10] binary watermark is embedding using spread spectrum techniques in Walsh Hadamard domain. In [11] the grayscale cover image with binary watermark is used which is also embedded using the spread spectrum watermarking and its dual mode architecture has been implemented.

In our work we have proposed an improved algorithm over [6] and here in this paper we embed all the Walsh Hadamard transformed coefficients of the watermark image in the cover image, thus if we do not have any other value to be transmitted, the watermarked image has to be sent only making it blind.

IV. PROPOSED IMAGE WATERMARKING ALGORITHM

BINARY AND GRAYSCALE WATERMARK EMBEDDING

Here a (256 x 256) size cover image is used and a (32 x 32) size grayscale watermark image of maximum pixel value of 15 is used to encode.

A. Partitioning the cover image and Walsh Hadamard transformation

The watermark image of size (32 x 32) is partitioned in (8 x 8) blocks. Then Walsh Transform is applied to all the blocks. Let the Walsh transformed blocks of the watermark image be denoted as 'w'. The transformed blocks are then converted to a linear array of size (1 x 1024).

B. Row and Column selection and corresponding block selection

The random selection of the block for inserting the watermark is inserted in by the user. To insert 8 coefficient values of the watermark image in the lowest row of the cover image selected block the row vector must have 32 random non repeating values as the watermark has 32 rows and 4 random non repeating values for column selection as in each row 8 values are inserted so 4 column select value is required.

The selected row value let be 'm' and column value be 'n' are used to select the first element of the selected block in which the watermark will be embedded. This element can be selected from the original image denoted as 'G', as

$$G(((m-1)*8)+1),((n-1)*8)+1)). \quad (3)$$

The corresponding block thus can be selected by incrementing both row and column values from the initial pixel location, as incrementing the column value as ((m-1)*8+1) to ((m-1)*8+8) and the row value as ((n-1)*8+1) to ((n-1)*8+8). Thus the complete block is selected. This block is Walsh Hadamard transformed.

C. Inserting watermark data

The one dimensional block of Walsh Hadamard transformed data is embedded in the last row of the selected transformed cover image block denoted as 'X" as

$$X(8,1 \text{ to } 8) = w(1, k \text{ to } (k+7)). \quad (4)$$

Here k is used to select the corresponding value to be embedded in the block, where k is initially to 1.

D. Watermarked image generation

The watermarked block is then inserted back into the original image after applying inverse Walsh Hadamard transform on 'X'. We then round up the values and the block is now denoted as 'X1'.This block is then inserted into the region of the image where it was initially taken from. Thus we get the watermarked image denoted as 'G1'.

E. Error values transmitted

For correct decoding of the transmitted watermark the fractional values which are generated due to Walsh transformation are stored in a matrix as

$$E=X1-X. \quad (5)$$

Again let the image right before the transmission be denoted G2.Now it may be possible that due to some reason some values which were actually embedded is altered then this error is also taken into account as

$$E1=G1-G2. \quad (6)$$

Thus the total error value transmitted is

$$Etotal=E1-E. \quad (7)$$

Thus this is the complete encoding method where along with the transformed the error Etotal is transmitted.

BINARY AND GRAYSCALE WATERMARK EXTRACTION

We receive the watermarked image G2 along with the error value Etotal.

A. Generating the decodable block

The received image G2 and error Etotal is used to generate the block from which we can decode the watermark as

$$Y=Etotal + G2. \quad (8)$$

B. Selecting the proper block

From the row and column value which was used at the time of encoding can be used here also to find out the corresponding block.

C. Inverse transform and finding the embedded data

The last row of the corresponding block is stored in a one dimensional array of size (1 x 1024), this is the decoded transformed value of the watermark.

D. Watermark decoding

The linear array is converted to (32 x 32) block which is then inverse Walsh transformed as (8 x 8) block and stored in a (32 x 32) matrix, which is the watermark image. Thus we get the decoded watermark image.

V. DESCRIPTION OF THE WATERMARK ENCODING AND DECODING UNIT

The block diagram of the watermarking method is divided in encoding and decoding blocks. The block diagram of the encoding block is shown in Fig. 2.

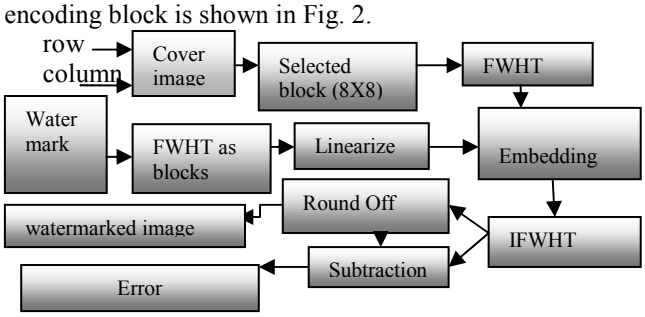

Fig. 2 Block diagram of the watermark encoding block.

The cover image considered here is of size (256 x 256) and the watermark is of size (32 x 32). Here the row and column select values are used to select a particular block from the original image. The row and column select value are inserted by the user at the time of embedding as linear arrays. Then the selected block is Fast Walsh Hadamard Transformed (FWHT). The watermark is also broken in blocks of size (8 x 8) and passed through FWHT block. Equation (4) is used for the Embedding block for performing the watermarking process. After embedding, the block is inverse transformed by the block IFWHT. The inverse transformed values are round off. These blocks are then embedded back in the original cover image to the place which was selected by the row and column select values and thus we get the watermarked image. Thus the Watermarked image and the error value is transmitted along with the image. This is the complete operation of the encoder block. Here the error while transmitting the image is not considered as the process used by the transmitter to transmit the image is not exactly known.

To decode the watermark the decoder block is used .The block diagram for the decoder shown in Fig. 3.

The decoder block gets as input the received watermarked image and the error values. These values are added to get the actual image block generated at the transmitter before rounding off the value for transmission. The row and column select values used at the transmitter is also used here for the selection of the proper block. The selected block is passed through the FWHT block. As the watermark was initially embedded in the last row of the block, the last row is selected and put in a linear array.

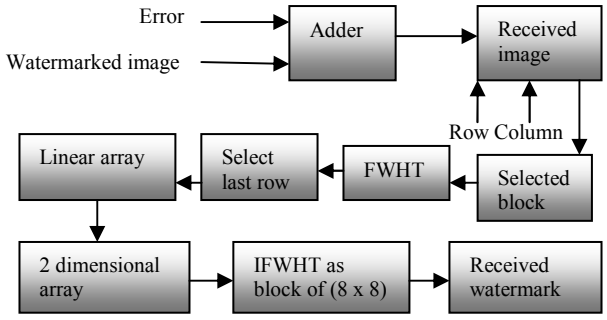

Fig. 3 Block diagram of the watermark decoding block.

The linear array is converted to two dimensional array. The two dimensional array is then inverse transformed block wise then combined to get the original watermark. Thus by using this architecture we can get the original watermark.

VI. ANALYSIS AND EXPERIMENTAL RESULTS

After performing the above stated algorithm in Matlab the following results have been obtained.

For Matlab simulation we used a (256 x 256) cover image and (32 x 32) and (64 x 64) watermark. The operation has been performed on both grayscale and binary watermark and the result obtained is illustrated in Table I. Here the index on which we have stated the quality of watermarking is the Mean Squared Error (MSE) and Peak Signal to Noise Ratio (PSNR).

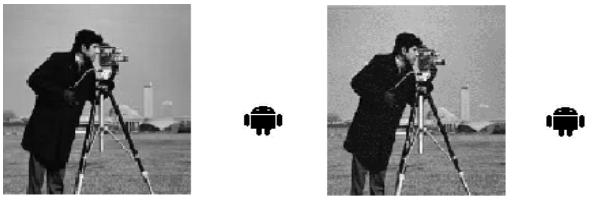
TABLE I
PERFORMANCE METRICS OF THE PROPOSED WATERMARKING ALGORITHM

Type of image	Water mark image size	Encoded image index		
		Normalization value	Peak Signal to Noise Ratio(dB)	Mean Squared Error(MSE)
Gray scale image	32x32	8	46.869	1.3372
		17	52.03	0.472
	64x64	8	42.58	3.588
		17	45.99	1.1134
Binary Image	32x32	1	69.81	0.0065

The normalization factor used here is the amount by which the pixel value is divided by, that is ,if the intensity of a pixel be 255 then after normalization by 17 we get the maximum pixel value as 15. Here are few image examples,

(a) (b) (c) (d)

Fig. 4 Watermark embedding and decoding for (64 x 64) grayscale watemark: (a) is the cover image,(b) is the watermark,(c) is watermarked image,(d) decoded watermark



(a) (b) (c) (d)

Fig. 5 Watermark embedding and decoding for (32 x 32) binary watemark: (a) is the cover image,(b) is the watermark,(c) is watermarked image,(d) decoded watermark

Now we have applied some common watermark attacks such as image sharpening and image scaling to see how the decoded watermark looks like.

TABLE III
DIFFERENT WATRMARK ATTACKS

Original watermark	Difference watermarks after operations	
	Operation	**Received watermarks**
Grayscale	Scaling by 0.75	
	Sharpening	
	Cropping	
Binary	Sharpening + Cropping	

The algorithmic time complexity of different blocks of both encoder and decoder are shown in the Table III as

TABLE IIIII
ALGORITHMIC TIME COMPLEXITY OF DIFFERENT BLOCKS

Unit	Blocks	Time Complexity
Encoder	Block Selection	$O(n^2)$
	Linearization	$O(n^2)$
	Embedder	$O(n^2)$
Decoder	Selection of last row	$O(n)$
	Linear array to 2 dimensional array	$O(n^2)$

The encoder has several blocks, we here select the block with size (n x n). The block selection block uses both row and column values, since both row and column values are to be selected thus we use two loops thus the time complexity is $O(n^2)$.

For linearization again we have to use array of the size 'n^2', Thus here the time complexity is also $O(n^2)$.

The embedder unit has first n.(n-1) elements at the output linearly, but the last row of the matrix is transmitted by logically substituting the lowest row of the original matrix by the transformed watermark image values. Thus here also we perform the operation both row and column wise of the block , hence it has time complexity $O(n^2)$.

In case of the decoder the row selection block is same as the encoder. For selection of the last row from the selected block, we fix the row value to 7 and then the column values are incremented, thus the time complexity here is O(n).

The last row values stored in the linear array is transformed in the 2 dimensional matrix to get the original watermark, thus here also two loops are needed, thus the time complexity is $O(n^2)$.

VII. CONCLUSION

From the above discussion we can finally draw some concluding remarks as: If the error value is not there , that is if the normalization used in the Walsh-Hadamard transform is not taken in consideration and if there is no error while transmission, then the proposed algorithm can be completely blind, which is an improvement over[6] that is we do not need any new values to be transmitted along with the image. The maximum value of the pixel which can be embedded without affecting the quality of the watermarked image is 32, that is each pixel can be represented by 5 bits in binary. The ratio of the of the cover image to the watermark must not be more than 8:1,that is if the cover image be of size (256 x 256) the watermark must be of size maximum (64 x 64) . For higher size of watermark, higher size of cover image is required, else the quality of the watermarked image will degrade. For embedding and decoding unit the time complexity is compatible to be implemented in hardware. In our proposed algorithm, both binary as well as grayscale watermark can be embedded and extracted which is an added advantage.

***Abstract* - The accuracy of speech recognition systems, to a large extent, depend on the feature sets used for representing the speech data. It has been a continuous process to develop feature sets to perform more accurate speech recognition through ASR (Automatic Speech Recognition) systems. Many feature sets and their different combinations have been tried to achieve better accuracy but the feature set providing completely accurate representation is yet to be formulated.**

This paper investigates the generation of reduced sets of MFCCs for vowel recognition. The study is more focused on the generation and behavior of MFCCs for different vowel sounds. The goal is to identify the features that enhance their discriminating capabilities and improve the performance of ASR systems for particular sounds. The results of the analysis show that the proposed reduced features perform well and can be further used to improve the accuracy of ASR systems, specifically the ones in resource constrained devices.

***Index Terms*—Reduced feature sets, MFCCs, Vowel Recognition**

I. Introduction

ONE of the first decisions in any pattern recognition system is the choice of what features to use: How exactly to represent the basic signal that is to be classified, in order to make the classification algorithm's job simple. In the field of speech recognition, the selection of features used for the proper representation of speech data must be capable of identifying and discriminating the underlying patterns in speech with utmost accuracy and reliability.

One of the most powerful speech analysis feature set is LPC (Linear Predictive Coefficients). LPCs are capable of encoding good quality speech at a low bit rate and provide extremely accurate estimates of speech parameters. The most popular feature representation currently used is the Mel-frequency Cepstral Coefficients or MFCCs. Another popular speech feature representation is known as RASTA-PLP, an acronym for Relative Spectral Transform - Perceptual Linear Prediction. PLP was originally proposed by Hynek Hermansky as a way of warping spectra to minimize the differences between speakers while preserving important speech information [4]. RASTA is a separate technique that applies a band-pass filter to the energy in each frequency sub-band in order to smooth over short-term noise variations and to remove any constant offset resulting from static spectral coloration in the speech channel e.g. from a telephone line [5].

In the decade 1980-90 development of speech recognition toolkits was started and from then on several such toolkits have been developed. Most of these toolkits are based on the HMM (Hidden Markov Model) framework. Two popular toolkits are Sphinx and HTK. Both these toolkits are open source and can be configured as per requirements.

In the last decade it has been observed that most of the feature sets like LPCs, PLPCs and MFCCs have reached saturation in providing more accurate results for speech recognition. It inherently stems the requirement of formulation of a better feature set for achieving higher recognition accuracy. In some recent attempts researchers have tried several combinations of different feature sets and have succeeded in achieving slightly better results. Such combinations of feature sets pose more resource requirements in terms of storage and computing power. Such requirements can only be fulfilled with high-end devices but these large feature sets cannot be handled by resource constrained devices because of limited storage, computing ability and power. It raises the requirement that the traditional feature sets need a critical study of the significance of each feature in delegating speech data.

There are many alternate techniques proposed for vowel recognition that are highly accurate, such as hybridization of cepstral analysis and acoustic analysis of waveforms [11] and fuzzy inference rules [12] but these techniques are quite expensive computationally.

This paper is focused towards the study of the most popular feature sets i.e. MFCCs and their significance in representing speech data so that a better feature set can be formed for providing higher accuracy and/or at least comparable accuracy on resource constrained devices.

II. Feature Set For Speech Analysis

There are several feature sets which are used for speech analysis purposes like LPCs (Linear Predictive Coefficients), MFCCs (Mel Frequency Cepstral Coefficients) and PLPCCs (Perceptual Linear Predictive Coefficients). The human ear resolves frequencies non-linearly in the audio spectrum, thus filter bank analysis is more appropriate than Linear Predictive Coding (LPC) analysis since it is a spectrally oriented method. Mel-scale resolves frequencies in the same manner as the human ear. It attempts to mimic sensing and resolution of frequencies similar to that of the human ear. The Mel-scale is a unit of measurement of perceived frequency (pitch) of a tone. FFT-derived *Mel*-scaled cepstral coefficients [6] are the most common form of cepstral analysis. The MFCCs generation and analysis of speech based on MFCCs is similar to [1, 2].

For generation of MFCCs, the HCOPY tool from HTK (Hidden Markov Tool Kit) has been used. HTK is a toolkit for building HMM-based acoustic models as well as statistical back-off n-gram language models for automatic speech recognition. It consists of a set of command line tools written in C language to construct various components of a speech recognition system.

The following configuration is used for feature extraction using HCOPY:

SOURCEFORMAT = WAV TARGETKIND = MFCC_0_D TARGETRATE = 100000.0 SAVECOMPRESSED = T SAVEWITHCRC = T WINDOWSIZE = 250000.0 USEHAMMING = T PREEMCOEF = 0.97 NUMCHANS = 26 CEPLIFTER = 22 NUMCEPS = 12 ENORMALISE=T	Qualifier: _0 — zeroth coefficient; _D — first differential Recordings are conducted with 16000 samples per second and stored as wave files. Each analysis frame contains 400 samples with step size of 160 samples.

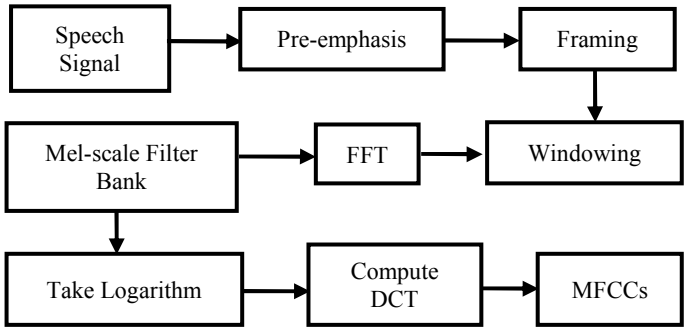

Fig 1.Block Diagram for Generation of MFCCs [3, 10]

The calculation of the MFCC [7] – [9] includes the following steps

1. Pre-emphasis: For pre-emphasis, a high pass finite impulse response (FIR) filter was used, given by the equation below.
$$H(z) = 1 - a * z^{-1} \quad (1)$$
where $0.9 \leq a \leq 1.0$.We take a as 0.97. The signal transformation is done according to the following equation.
$$y(n) = x(n) - a * x(n-1) \quad (2)$$
2. Then frames of 25 ms each were constructed with overlapping of 15 ms and step size of 10 ms.
3. Next the following window was applied on each frame
$$W(n) = 0.54 - 0.46 \cos\left(\frac{2\pi n}{N-1}\right) \quad (3)$$
where $0 \leq n \leq N-1$ and N is the number of samples in a frame.
4. Let us refer to the time domain signal after applying Hamming window as $s(n)$. After applying framing and Hamming window we obtain $s_i(n)$ where $0 \leq n \leq N-1$ and i the number of frames. Now after calculating the complex DFT for each frame, we get $S_i(k)$ corresponding to the ith time-domain frame.
$$S_i(k) = \sum_{n=0}^{N-1} s_i(n)\, e^{-\frac{i2\pi kn}{N}} \quad (4)$$
where $1 \leq k \leq K$ and K is the length of the DFT. We get the periodogram estimate of the power spectrum $P_i(k)$ for i^{th} speech frame as follows:
$$P_i(k) = \frac{1}{N}|S_i(k)|^2 \quad (5)$$
5. Next Mel-spaced filter-banks were computed. It comprises of 26 triangular filters that are to be applied to the power spectral estimate from the previous step.
Each of these 26 filters is a vector that is applied to power spectral estimate of each speech frame. The values thus obtained, for each filter, are summed up to calculate energies passed through each filter.
6. Then the logarithm of each of the 26 energy values was obtained from the previous step.
7. Then discrete cosine transform (DCT) was applied to these 26 log energies.
8. After the application of DCT we obtain 26 coefficients. From these we choose 13 lower order coefficients which are called Mel Frequency Cepstral Coefficients (MFCCs).

From these 13 MFCCs we drop the 0th coefficient for our analysis and use 12 higher order coefficients.

III. Analysis Of MFCCS

After computing the MFCCs, we conducted a series of initial experiments to analyze the behavior of MFCCs for the five out of eight primary cardinal English vowel sounds (viz. /a/, /e/, /i/, /o/ and /u/) segments.

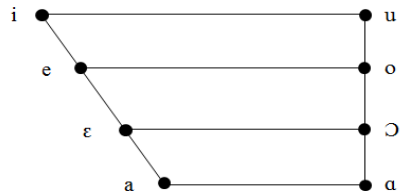

Fig 2. Sets of primary cardinal vowels produced by Daniel Jones

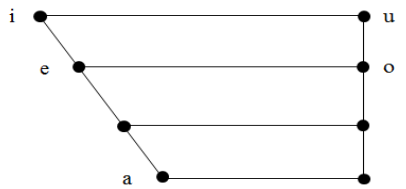

Fig 3. Sets of cardinal vowels taken into account for analysis

The results were further used to determine the importance of each of the MFCCs in representing the vowels in their steady states and to identify the subset of MFCCs that produces more sophisticated delegation of vowels in their steady states as compared to others.

Outline of the Experiment:

- For each speaker in the database, conduct the following:
  1) Collect multiple (10) utterances of each vowel.
  2) Extract the steady state segment of each vowel from every recorded utterance.
  3) Use HCopy software to generate the Mel Frequency Cepstral Coefficients (MFCCs) for the segmented steady state of each utterance.
  4) Collect each MFCC for all the steady state utterances of a vowel in separate files.
  5) Prepare plots of collection of each MFCC for every vowel.
  6) Select the four least varying MFCCs from the set of 12 coefficients.
- From previous results, for each steady state vowel consolidate three most frequent MFCCs.
- Finally, verify the results.

IV. Observations

From the plots of Fig. 2-5 it is observed for vowel /a/ that the MFCCs c_1, c_2, c_4 and c_6 give steady plots while for other

MFCCs (viz. c_3, c_5, c_7, c_8, c_9, c_{10}, c_{11} and c_{12}) the values do not exhibit any regularity.

It is intuitive to examine and verify that the MFCCs that follow this regularity contribute significantly in identifying the vowel while the non-regular MFCCs reduce the recognition of that particular vowel because of their divergent behavior.

This leads us to infer that if we could identify the set of regular MFCCs for each vowel in its steady state, we can develop a superior vowel recognition system with higher recognition rate.

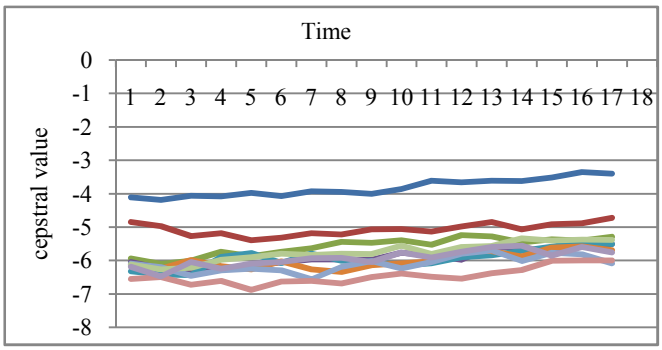

Fig 4. Plot of 2nd MFCC for Vowel /a/

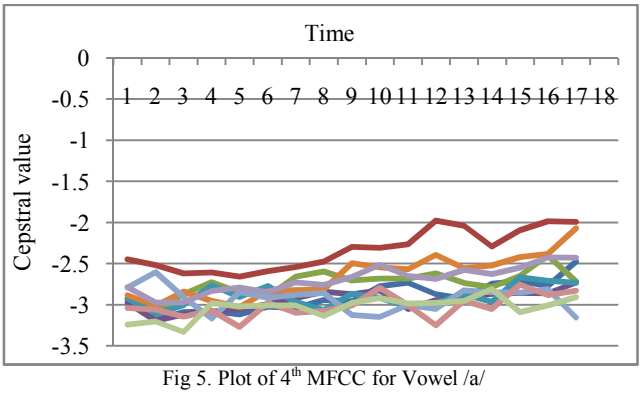

Fig 5. Plot of 4th MFCC for Vowel /a/

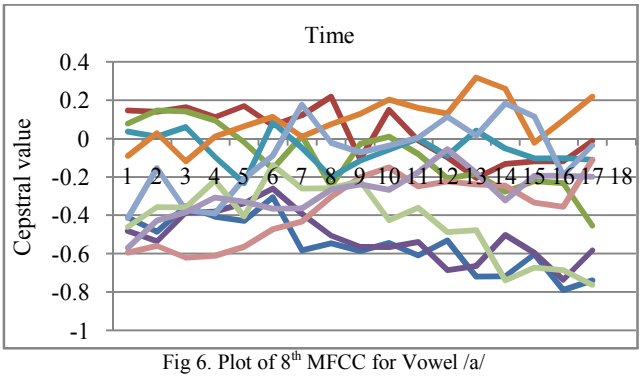

Fig 6. Plot of 8th MFCC for Vowel /a/

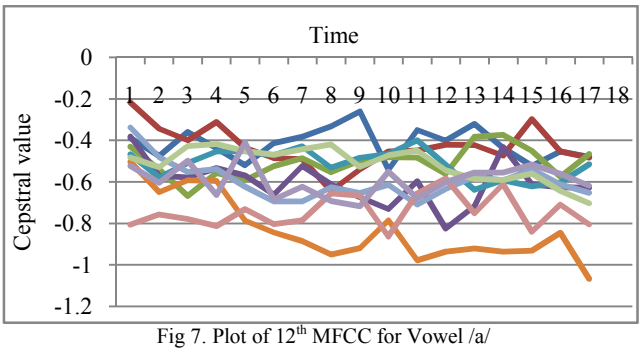

Fig 7. Plot of 12th MFCC for Vowel /a/

Similar analysis is performed for all the five English spoken vowels several times to find out these regular and non-regular set of MFCCs. The experimental results are as follows:

A. Experimental Outcomes:

The following observations were found based on the five English vowels using two recorded data sets and are tabulated in Tables I and II.

TABLE I & II
VOWELS AND REGULAR MFCCS FROM TWO EXPERIMENTS

Vowel	Regular MFCCs
/a/	c_1, c_2, c_4, c_6
/e/	c_1, c_2 , c_3 ,c_5
/i/	c_1, c_3, c_4, c_5
/o/	c_4, c_5, c_6, c_7
/u/	c_3, c_4, c_8, c_{10}

Vowel	Regular MFCCs
/a/	c_2, c_4, c_5,c_6
/e/	c_1, c_2 , c_3 ,c_5
/i/	c_1, c_3, c_5, c_7
/o/	c_2,c_4, c_5, c_6
/u/	c_4, c_5, c_8, c_{10}

From Tables III and IV we can observe that c_8, c_9, c_{11}, c_{12} do not contribute in formation of regular sets of MFCCs and hence might only be contributing in degradation of the recognition results.

TABLE III
CONSOLIDATED SET OF THREE MFCCS FOR EACH VOWEL

Vowel	Regular MFCCs	Vowel	Regular MFCCs
/a/	c_2, c_4, c_6	/o/	c_4, c_5, c_6
/e/	c_1, c_2 , c_3	/u/	c_4, c_5, c_{10}
/i/	c_1, c_3, c_5		

TABLE IV
MFCC-WISE CONTRIBUTION FROM REGULAR SETS

MFCC	Vowel	MFCC	Vowel	MFCC	Vowel
c_1	/e/,/i/	c_5	/e/,/i/,/o/	c_9	
c_2	/a/,/e/	c_6	/a/,/o/	c_{10}	/u/
c_3	/e/,/i/	c_7	/i/	c_{11}	
c_4	/a/,/o/	c_8		c_{12}	

After formation of regular sets we proceed further to verify the results for each of the vowels. For this we take up several test steady state vowel instances and computer their distances from standard steady state vowel instances. First, taking all MFCCs and then using regular set of MFCCs, we compute the distance as the distinctiveness capability of different feature sets. The step-wise verification procedure is as follows:

1) Select 5 instances of steady states of vowels (one for each vowel) having same length and fix them as references i.e. standard steady state vowel instances.
2) Record multiple test utterances of different vowels and generate multiple test instances from steady states for each vowel.
3) Compute distance of test steady state instance with each of the reference steady state, initially taking all 12 MFCCs and then taking the set of 3 regular MFCCs using Euclidian distance:

$$D = \frac{1}{n}\sum_{i=1}^{n}(r_i - t_i)^2 \qquad (6)$$

where D is the distance, r_i is the ith MFCC for reference steady state vowel instance, t_i is the ith MFCC for test steady state vowel instance and n is the number of MFCCs used.

4) After computing the distances for all instances of each test–reference vowel pair, we calculate the average distance values and tabulate them.
5) Compare the results.

TABLE V
DISTANCE MATRIX WITH 12 MFCCS

/u/ 4	66.18	200.60	191.90	49.42	8.56
/u/ avg	66.63	215.10	192.58	36.55	**7.24**

From results shown in Tables V and VI it is evident that for different test–reference vowel pairs, distance values obtained through regular MFCCs sets are more than the distances obtained using all 12 MFCCs for most vowels. It is also clear that the distinctiveness of the distance is more as the dissimilar vowels show large dissimilarity.

VI. CONCLUSION

From these preliminary experiments we conclude that specific subsets of features of conventional MFCC feature sets exhibit more uniform behavior for particular vowel sounds than for others. Taking that as a back drop, more experiments are to be conducted to substantiate this fact for several utterances as well as for several speakers so that a speech recognition system with a reduced set may be made possible with at least with same recognition accuracy or better.

ACKNOWLEDGMENT

The authors gratefully acknowledge the funding support provided by DeiTy, New Delhi to carry out this research work.

***Abstract*—Affinity detection has been largely motivated by the increasing interest in modelling the social behavior of humans. This paper presents a supervised learning method for affinity detection which is based on an inference obtained from tracking trajectories of the human subjects captured in video sequences. In particular, the proxemic cues of group detection such as the pair-wise similarity of the positional and translational measurements of the tracked people are used in the well-known principal component analysis-based feature extraction process. The existence or non-existence of pair-wise affinities is recognized using the nearest neighbor detector applied on the proposed features and the majority voting-based fusion of decisions. Experiments conducted on surveillance video captured in diverse-type of movements of the subjects show favorable results in terms of accuracy of detecting affinities when compared with the ground truth.**

***Index Terms*—Affinity, social interactions, tracking, video surveillance**

I. Introduction

Social interactions are ubiquitous in our daily life. People organize themselves in groups not only to perform activities, but also to share views, opinions and thoughts. Through the observations of social interactions many behavioral traits of the interlocutors can be inferred [1]. For this reason, in order to find a group, the automatic detection of affinity from movement dynamics of people has become an active research topic over the last few years especially in the area of video surveillance. In general, a group refers to a collection of people those maintain relative closeness of in terms of position or moving trajectory in a given local area.

The seminal work in computer vision on movement of a group of living being may be attributed to Reynolds [2], where it was reported that the motions of flock of birds avoid collisions as well as they maintain matching velocity and remain close to the flock center. The social force model reported in [3] shows that the walking patterns of group of humans have a moving tendency towards a single destination with similar velocity. Further, the subjects in the group maintain certain distance to avoid collision and possess equal strength attractive or repulsive proneness. The perceived personal space and comfort levels defined by sociologists have been incorporated in the Voronoi diagrams to find the voluntary or involuntary groups formed in crowds [4]. The Bayesian nonparametric probabilistic models have also been introduced for group classification by considering the interpersonal distance and velocity as random variables [1].

In many cases, the affinities are interactively used to improve the accuracy of the trajectories of the individuals within a group. For example, a conditional random field is used to find the association of a membership in a group and thereby accuracy of the motion trajectory of that person is improved in an iterative way in [5]. An energy functional comprising a number of terms including the velocity, change of velocity, moving direction, attraction, grouping, and collision are minimized to obtain reasonably accurate motion trajectories of the pedestrian in [6]. In [7] and [8], it has been shown that the learning of the affinities of motion tracklets (fragments of tracks) and thereby linking of these supervised tracklets using the Hungarian or K-means clustering algorithm may increase the accuracy of tracking trajectories. Detection tracklets and trajectory tracklets have also been used to overcome the problems of occlusion while tracking of groups [9]. A more detail about such algorithms those have used the affinities of the tracklets for improving the accuracies of motion trajectories may be found in [10].

The understandings of affinities hidden in the interpersonal distances and moving velocities are not only required for classifying the groups and improving accuracies of motion trajectories, but also for the detection of social events or abnormalities. In [11], the trajectories and histograms of the subjects have been used in the hidden Markov tree model for classification of three types of unusual events, namely, the subject moving in opposite direction, still subject in a moving crowd, and subject moving faster than the crowd. Symmetric and asymmetric events are identified in [12] by considering activity features based on group representative.

In the literature, the hidden affinity information obtained from the positional or translational measurements are often used for classification of groups and events commonly seen in our social life. Even in many cases, these information are interactively used to improve the accuracies of the measured quantities. In our view, the existence of affinity should be detected first, before using such information for the classification of groups and events or for improving the accuracy of the measurements. In this context, this paper presents a novel supervised detection algorithm to identify the existence of pair-wise affinity of two persons in video surveillance. The existence of affinity is detected using the principal component analysis (PCA)-based learning process of the positional and translational features obtained from trajectories. Experiments are conducted on a developed video database to evaluate the performance of the proposed affinity detection algorithm.

The paper is organized as follows. In Section II, the proposed affinity detection algorithm is presented. In Section III, experimental results of affinity detection on the video database are given. Finally, concluding remarks are provided in Section IV.

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

II. Affinity Detection Method

The proposed affinity detection method takes the measurements of a tracking algorithm as inputs. The tracking algorithm must be capable of providing frame-by-frame positions of multiple subjects in a video sequence. Let O_k^i $(i \in 1, 2, \cdots, M)$ $(k \in 1, 2, \cdots, N)$ represent a subject in a tracklet of video sequence, where M and N are the number of individuals and number of frames in the tracklet, respectively. The proposed method first extracts the affinity features of pair-wise groups from a suitable set of measurements obtained from training tracklet, then the supervisory feature extraction process is applied to the pair-wise groups in the testing phase. The closeness of the test features with the training features determines the existence of affinity in question. Next, we present the step-by-step procedure of obtaining the pair-wise affinity using the trajectories of multiple subjects. The steps include the pair-wise group selection, construction of affinity vector, feature selection from the tracklets, and feature comparison and fusion for affinity detection.

A. Pair-Wise Affinity Group Selection

Let the affinity of a pair of subjects be denoted as $\mathcal{A}^{ij}$ $(i \neq j)$, the logic value one of which shows the existence of affinity and vice versa. Let $\mathcal{S}_n$ $(n \in 1, 2, \cdots, Z)$ denote a social group formed by a pair of subjects in a scene, where total number of groups in a frame k is given by

$$Z = \binom{M}{2} = \frac{M(M-1)}{2} \tag{1}$$

The number of frames N in a tracklet is chosen in such a way that Z remains same for the entire frames in the tracklets with the exceptions due to occlusions. It is noted that although this study concentrates on the pair-wise affinity, the decision on affinity of multiple persons can be reached easily by identifying the common individuals in such pair-wise groups.

B. Construction of Affinity Vector

The proxemic cues such as the positional and translational measurements of humans are used for quantifying affinity [13]. In the proposed method, the features of affinity are obtained from the positions and velocities of x- and y-coordinates measured by the tracker from a video. Let each of four measurements be denoted as ϕ_{km}^i $(m \in X, V_x, Y, V_y)$, where X, V_x, Y, V_y represent the coordinate position and velocity of a subject $\mathcal{O}_k^i$ in x and y-axes, respectively. It is noted that if the frame rate of the video is known, then the velocity of a subject can be measured only from his or her positions in the frames. Since the closeness of these measurements of a pair of subjects indicates the affinity between two, the affinity can be quantified as

$$\gamma_{km}^{ij} = \left\| \phi_{km}^i - \phi_{km}^j \right\|_2 \qquad i \neq j \tag{2}$$

where $\| \cdot \|_2$ denotes the Euclidean norm. The affinity vector of size $(N \times 1)$ for a pair-wise group S_n in the tracklet can be constructed from a measurement-type m as

$$\mathbf{\Gamma}_m^n = \left[\gamma_{1m}, \gamma_{2m}, \cdots, \gamma_{Nm} \right]^T \tag{3}$$

where T represents the transpose of the vector.

C. Feature Selection from Tracklets

Let η $(\eta < Z)$ be the number of pair-wise group for which the existence of affinity is confirmed in a training tracklet. Thus, an affinity existence matrix (AEM) of size $(N \times \eta)$ may be formed from the observed vectors as

$$\mathbf{\Psi}_m^\alpha = \left[\mathbf{\Gamma}_m^1, \mathbf{\Gamma}_m^2, \cdots, \mathbf{\Gamma}_m^\eta \right] \tag{4}$$

In a similar fashion, the affinity non-existence matrix (ANM) of size $(N \times (Z - \eta))$ can be formed as

$$\mathbf{\Psi}_m^\chi = \left[\mathbf{\Gamma}_m^1, \mathbf{\Gamma}_m^2, \cdots, \mathbf{\Gamma}_m^{(Z-\eta)} \right] \tag{5}$$

The positional or translational measurements in the matrices AFM and ANM must go through a dimension reduction process, so that affinity or non-affinity features can be extracted efficiently. In the proposed method, we prefer to use the PCA-based dimension reduction technique, since such method uses the singular value decomposition which is independent of data-type. In the PCA-based approach, the unitary vector $\boldsymbol{W}_m^\alpha$, i.e., the optimal projection axis, for the AFM is sought in such a way that the vector maximizes the generalized total scatter criterion defined by [14]

$$\mathcal{J}(\boldsymbol{W}_m^\alpha) = \boldsymbol{W}_m^\alpha \boldsymbol{C}_m^\alpha [\boldsymbol{W}_m^\alpha]^T \tag{6}$$

where $\boldsymbol{C}_m^\alpha$ is the covariance or scatter matrix of size $(\eta \times \eta)$ given as

$$\boldsymbol{C}_m^\alpha = E\Big([\mathbf{\Psi}_m^\alpha - E(\mathbf{\Psi}_m^\alpha)]^T [\mathbf{\Psi}_m^\alpha - E(\mathbf{\Psi}_m^\alpha)] \Big) \tag{7}$$

with $E(\cdot)$ being the expectation operator. It can be shown that the optimal projection axis $\tilde{\boldsymbol{W}}_m^\alpha$ is the eigenvector of $\boldsymbol{C}_m^\alpha$ corresponding to the largest eigenvalue [14]. In general, it is not enough to have only one optimal projection axis, instead the vectors corresponding to d $(d \ll N, \eta)$ number of eigenvalues are used to form the projection matrix of size $(d \times \eta)$ denoted as $\boldsymbol{P}_m^\alpha$. Finally, the features of affinity groups of training tracklets having size $(d \times N)$ are obtained as

$$\boldsymbol{G}_m^\alpha = \boldsymbol{P}_m^\alpha [\mathbf{\Psi}_m^\alpha]^T \tag{8}$$

In a similar fashion, the projection matrix of non-affinity groups $\boldsymbol{P}_m^\chi$ can be obtained and the features of the corresponding groups in the training tracklets are estimated as

$$\boldsymbol{G}_m^\chi = \boldsymbol{P}_m^\chi [\mathbf{\Psi}_m^\chi]^T \tag{9}$$

D. Feature Comparison and Fusion

At a given instance, the measurement-type m $(m \in X, V_x, Y, V_y)$ may form an observation matrix $\mathbf{\Psi}_m$ for which the belongingness to affinity or non-affinity is to be detected. The features of these observations obtained from the projection matrices corresponding to AFM and ANM, viz., $\boldsymbol{P}_m^\alpha$ and $\boldsymbol{P}_m^\chi$, may be denoted as $\boldsymbol{F}_m^\alpha$ and $\boldsymbol{F}_m^\chi$, respectively. In the proposed method, we prefer to use the cosine angle to measure the feature similarity. The angles between the observed feature and any of the training features in the cases of affinity and non-affinity conditions are given by

$$\theta_m^\alpha = \cos^{-1} \frac{\langle \boldsymbol{F}_m^\alpha, \boldsymbol{G}_m^\alpha \rangle}{\|\boldsymbol{F}_m^\alpha\|_2 \|\boldsymbol{G}_m^\alpha\|_2} \tag{10}$$

$$\theta_m^\chi = \cos^{-1} \frac{\langle \boldsymbol{F}_m^\chi, \boldsymbol{G}_m^\chi \rangle}{\|\boldsymbol{F}_m^\chi\|_2 \|\boldsymbol{G}_m^\chi\|_2} \tag{11}$$

where $\langle \cdot, \cdot \rangle$ represents the inner product. Existence of affinity with a single-type measurement m is detected by taking the

(a) (b)

Fig. 1. First and last frames of a typical video clip comprising variable number of subjects of interest with tracking trajectories. Number of subjects are such that one pair-wise affinity exists in (a) five subjects (b) four subjects.

decision obtained from the observed and training sets that produces the minimum angular distance of the features. Hence, the decision on a group in a tracklet is determined from the observation m as

$$\tilde{\mathcal{A}}_m = \begin{cases} A^1 & \text{if } (\theta_m^{\alpha})_{\min} < (\theta_m^{\chi})_{\min} \\ A^0 & \text{if } (\theta_m^{\alpha})_{\min} \geq (\theta_m^{\chi})_{\min} \end{cases} \tag{12}$$

where A^1 and A^0 correspond to the existence and non-existence of the affinity in the group, $(\theta_m^{\alpha})_{\min}$ and $(\theta_m^{\chi})_{\min}$ are the two minimums of the angular distances of the observed feature from the affinity and non-affinity training features, respectively. Since the existence of affinity in a pair-wise group is detected from four features defined by m, in order to reach to the final decision on the existence of affinity requires a fusion mechanism. In the proposed method, we use a majority voting-based decision fusion to detect the affinity of a pair-wise group given by

$$\hat{\mathcal{A}} = \text{maj}_m(\tilde{\mathcal{A}}_m) \tag{13}$$

where maj$(\cdot)$ provides the majority of the individual feature-based decisions. Due to the fact that four measurements are used in the proposed detection method, a tie may occur in which case the preference on fusing the decisions was assigned to the lateral direction of the motion trajectory of the subjects. In other words, if the flow direction is in y-direction then the preference is X, V_x, Y, and V_y, otherwise for flow of x-direction it is Y, V_y, X, and V_x.

III. Experimental Results

Evaluation of the performance of video-based detection of the affinity in a group is a challenging task. This is mainly due to the absence of well accepted evaluation protocol or publicly available database considering different scenarios. In this context, we have developed a typical video-based affinity detection database consisting of 30 video clips each with a length of at least 6 seconds captured in the vicinity of university area. The frame rate of the clips is 50 fps, wherein the pixel resolution of each frame is 480×640. One third of the clips are captured in such a way that at least three human-subjects are in slow moving condition among which at least one pair-wise affinity is assured. One third of the video clips have subjects with notable variations of the speeds such as strolling, running, and cycling. Trajectories of the subjects in these clips include the uniflow forward or reverse directions and curvature-type. Finally, the third set of clips comprises subjects with random walks in crowds. On average, half of the video clips are captured in the sunny conditions and half in cloudy or low illumination conditions.

The tracking trajectories of the subjects of interests in the video clips are estimated using the Gaussian-scale mixture models of the background and foreground developed in [15]. Fig. 1 shows first and last frames of a typical video clips used in the experiments along with the trajectories of the subjects of interests. From the frames shown in this figure, it can be seen that the number of subjects vary over the period of observation. The variations of the speeds include the walking, running, and cycling. The direction of trajectories are uniflow forward and backward as well as curvature-type. In the figure, the ground truth affinity is shown using green color boundaries of the subjects, whereas non-affinities are shown using red color boundaries.

In the proposed method, an important choice is the number of frames N chosen to form the tracklets. In the experiments, it is observed that for video clips wherein the variations of speed is low for the subjects of interests, a long sequence of frames can be used to form tracklets for increasing the accuracy of affinity detection. On the other hand, for high level of movements in a crowd, a short sequence is preferable to construct the tracklets. It is also noted that computational load of the affinity detection method increases with the length of sequence used in forming the tracklets. As a compromise between overall accuracy and computational complexity, the results of affinity detection presented in this paper use $N = 10$ to form the tracklets in all video clips. In order that the results obtained are statistically robust, the tacklets are formed by randomly chosen N number of chornological sequence in a clip and then accuracy of affinities or non-affinities are detected. The average results of accuracy shown in this paper use 20 number of such randomly selected set of sequences.

Table I shows the average of accurately detected pair-wise affinity or non-affinity groups those exist in three-types of video clips considered in the experiments. Here, the accurately

†The values inside the brackets indicate the accuracies in percentage of the detections.

detected groups using four-types of features those are obtained from positional and translational measurements of the trajectories are presented individually as well as the final results obtained from decision fusion are also given. A comparison of detection results with the ground truth reveals the following notable observations:

- Accuracies of detecting affinities decrease with the speed as well as the randomness of the movements of the subjects.
- In a slow moving groups, information obtained from the lateral distance X as well as the translational measurements V_x and V_y are effective for affinity detection.
- In case of speed variations within the subjects, information obtained from the lateral distance X and velocity V_x are more useful than the flow directional measurements.
- If the subjects are in a crowd, positional measurements X and Y are more effective than the translational information.
- The fusion of decisions provides the overall best results on affinity detection, if the types of movements of the subjects are not known to the algorithm. In such a case, however, the positional information plays the significant role as compared to the translational information.
- The proposed features are capable of detecting the non-existence of affinity without any significant deviations.

IV. CONCLUSION

Affinities inferred from the trajectories of video surveillance have potential applications in understanding the social interaction of humans, prior detection of possible events, or even improving the accuracy of tracking. This paper has presented a supervised learning method to automatically detect the existence of affinity, which can latter be used for further inference as necessary. In order to detect the affinities, the proxemic cues such as the positional and translational measurements have been used to obtain the affinity-related features. The PCA-based dimensionality reduction approach and the cosine angle-based similarity comparison method have been adopted to determine the existence of affinity in a pair-wise subjects. Experiments have been carried out on a number of video sequences having subjects with diverse type of movements such as slow moving, notable speed variations, and crowd to investigate the implications of the proposed feature sets on distinguishing between affinity and non-affinity. It is found that the measurements of position are more effective than that of translation of the subjects. Further, if the movement types of the subjects are unknown, a fusion of the feature-based decisions is necessary to reach to the conclusion about the existence of affinity in a group.

***Abstract*—The reliability of iris-based biometric recognition faces challenges due to non-cooperative image acquisition. This paper presents a novel non-cooperative recognition method by adopting a step-by-step segmentation process of the iris regions and modifying the generated IrisCodes in a way that the bits having significant discriminatory power are selected using an effective masking process. Both the statistical inter- and intraclass consistencies are used to estimate the discriminatory power of each bit position of the IrisCodes. Experimental results on commonly-referred non-cooperative iris image database show the significance of using discriminatory bits to improve the recognition accuracy for both the log-Gabor and discrete cosine transform-based IrisCodes.**

***Index Terms*—Discriminative masking, IrisCodes, non-cooperative iris recognition**

I. Introduction

Due to the increasing demand of security, the deployment of biometric identification systems that use physiological or behaviorial characteristics of humans becomes inevitable. Among different types of physiological biometrics, the increasing interest towards 'iris recognition' system for a large population is well-known. This is mainly due to the fact that the iris patterns such as furrows, freckles, crypts, and coronas possess lifetime permanence and the acquisition of iris images requires a noncontact process.

In 1987, Flom and Safir first developed the iris-based person identification system [1]. In general, an iris recognition system consists of three major components: (a) acquisition and localization of iris regions from eye images, (b) feature extraction and encoding of iris patterns, and (c) feature or code classification. Pioneering work for commercialization of iris recognition system may be attributed to Daugman [2]. It was reported that in case of cooperative acquisition of eye images, the annular region of iris image may be extracted by using a suitable integro-differential operator [2] or the Hough transform [3]. Next, the normalized and size-invariant templates are obtained by mapping the iris regions from the Cartesian coordinates to a nonconcentric coordinate system.

A considerable amount of research studies have been carried out in order to obtain suitable binary features, known as IrisCodes, from the iris templates [4]. Among these, the most common codes are generated from the binary phase of the Gabor filtered coefficients of the iris templates [2]. Ma *et al.* [5] proposed an IrisCode generation method by using the block-based local means and standard deviations of the Gabor filtered coefficients of the templates. The two dimensional (2D) Gauss-Hermite moments of the square-shaped non-overlapping blocks of the iris templates have also been used to obtain the IrisCodes [6]. Monro *et al.* [7] have generated IrisCodes using the zero-crossings of the differences of the 1D discrete cosine transform (DCT) of two suitably grouped and 45° rotated vertical scan lines of the iris templates. Other features used to generate IrisCodes from the rectangular templates include those are obtained from the dual-tree complex wavelets, directionlets, Laplacian and derivative of Gaussian, log-Gabor [8], Gabor energy, ridge energy, geometric moments, and improved scale invariant feature transform. In general, the bits of the IrisCodes contributed from the middle bands of the cooperative iris images are more consistent than the inner bands [9]. It was reported that the existence of inconsistent fragile-bits and their positions vary across genders and types of filters used to generate the codes. In [8], the fragile-bits are obtained by locating the positions for which the bit values change within a class. A class-dependent weight mask to locate the consistent bits in cooperative iris images using a computationally highly expensive optimization technique was reported in [10].

In the literature, most of the iris recognition schemes focus on the IrisCodes obtained from cooperative eye-images. The cooperative environment demands that the users are fully aware of recognition process and actively participate in highly constrained imaging conditions while capturing eye images. Images captured in less constrained conditions may lead to extremely heterogeneous data wherein iris regions may have severe obstructions arises from eyelids, eyelashes, or glasses due to off-angle camera view, reflected light on iris regions caused by illumination variations, poor quality intricate pattern caused by motion blur or out-of-focus camera lens. With a view to encompass the success of iris recognition algorithms in a broader range of applications, increasing interests have been found over the last few years considering non-cooperative iris recognition technique with specific degradation. For example, in [11], the off-axis iris images are corrected to frontal view images using the asymmetry of segmented regions and a suitable map of refractive indexes. The depth-of-field of the iris images has been improved by using suitable modulation transfer function [12] or simulated wavefront-coded image [13] for increasing recognition performance of out-of-focused iris images. Selection of frames having good quality iris regions or fusion of such frames in video sequences have also been attempted to take care about the problems of non-cooperative acquisition [14]. The success of recognition from nonideal iris recognition highly depends on the robust segmentation of the iris regions and the IrisCodes generated from the corresponding templates [15].

This paper presents a novel non-cooperative iris recognition algorithm in which the effective iris regions are isolated

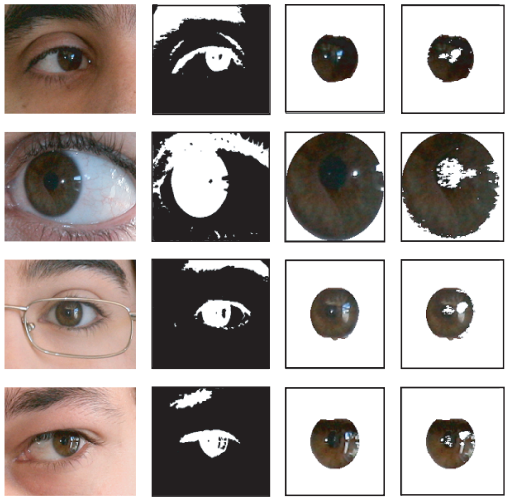

Fig. 1. Visual outputs of segmentation of iris regions from the non-cooperative images. Left most column shows sample images. The second column presents the non-skin regions. The iris and pupil regions are shown in third column. Finally, the iris regions excluding the pupils are shown in the rightmost column.

using a step-by-step segmentation process. Then, the IrisCodes are generated from the templates using the log-Gabor or DCT coefficients of the templates. A discriminative masking approach, which is independent of any kind of degradations, is proposed by estimating the statistical consistency of each bit in the IrisCodes. The significance of the masking is investigated on commonly-referred iris image database, in which images are captured from individuals with very little cooperation.

The paper is organized as follows. In Section II, the method of obtaining IrisCodes by segmentation of iris regions is given. The proposed approach of generation of discriminative mask is presented in Section III. In Section IV, experimental results of recognition on iris image database are given. Finally, concluding remarks are provided in Section V.

II. Generation of IrisCodes from Eye Images

In order to generate the IrisCode, the eye region is required to detect first from the acquired image. Then annular-shaped iris region is to be isolated from the eye image. The iris region is then mapped to a rectangular-shaped iris template, from which the binary IrisCode is generated using suitable feature extraction process. The step-by-step procedures of obtaining the IrisCode from the acquired image are given below.

A. Segmentation of Eye Region

In the non-cooperative iris recognition algorithm, the first task is to isolate the eye regions from the skin color face regions and hairy eyebrows. For such segmentation, statistical feature-based classification is adopted. In particular, the mean and standard deviation calculated from three local neighborhoods of sizes 3×3, 5×5, and 7×7 centered at each pixel of the color images are used as region features. Then, pixels each represented by nine features for skin and non-skin regions are clustered using the fuzzy C-means algorithm. The skin and non-skin areas are isolated by the K-nearest neighbor classifier, wherein the clustered training features are used and the K value is chosen as unity. It is noted that the eyes are the regions of interest that include the iris, pupil, and sclera in the non-skin areas excluding the eyebrows.

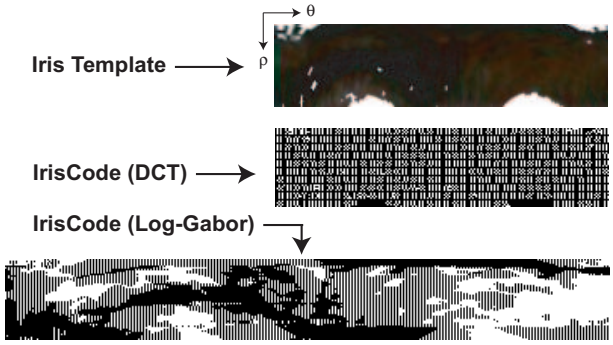

Fig. 2. Visual outputs of typical iris template as well as the corresponding DCT and log-Gabor-based IrisCodes.

B. Segmentation of Iris

Since the chromatic values of the iris regions, pupil inside the iris regions and the eyebrows are very close to each other, they can be treated as non-sclera regions. The sclera and non-sclera regions are segmented using the similar method adopted for classifying the skin and non-skin regions explained previously. The non-sclera regions comprise the circular-type iris regions including the pupil and arch-type eyelashes or eyebrows. In order to obtain the circular edges from the non-sclera regions, we have used the gradients of the pixel intensities obtained from the Canny edge detector and the circular Hough transform [6]. The closed-circular boundary includes the iris region and pupil, which is latter separated using the popular Otsu's thresholding method [16]. Fig. 1 shows the visual outputs of the segmentation of iris regions from typical four samples of images obtained from the database UBIRIS v2.0 [17]. The non-cooperative nature of the acquisition are obvious from the images shown in the left most column. The second column shows the non-skin areas that include the regions of interest. The third column shows the circular patterns inside the eye regions that include the iris as well as the pupil, wherein a zoom-in factor two is applied. Finally, the iris patterns are shown in the right most column by isolating the pupils remaining in the center area. These results clearly reveal that the proposed segmentation method can provide the iris regions very efficiently from the non-cooperative images.

C. Generation of IrisCode

Let the segmented region of an iris image be denoted as 2D continuous signal $I(x, y)$ in a Cartesian coordinate system of (x, y). Let r $(r > 0)$ be the radius of the circular iris/sclera boundary with a center (x_c, y_c) obtained from the Hough transform. According to the homogeneous rubber sheet model [6], the mapping of $I(x, y)$ to a doubly dimensionless and nonconcentric coordinate system of (ρ, θ) $(0 \leq \rho \leq 1)$, $(0 \leq \theta \leq 2\pi)$ can be represented as

$$I(x(\rho, \theta), y(\rho, \theta)) \longrightarrow I(\rho, \theta) \tag{1}$$

with

$$x(\rho, \theta) = (1 - \rho)x_c + \rho x_s(\theta) \tag{2}$$

$$y(\rho, \theta) = (1 - \rho)y_c + \rho y_s(\theta) \tag{3}$$

where the coordinates $(x_s(\theta), y_s(\theta))$ are on the circular iris/sclera boundary at an angle θ. The iris templates generated from this mapping process are ensure to have only the iris patterns obtained in the segmentation stage excluding

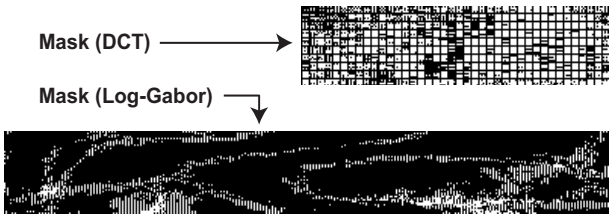

Fig. 3. Visual outputs of typical discriminative masks considering the DCT and log-Gabor-based IrisCodes.

the unnecessary regions such as the pupils, occlusions, and reflections. The iris templates generated may be used to obtain IrisCodes using different strategies adopted in the literature. In this study, we consider two types of IrisCodes obtained from the intensity image of iris templates. The first code is obtained from the quantization of the complex phase of log-Gabor coefficients of templates [8] and the second from the zero-crossings of 1D DCT coefficients of the recommended scan lines in the templates [7] except for choosing the non-overlapping windows both on the horizontal and vertical directions. Fig. 2 shows the visual outputs of a typical iris template and its corresponding codes using the DCT and log-Gabor-based features. It can be seen from this figure that the iris template generated from the proposed method effectively excludes the pupil and other unwanted regions. Due to the real and imaginary parts of complex phase, the log-Gabor-based IrisCode appears as twice the size of the DCT-based one.

III. Discriminative Masking of IrisCodes

It is well known that the random occurrence of each bit in the IrisCodes follows the binomial distribution. In order to recognize an identity using the IrisCodes, a significant number of bits should have close matching within the class. In practice, however, the occurrences of bits in a number of positions within a class appear to be independent when the codes are generated from non-cooperative images. Notably, the inclusion of such inconsistent bits rather acts as an impediment to obtain the minimum within class distance of IrisCodes. In such a case, the discriminant masks can be estimated from each class of the training IrisCodes, so that only the bits in the consistent positions may be used for recognition of a test code. To obtain the class-specific discriminant mask, we determine the within and between class consistencies for each bit position of the codes. Let an IrisCode of size $(M \times N)$ belong to a class label ℓ $(\ell \in 1, 2, \cdots, L)$ in a database of L number of classes. Let μ_{k1}^{ℓ} and μ_{k0}^{ℓ} $(0 \leq \mu_{k1}^{\ell}, \mu_{k0}^{\ell} \leq 1)$ represent the within class mean values of the bits '1' and '0', respectively, for a certain bit position k $(k \in 1, 2, \cdots, MN)$. Since perfectly followed random binomial distribution possesses equal valued mean for both the bits, the deviation of these mean values represents the within class consistency given by

$$\mathcal{W}_k^{\ell} = \left| \mu_{k1}^{\ell} - \mu_{k0}^{\ell} \right| \quad \ell = 1, 2, \cdots, L \quad k = 1, 2, \cdots, MN \tag{4}$$

In a similar fashion, the between class consistency of the bits at the same position can be estimated as

$$\mathcal{B}_k^{\ell} = \frac{1}{2L} \sum_{\ell=1}^{L} \left| (\bar{\mu}_{k1} - \mu_{k1}^{\ell}) - (\bar{\mu}_{k0} - \mu_{k0}^{\ell}) \right| \tag{5}$$
$$\ell = 1, 2, \cdots, L \quad k = 1, 2, \cdots, MN$$

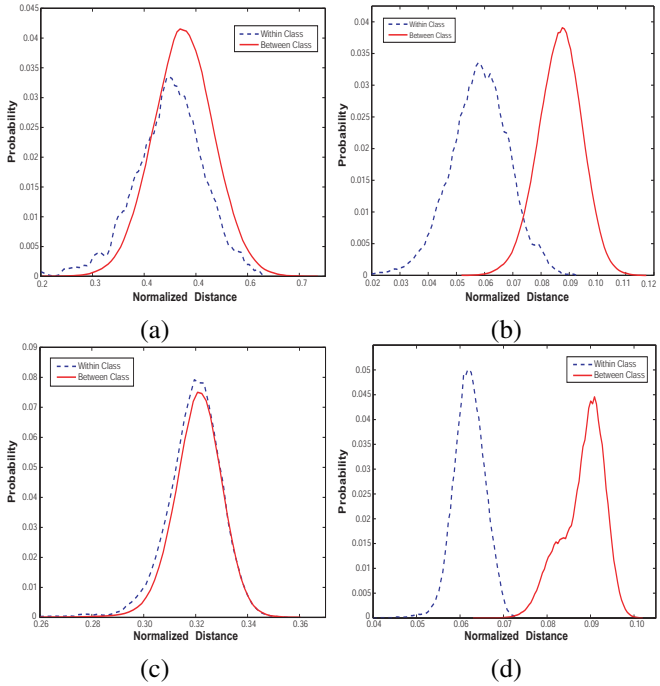

Fig. 4. Histograms of the within- and between-class Hamming distances showing the effect of masking in the IrisCodes. (a) Log-Gabor-based codes without mask [8], (b) log-Gabor-based codes with proposed mask, (c) DCT-based codes without mask [7], and (d) DCT-based codes with proposed mask.

where $\bar{\mu}_{k1}$ and $\bar{\mu}_{k0}$ $(0 \leq \bar{\mu}_{k1}, \bar{\mu}_{k0} \leq 1)$ are the mean values of the equiprobable bits '1' and '0', respectively, considering the entire database. A bit in the IrisCode will be effective for recognition, only if the bit position has a high within-class consistency and a low between-class consistency. In other words, the class-specific discriminant capability of a bit position can be measured as

$$\mathcal{D}_k^{\ell} = \frac{\mathcal{W}_k^{\ell}}{\mathcal{B}_k^{\ell}} \quad \ell = 1, 2, \cdots, L \quad k = 1, 2, \cdots, MN \tag{6}$$

In constructing the discriminative mask, we prefer to use only the first αMN $(0 < \alpha \leq 1)$ number of bit positions in the IrisCodes that have high values of $\mathcal{D}_k^{\ell}$. Fig. 3 shows typical class-specific discriminative masks obtained for the DCT and log-Gabor-based IrisCodes using the proposed method using $\alpha = 0.50$ and 0.20, respectively. From this figure, it can be seen that the significant discrimination exists in bit positions of the radial axis as compared to that of the angular axis for both the cases.

IV. Experimental Results

Extensive experimentations have been carried out to evaluate the clustering performance of the proposed discriminative iris recognition method as compared to the existing ones. In this section, the recognition results are given for a generic set of iris images, which are obtained from a well-known database, namely, UBIRIS v2.0 [17]. The database has 11,102 images each having a size of 800×600. The iris images were collected from two eyes of 261 persons. The database contains 14 types of non-cooperative factors, classified into two major categories: local and global. The local category is comprised of iris obstructions, reflections, off-angle, and partial images, while the global comprises poor focused, motion-blurred, rotated, improper lighting, and out-of-focus iris images. In order to obtain the generic database,

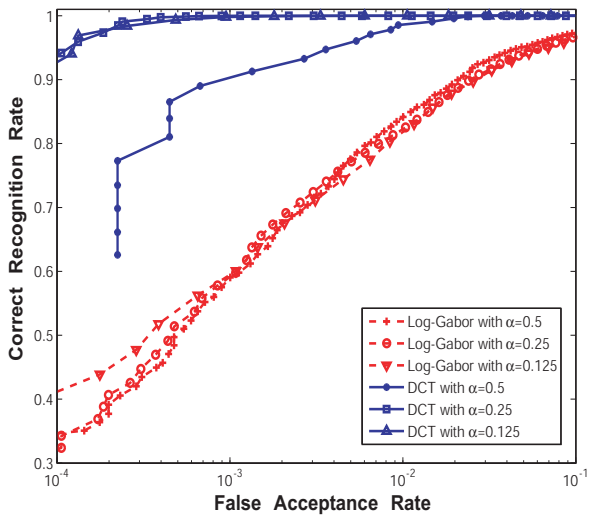

Fig. 5. ROC curves showing the correct recognition rate as a function of false alarm rate with varying α used in the masking of the log-Gabor and DCT-based IrisCodes.

we consider entire set of 261 classes with each having 15 iris images. The significance of using the proposed class-specific masking on the recognition accuracy is evaluated in two ways. First, the intra- and interclass distances are measured and the histograms are constructed to identify the separability of IrisCodes. Second, the receiver operating characteristics (ROC) curves are estimated to identify the probability of correct recognition for a given false alarm rate. In order that the experiments conducted are statistically robust, the histograms and the ROCs curves are estimated from a randomly chosen 50 persons each having 10 iris images and using the leave-one-out method. The average results presented in this paper are obtained by repeating the same process for 20 times.

Fig. 4 shows the histograms depicting the effect of proposed masking on the normalized inter- and intraclass Hamming distances of the log-Gabor [8] and DCT-based [7] IrisCodes with $\alpha = 0.25$. From this figure, it can be seen that in both the cases, the conventional IrisCodes fail to distinguish the classes from the distances estimated. On the other hand, if the proposed mask is applied with the codes, the mode of the histograms shifted significantly showing the capability of recognizing the iris images captured in non-cooperative environments. In the experiments, it is observed that such shifting of the modes is significant for the DCT-based codes than that of the log-Gabor-based codes. Fig. 5 shows the ROC curves obtained from the proposed mask-based IrisCodes depicting the impact of using the reduced number of discriminatory bits on the recognition rate for a given false alarm. From this figure, it is seen that the recognition rate for the log-Gabor-based IrisCodes does not change significantly with the selection of discriminatory bits through the masking process. It is noted that the masking on the DCT-based IrisCodes results in excellent performance on the recognition rate. It can be seen from Fig. 5 that only using the discriminatory bits having a size of 12.5% of the traditional IrisCodes may provide a recognition accuracy of approximately 94% at a very low false alarm rate of 10^{-4}. It is worth mentioning that the proposed discriminative masking method reduces the computational complexity of comparisons of codes significantly with a slight increasing load of enrollment process.

V. Conclusion

Iris recognition from non-cooperative image acquisition is a vision for the future biometric system, as an example, please refer to the science fiction feature film, Minority Report, released in 2002. Traditional IrisCodes designed for cooperative iris images completely fail in recognizing identity in non-cooperative environments. In this context, this paper has first presented a new step-by-step approach of segmentation of iris regions from the eye images captured in such environments. Then a class-specific mask has been introduced by estimating the discrimination capability of each bit of the IrisCodes generated from the DCT and log-Gabor-based coefficients of templates. Experiments have been conducted on a well-known UBIRIS v2.0 database that was designed for investigating the performance of non-cooperative iris recognition. The histograms of the inter- and intraclass distances and the ROC curves obtained from the DCT-based and log-Gabor-based IrisCodes show that the proposed segmentation and masking process are highly effective for non-cooperative recognition, especially for the former than the latter.

***Abstract*—This paper reports some of the observations carried out on SUSE database for emotion classification. A comparative study is made to evaluate the performance of Linear Prediction Cepstral Coefficients (LPCCs) and Mel Frequency Cepstral Coefficients (MFCCs) for designing the emotion classification system for word level utterances. The significance of the orders of the coefficients has been carried out during this study. The results obtained using 12th order LPCC and 13th order MFCC are compared with respect to their reduced dimensions of lower orders. A new classification system based on the feature extraction technique using the 2nd, 3rd and 4th order coefficients of both MFCCs and LPCCs is also proposed. This paper compares the accuracy level of both MFCC and LPCC, enabling us to decide which orders of the parameters (both MFCC and LPCC) are more efficient in conveying the emotion for word level utterances. The initial experiments performed at word level utterances reveal that LPCC is more efficient in detecting emotion as compared to MFCC. Further, we noticed that the emotions conveyed in word level utterances are detected more accurately than that in sentence level utterances. The result suggests that word level approach provides better performance for emotion classification as compared to sentence level approach if the system is designed using vocal tract information only.**

***Index Terms*—Emotion, Classification, Vocal tract Characteristics, LPCC, MFCC, LP Residual, Mean Value Distance, Normalized Mean.**

I. INTRODUCTION

In present scenario, emotion classification finds its applications in several areas like human-computer interaction, speaker verification system, software engineering, animated characters, natural sounding voices [1], [2] etc. In any conversation, in addition to the information conveyed through the speech signal, the fashion in which the words are uttered also carries some important non-linguistic information such as the emotional characteristics of the speaker at that instant. Such characteristics may be parameterized to act as an emotion classifier for the speaker. The accurate classification of emotion becomes difficult in this sense that there is hardly any fixed parameter for differentiating among emotions i.e. there is no clear answer as to what the 'correct' emotion is for a given speech [2]. The situation becomes more critical when it comes to classifying similar emotions for different speakers. For example, a '*fellow'* might utter '*hello*' with a welcoming happy attitude as well as it can also mean an irritating kind of statement and certain other kind of emotions may be associated with it. Hence, it is a tough task to design a robust emotion classification system which may accurately detect the emotions of the speakers.

In order to design and train an emotion classification system, several databases (generally sentence based) have been employed like Chinese emotional database, Berlin emotional database [3], [2], SUSAS [4], IITKGP-SESC [5] etc. Generally the features extracted from a large number of speech samples are used for training the emotion classification system. However, as the databases are created by the speech samples of a fixed number of professional speakers (actors/actresses), so the parameterization of a non-professional speaker in an uncontrolled environment is going to be completely different.

Most of the algorithms used in emotion recognition are based on features extracted at sub-segmental (source excitation), segmental (vocal tract system) and supra-segmental (prosody) characteristics [6]. Though the excitation source signal contains some useful emotion oriented information, these features alone are not sufficient to provide appreciably high emotion detection performance. However the performance may be enhanced by combining spectral features. The results provided in the literature suggest that the vocal tract characteristics carry significant information about emotion. Therefore, in this paper, a comparative analysis has been carried out using MFCCs and LPCCs as acoustic features for classification of emotions. Moreover, the significance of the order of the coefficients with respect to emotion classification has also been carried out during this study. The contributions of the paper are: (a) a comparative analysis of LPCC and MFCC in context of emotion classification, (b) the significance of the order of the coefficients (either LPCC or MFCC) in case of emotion classification, (c) the word level versus sentence level utterances in conveying emotion when the system is designed using vocal tract information only.

The rest of the paper is organized as follows. Section II deals with the database used for this study and different feature extraction techniques for extracting vocal tract information from the speech signal. The emotion modeling technique used in this paper has been discussed in section III. Section IV highlights the experimental observations made during this study. Section V summarizes the results along with the scope for future work.

II. EMOTION CLASSIFICATION USING SUSE DATABASE

A. Database

The SUSE (Speech under Simulated Emotion) database [4] has been used during this study. The emotions considered in the database are neutral, happy, angry, loud, compassion, sad, bore, fear, lombard and question. The database contains the words like break, degree, destination, hot, ten, hello etc. uttered by different speakers (two utterances per speaker) for different words in all the emotions. All speeches collected in this database are sampled at 8 KHz and sampling frequency with 16 bits/sample resolution.

For the system proposed here, only four emotions-anger, lombard, neutral and question-have been used.

B. Feature Extraction Technique

The emotions of a particular speaker lies at sub-segmental (source excitation), segmental (vocal tract system) and supra-segmental (prosody) levels in the speech signal. The literature reveals that vocal tract characteristics are more significant in case of emotion classification. Two acoustics such as LPCC and MFCC are generally used to represent the vocal tract characteristics. These two feature extraction techniques are discussed as:

1) Mel Frequency Cepstral Coefficients:

Non-linear Mel scale filter bank is used to emphasize lower frequency components over higher ones because of the following two reasons:

- Lower frequency components of any speech sample carry more phoneme information.
- Human auditory system processes speech signals in a non-linear fashion.

In speech processing, Mel Frequency Cepstrum Coefficients (MFCC) is a representation of the short term power spectrum of a speech frame using linear cosine transform of log power spectrum on a non-linear Mel frequency scale. The notable difference between the normal cepstrum and MFCC is that in MFCC, the frequency bands spacing in the Mel scale increases gradually as we move from lower to higher frequency regions and gives the perception of a human ear, which approximates our auditory system's response more closely than the linearly spaced frequency bands.

Conversion formula from normal frequency *f (linear scale)* to Mel frequency *m (Mel scale)* is:

$$m = 2595 \log_{10}\left(\frac{f}{700} + 1\right) \tag{1}$$

The various studies suggest that MFCCs provide an appreciable performance while classifying various emotions. The experiments carried out on IITKGP-SESC database suggest that the average emotion classification performance using MFCC features (using block processing approach) is 63.38%, while that using MFCC with Formant features is 68% [7].

2) Linear Prediction Cepstral Coefficients:

In the context of emotion classification, LPCCs are used to capture emotion specific information manifested through vocal tract characteristics of the speaker. In this paper, the 12th order LPCC has been calculated per speech frame of 20 ms using a frame shift of 10ms (20±50%).

The key idea behind LP analysis is that m^{th} speech sample can be predicted by linear combination of its previous n samples i.e.

$$S(m) \approx a_1 S(m-1) + a_2 S(m-2) + \cdots + a_n S(m-n) \tag{2}$$

where $a_1, a_2, a_3, \ldots$ are the constants (known as LP Coefficients) over a speech analysis frame. These coefficients are employed to predict the speech samples. Further the error in prediction $(e(m))$is calculated by

$$(e(m)) = S(m) - \hat{S}(m) = S(m) - \sum_{k=1}^{n} a_k\, S(m-k) \tag{3}$$

where $S(m)$ and $\hat{S}(m)$ are the original and predicted speech signals respectively. Now in order to compute a unique set of predictor coefficients, sum of squared

$$E_m = \sum_p [S_m(m) - \sum_{k=1}^{n} a_k S_m(p-k)]^2 \tag{4}$$

where p is the number of samples in a particular analysis frame. To solve above equation for LPCC, E_m has to be differentiated with respect to each a_k and equating the result to zero as

$$\frac{\partial E_m}{\partial a_k} = 0 \qquad for\ k = 1, 2, 3 \ldots n \tag{5}$$

After evaluating all a_k, we may find Cepstral coefficients using the following recursion:

$$C_0 = \log_e n \tag{6}$$

$$C_p = a_p + \sum_{k=1}^{p-1} \frac{k}{p} C_k\, a_{p-k} \quad for\ 1 < p < n \tag{7}$$

$$C_p = \sum_{k=p-n}^{p-1} \frac{k}{p} C_k\, a_{p-k} \qquad for\ p > n \tag{8}$$

The emotion classifier using LPCC provides better results as compared to MFCC. The experimental observation (performed on IITKGP-SESC) indicate that the average emotion recognition using LPCC features (using block processing approach) is 68%, while that using LPCC with Formant features is 69% [7].

III. EMOTION MODELING TECHNIQUE

Several authors have proposed their algorithms using excitation source, vocal tract system and prosodic features. While using spectral features, more often vector quantization

[8] is performed and consequently LBG algorithm [9], [10] is used for training purposes

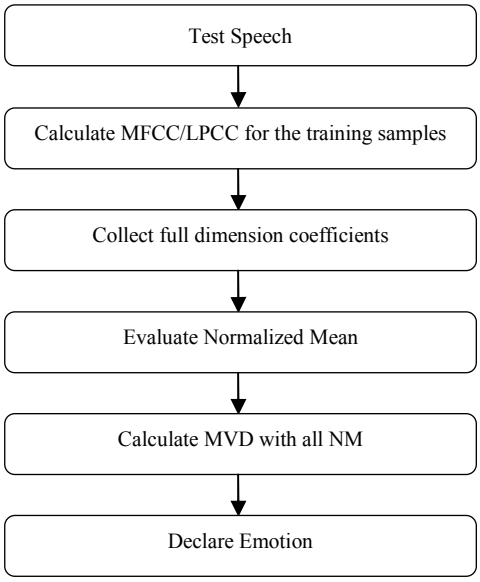

Fig. 2. System Modeling (full dimension)

.

The modeling technique has been devised using both LPCC and MFCC. Initially the technique was formulated using the full dimension of the spectral features (i.e. up to 12th order and 13th order in case of LPCCs and MFCCs respectively). The reduced dimension using various orders has been explored for designing emotion classification system. It has been observed that the feature vector derived using the 2nd, 3rd and 4th order dimension provides an almost equivalent performance as compared to its full dimension.

For training purposes, ten speech samples (regardless of the speaker and the text) for all the four emotions were taken. Initially, using the full dimension MFCC/LPCC, a normalized mean (NM) was set as a reference template for all the four emotions. While testing, when some input speech sample was fed, the mean value distance (MVD) between the full frame coefficients (MFCC/LPCC) of the input sample and the reference template of all the emotions was evaluated. The emotion was declared to be one which showed minimum distance with the input sample.

Later, while using reduced dimension (for both LPCC/MFCC), the same methodology was followed but this time, the normalized mean was set using only the 2nd, 3rd and 4th order coefficients. The flow chart depicting the full dimension model in Fig.2 and reduced dimension in Fig.3.

IV. Experimental Observations

The experimental observations (using full dimension) carried out on the sentence level utterances (IITKGP-SESC) depict that the average emotion recognition using MFCCs is 63.38%, whereas it is 68% using LPCCs [7]. In the proposed system (carried out on SUSE database), the performance of emotion classification using full dimension is provided in table I.

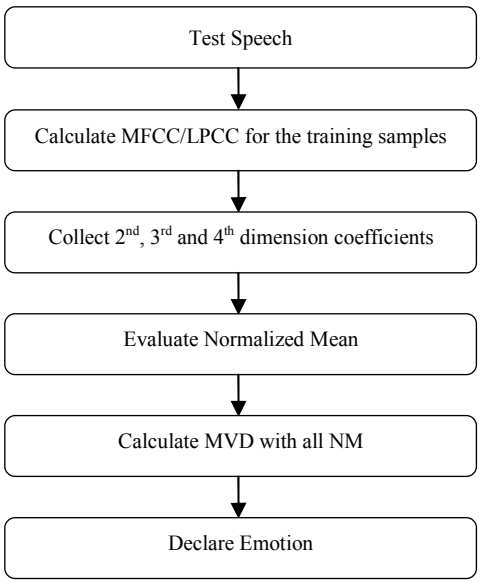

Fig. 3. System Modeling (reduced dimension)

It has been observed table I, in case of full dimension approach, the accuracy of emotion classification system designed using MFCC as acoustic feature is 79.52% (EER 20.48%) and that for LPCC is 83.60% (EER 16.40%).

The experiment has been carried to verify the importance of acoustic dimension of LPCC/MFCC with respect to their contribution in the spoken utterances like words. The framework of the experiment is designed using the reduced dimensions of LPCC/MFCC. Various combinations of the dimensions have been explored during this study. The study reveals that the feature vectors designed using the reduced dimensions provide comparable results as that of the full

TABLE I. Emotion Recognition Performance (In %) Using Full Dimension MFCC/LPCC

Emotion	MFCC Approach		LPCC Approach	
	EER	Accuracy	EER	Accuracy
Anger	20.99	79.01	23.67	76.33
Lombard	14.61	85.39	12.61	87.39
Neutral	18.67	81.33	18.67	81.33
Question	27.68	72.32	10.68	89.32
Average	20.48	79.52	16.40	83.60

TABLE II. Emotion Recognition Performance (in %) using reduced dimension MFCC/LPCC

Emotion	MFCC Approach		LPCC Approach	
	EER	Accuracy	EER	Accuracy
Anger	10.27	89.73	15.00	85.00
Lombard	28.61	71.39	20.00	80.00
Neutral	30.00	70.00	23.89	76.11
Question	31.94	68.06	26.39	73.61
Average	25.20	74.80	21.32	78.68

dimension for emotion classification. The experimental results showed that the performance for reduced dimensions is less than 4-5% as compared to that of full dimensions. It has been observed from table II, the accuracy of reduced MFCC based system is 74.80% (EER 25.20%) and that for LPCC based system is 78.68% (EER 21.32%).

The results obtained from the tables suggest that the acoustic feature derived using lower order coefficients (2nd, 3rd and 4th) carry significant information about the emotion in a spoken utterance. It is apparent that the emotional characteristic may contain in the low frequency regions of the spoken utterances. Further, it has been observed that LPCCs provides a relatively better performance as compared to MFCCs used as acoustic feature to represent the vocal tract transfer function. This may be due to more emphasis given by LPCC feature to the mid frequency bands of the spoken utterance.

The experiment has been carried out on sentence level utterances along with the word level utterances and the results were obtained as shown in table III. The experiment results obtained for sentence level utterances are similar to that of the results obtained with IITKGP-SESC [7].

The results suggest that emotion classification system designed using word level utterances provide better performance as compared to system designed using sentence level utterances. This may due to exploration of vocal tract characteristics during designing the system. However, the performance may be different when other level of acoustic features is used as complementary cues to represent the emotion.

The lower order acoustic features contain significant information about a particular emotion. The new feature set derived using the subspace has lower dimensionality. Therefore, the computational complexity as well as storage requirement may have significantly reduced. This may be helpful in case of implementation of a real time system having large databases.

TABLE III. PERFORMANCE OF SYSTEM BASED ON SENTENCE LEVEL UTTERANCES

Emotion	Emotion Recognition Performance (in %)	
	LPCCs	MFCCs
Anger	53.00	40.00
Lombard	63.00	50.00
Neutral	63.00	60.00
Question	53.00	47.00
Average	58.00	49.25

V. SUMMARY AND CONCLUSIONS

The LPCCs and MFCCs are two of the widely used acoustic features used for emotion recognition. This paper compares the relative performance of the two acoustic features for emotion classification on SUSE database. It exploits the full dimension as well as reduced dimension of both the acoustic features and tries to evaluate the relative performance of reduced dimensional acoustic feature. It has been observed that the lower order coefficients carry significant emotion specific information as compared to the higher order coefficients. It may also be concluded that LPCCs serve as a better acoustic feature as compared to MFCC for designing an emotion classification system. The study also suggests that the system designed using word level utterances provides better performance as that of sentence level utterances, using vocal tract characteristics alone. Rigorous analysis may be made based on this initial study to analyze the significance of acoustic dimensions with respect to emotion. The system may be designed with reduced acoustic dimension complemented by other level of acoustic features (such as sub-segmental and supra-segmental) to provide a robust and satisfactory performance. The high level acoustic features may also be explored to enhance the performance of emotion classification system.

Abstract—**This paper presents a watermarking approach for recovering crime scene image when the crime scene image has been tampered, based on chaotic system and singular value decomposition (SVD). At first, authentication information has been embedded into the region of information (ROI) of the scrambled crime scene image. The authentication information has been generated by using logistic map, while the scrambled crime scene image has been obtained by two dimensional Arnold's cat map. After then, ROI has been compressed by discrete cosine transform (DCT) and the compressed ROI has been embedded into region of background (ROB) by using singular value decomposition. In extraction stage, the authentication information has been extracted from the ROI of the watermarked crime scene image. If the extracted authentication information is not same as the embedded information, ROI has been extracted from the ROB. The results of the proposed method has been evaluated by using peak signal to noise ratio (PSNR) and mean squared error (MSE) performance parameters. At the same time, the proposed watermarking approach has also been compared with other methods. The proposed method gives better values of MSE and PSNR than the compared methods.**

Index Terms—**Image watermarking, Logistic map, Arnold's cat map, Singular value decomposition (SVD), PSNR, MSE.**

I. Introduction

The authenticity and integrity of an image can be ensured by using digital image watermarking scheme [1]. In many real life applications need exact authentication, such as: for diagnosing the medical images, for detecting the criminals from crime scene images.

Crime scene images consist of two parts- region of information (ROI) and region of background (ROB). For crime images, exact authentication is required in region of information. Any alternation of ROI may cause suspecting a person other than actual criminal. Watermarking is one of the possible solutions to give exact authentication in crime scene images by embedding authentication information, which is usually imperceptible.

The embedded information can be spatial domain based or transform domain based. In spatial domain based watermarking scheme, the authentication information is directly embedded into the pixels gray intensities. The authentication information has been embedded into the coefficients of transformed image in transform domain based watermarking [2]-[4].

The watermark can be classified into two ways as fragile and robust watermark according to its nature. Further, fragile watermark can also be classified into two ways as complete fragile and semi-fragile watermarks. Complete fragile watermarks are used for image tamper detection [5], [6]. Semi-fragile watermarks are commonly used for detecting the modified areas which has been tampered by the attackers and recovering the remaining watermarks from the undamaged areas [7]. Robust watermarks are difficult to remove by the attackers and shows robustness against different types of attacks [8].

In recent years, various watermarking methods have been proposed for recovering the tampered areas, which are applicable in crime detection [9], [10]. In these methods, the input image has been divided into two regions, ROI and ROB. The information of ROI has been embedded into ROB. Therefore, if ROI has been tampered, it can be recovered from ROB.

In this paper, SVD and chaotic system based watermarking approach has been proposed for recovering crime scene image from tampered image. The authentication information generated by logistic map has been embedded into scrambled ROI. After that, compressed ROI has been embedded into ROB. ROI has been extracted in the extraction stage, when the extracted authentication information is not same as the embedded authentication information.

The rest of this paper is organized as follows. The proposed watermarking approach with details has been explained in section II. Section III depicts the experimental results and comparison. Finally, section IV concludes the paper.

II. Proposed Watermarking Approach

In the proposed watermarking approach, gray scale crime scene image has been considered, which consists of region of information (ROI) and region of background (ROB). The proposed scheme designed the algorithm in four stages. In first stage, the authentication information has been embedded into ROI of the image. After that, ROI has been compressed in the second stage. After completing second stage, the compressed ROI has been embedded into ROB of the image in the third stage. Finally, in fourth stage or extraction stage, the ROI has been extracted from the ROB. ROI extraction only occurs when the extracted authentication information is not same as the embedded authentication information.

A. Embedding Authentication Information into ROI

In this stage, the authentication information has been embedded into ROI of crime scene image, depicted in Algorithm 1. The proposed model generates random number sequences as authentication information by using logistic map,

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

which is one of the simplest chaotic maps. The map generates random number sequences or authentication information for the proposed scheme as follows-

$$x_{n+1} = \mu x_n (1 - x_n) \tag{1}$$

where, $0<\mu\leq 4$. The map is highly sensitive to the initial conditions. Different initial values generate different random number sequences, which are shown in Fig. 1.

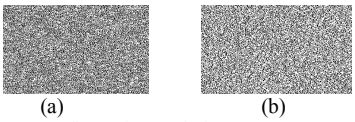
The generated authentication information has been embedded into ROI image, but not in a consecutive way. The generated authentication information has been embedded into the least significant bit (LSB) plane of scrambled ROI image. Therefore, the attacker will not be able to forge the authentication information as the information has been embedded into the scrambled ROI image. ROI image has been scrambled by using 2D Arnold's cat map to improve the security of embedding the authentication information. Without changing pixels gray level intensities, 2D Arnold's cat map shuffles the pixels positions according to the initial conditions and number of iterations. Arnold's cat map shuffles the pixels positions as follows-

$$\begin{bmatrix} x_{n+1} \\ y_{n+1} \end{bmatrix} = \begin{bmatrix} 1 & a \\ b & ab+1 \end{bmatrix} \begin{bmatrix} x_n \\ y_n \end{bmatrix} \bmod N = A \begin{bmatrix} x_n \\ y_n \end{bmatrix} \bmod N \tag{2}$$

where, N is the dimension of the image, a and b are the control parameters and $det\ (A) = 1$. The map is periodic in nature, which means pixels back to their original positions after performing several iterations. The periodic phenomenon of Arnold's cat is shown in Fig. 2. After embedding authentication information into the scrambled ROI image, inverse cat map has been applied to the scrambled ROI image to back the pixels to their original positions.

B. Region of Information (ROI) Compression Using DCT

The ROI of crime scene image has been compressed using discrete cosine transform (DCT), described in Algorithm 2. JPEG image compression standard uses DCT which is a fast transform, widely used and robust method for image compression. At first, ROI image has been divided into several $m_1 \times n_1$ blocks. After then, DCT has been applied to each block to obtain DCT coefficients. The upper half part of DCT coefficients of each $m_1 \times n_1$ block has been taken and the lower half part of each $m_1 \times n_1$ block has been made to zero. After performing this action, inverse discrete cosine transform (IDCT) has been applied to each block to get the compressed ROI crime scene image.



(a) (b)

Fig. 1 Two random configurations of size 128×128, generated by logistic map, initial conditions of (a) μ=3.90 and x(1)=0.4545; (b) μ=3.93 and x(1)=0.4545.

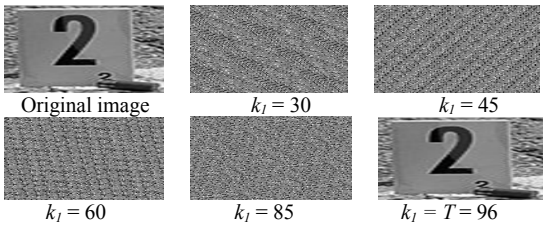


Fig. 2 Periodic phenomenon of Arnold's cat map, shows period (T) at $k_1 = 96$ of 128×128 image.

Algorithm 1 Embedding authentication information

1. Input: ROI of crime scene image
2. Output: ROI crime scene image with authentication information.
3. Scramble ROI using 2D Arnold's cat map.
4. Generate random number sequences as authentication information (*AI*) using logistic map.
5. Embed authentication information into LSB of scrambled ROI image.
6. Apply inverse cat map and obtain ROI image with authentication information.

Algorithm 2 ROI compression

1. Input: ROI image.
2. Output: Compressed ROI image.
3. Extract ROI from the crime scene image.
4. Apply DCT to ROI image to obtain its DCT coefficients.
5. Make the lower energy of DCT coefficients to zero
6. Apply IDCT to obtain compressed ROI image.

C. Embedding ROI into ROB of Crime Scene Image

The information of compressed ROI has been embedded into the ROB of crime scene image, described in Algorithm 3. For this process, singular value decomposition (SVD) [11] has been applied to the ROB of crime scene image. SVD decomposes ROB in orthogonal matrix U_{ROB}, diagonal matrix S_{ROB} and transpose of orthogonal matrix V_{ROB}. The singular values diagonal matrix (S_{ROB}) has been used as a marking space in which ROI information has been embedded. On the other hand, SVD has also been applied to ROI to decompose ROI in U_{ROI}, S_{ROI} and V_{ROI}. After applying SVD to ROI, S_{ROI} has been converted to real numbers in [0 255] domain as follow-

$$\beta = 255 / S^1_{ROI} \tag{3}$$

$$S^i_{c_ROI} = S^i_{ROI} \times \beta \tag{4}$$

where, S_{c_ROI} represents converted S_{ROI}, r is the rank of the matrix S_{ROI} and β is the converting coefficient. S_{ROI} has been converted to S_{c_ROI} to increase the perceptual similarity of watermarked image.

After then, the S_{c_ROI} has been embedded with S_{ROB} as follows-

$$S'_{ROB} = S_{ROB} + \left(\alpha \times k \times S_{c_ROI}\right) \tag{5}$$

where, α and k are the embedding factors. Finally, inverse SVD has been applied to ROB image to obtain watermarked ROB image in which the information of compressed ROI has been embedded. Therefore, watermarked crime scene image consists of authentication information into ROI and the information of ROI into ROB, which are invisible to human eyes.

D. Recovering ROI from ROB of Crime Scene Image

At first, the authentication information has been extracted from the scrambled ROI image. If the ROI image has been tampered, the extracted authentication information will not be same as the embedded information. In that case, the tampered areas can be located by applying logical Exclusive-or (X-or) between embedded and extracted authentication information.

At the same time, tampered areas can also be recovered from ROB of watermarked crime scene image.

For recovering the embedded information of ROI from the watermarked ROB, SVD has been applied to the watermarked ROB to obtain singular values diagonal matrix (S'_{ROB}). The singular values diagonal matrix which was embedded with singular values diagonal matrix of original ROB (S_{ROB}), can be extracted by-

$$(S_{c_ROI})^{ext} = \left(S'_{ROB} - S_{ROB}\right)/\left(\alpha \times k\right) \tag{6}$$

After extraction, $(S_{c_ROI})^{ext}$ has been converted to the original range to obtain the original singular values diagonal matrix (S_{ROI}) of ROI image, which has been obtained by-

$$S_{ROI}^{ext} = (S_{c_ROI}) / \beta \tag{7}$$

Finally, the ROI of crime scene image can be recovered by applying inverse SVD, which can be described by-

$$ROI' = U_{ROI} S_{ROI}^{ext} (V_{ROI})^T \tag{8}$$

where, ROI' is the recovered ROI from the watermarked ROB image, when the image has been tampered by the attackers.

III. Experimental Results and Comparison

In experimental evaluation, various crime scene images of different sizes have been taken as input images and proposed scheme has been applied on them.

The proposed approach firstly uses Algorithm 1 to embed the authentication information into the region of information of the crime scene image. Using Algorithm 2, ROI image has been compressed by discrete cosine transform (DCT). With the help of singular value decomposition (SVD), compressed ROI has been embedded into ROB by using Algorithm 3.

Algorithm 3 Embedding information of ROI into ROB

1. Input: Crime scene image I, ROB, compressed ROI image.
2. Output: Watermarked crime scene image I_w.
3. Apply SVD to ROB to obtain singular values diagonal matrix (S_{ROB}).
4. Apply SVD to compressed ROI to obtain S_{ROI}.
5. Convert S_{ROI} into the range of [0-255].
6. $S'_{ROB} = S_{ROB} + (\alpha \times k \times S_{c_ROI})$, where S_{c_ROI} represents converted S_{ROI}, α and k are the scaling factors.
7. Apply inverse SVD on ROB to obtain I_w, in which ROI information is embedded into ROB.

Algorithm 4 Recovering information of ROI from ROB

1. Input: Watermarked crime scene image I_w.
2. Output: Recovered ROI from ROB.
3. Extract authentication information (AI') from ROI.
4. **if** $AI' == AI$
5. Do nothing
6. else
7. Apply SVD to ROB to obtain S'_{ROB}.
8. $S_{c_ROI} = (S'_{ROB} \square S_{ROB}) / (\alpha \times k)$.
9. Convert S_{c_ROI} to original range to get S_{ROI}.
10. Obtain recovered ROI by applying inverse SVD.
11. **end**

Finally, by applying Algorithm 4, the ROI has been recovered from ROB in the extraction stage.

Fig. 3(a) shows a crime scene image of evidence marker with bullet shell. The ROI of this crime scene image is shown in Fig. 3(b), while Fig. 3(c) shows the ROB of the image. Fig. 3(d) shows the watermarked crime scene image in which the authentication information has been embedded into ROI and the DCT compressed ROI has been embedded into ROB image. The bullet shell that was shown in Fig. 3(a) has been removed from ROI, which is shown in Fig. 4(b). Fig. 4(c) depicts the located tampered areas and Fig. 4(d) shows the recovered bullet shell have been obtained by the proposed approach.

Fig. 5 shows another crime scene image which has been tampered and recovered subsequently in Fig. 6. Fig. 5(b) shows the ROI of crime scene image of Fig. 5(a), while ROB is shown in Fig. 5(c). The watermarked image of Fig. 5(a) is shown in Fig. 5(d). In Fig. 6(b), the ROI of Fig. 5(a) has been tampered by the third parties, in which the spot of attacked leg by bullet has been removed. The tampered areas have been located by the proposed scheme, which is shown in Fig. 6(c). The tampered image has also been recovered by the proposed approach, as shown in Fig. 6(d).

The performance of the proposed approach has been evaluated by using two performance parameters- (1) mean square error (MSE) and (2) peak signal to noise ratio (PSNR).

A. Mean Squared Error (MSE)

MSE is used to test the similarity between two images. The MSE between original image and watermarked image can be obtained by-

$$MSE = \frac{1}{MN}\sum_{x=0}^{M-1}\sum_{y=0}^{N-1}\left(I(x,y)-I'(x,y)\right)^2 \quad (9)$$

where, I and I' are the original image and watermarked image, respectively, having resolution of $M \times N$ pixels.

B. Peak Signal to Noise Ratio (PSNR)

PSNR is usually used to measure the quality of the image which is attacked by low quality of noise. In the proposed watermarking scheme, PSNR has been used to measure the quality of the watermarked image and also the quality of the recovered image. PSNR can be obtained by-

$$PSNR = 10\log_{10}\frac{\max^2}{MSE} \quad (10)$$

where, max is the maximum gray level of the image. For 8-bit image $max = 255$.

TABLE I shows MSE and PSNR values of watermarked image of the proposed watermarking approach with different values of embedding factor. For embedding ROI into ROB using (5) two embedding factors (k and α) have been used. Different values of α and a fixed value of k (k = 0.01) have been used in the proposed watermarking scheme for embedding ROI into ROB. Investigating TABLE I, it can be seen that with the increasing values of α, values of MSE increases and Values of PSNR decreases. But for all values of embedding factor, the proposed approach maintains satisfactory results of MSE and PSNR, which proves that the watermarked image maintains perceptual similarity with good quality. Fig. 7 graphically shows the relationship between α and PSNR values of the proposed method for both given images.

TABLE II depicts the performance comparison between the proposed watermarking method and other two methods for bullet shell image. MSE and PSNR values of watermarked image and recovered image for proposed method and other methods have been shown in TABLE II. From TABLE II, it can be said that the proposed method dominates the other methods in MSE and PSNR values.

TABLE I
MSE AND PSNR VALUES OF WATERMARKED IMAGE

Embedding factor (α)	Bullet Shell		Attacked Leg	
	MSE	PSNR	MSE	PSNR
10	0.59	50.44	0.49	51.23
20	1.17	47.43	0.93	48.46
30	2.66	43.88	2.52	44.12
40	4.38	41.72	4.12	41.98
50	6.83	39.78	6.35	40.10
60	9.71	38.26	8.34	38.92
70	13.15	36.94	11.22	37.63
80	17.10	35.80	15.42	36.25

TABLE II
COMPARISON RESULTS OF MSE AND PSNR VALUES OF WATERMARKED IMAGE AND RECOVERED IMAGE

Methods	Watermarked Image		Recovered Image	
	MSE	PSNR	MSE	PSNR
Method [9]	6.94	39.72	10.52	37.91
Method [10]	4.51	41.59	9.91	38.17
Proposed Method	0.59	50.44	1.17	47.46

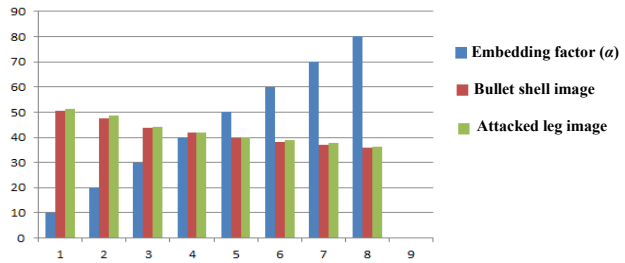

Fig. 7 (a) Relationship between α and PSNR values of proposed method for both images.

IV. CONCLUSION

This paper proposed a watermarking approach for recovering crime scene image from tampered image. Using chaotic system, authentication information has been embedded into ROI and the information of ROI has been embedded into ROB. SVD has been used for embedding process to increase the perceptual similarity. High values of PSNR have been obtained both for watermarked image and recovered image of the proposed watermarking approach. In addition, the presented method has also been compared with other two state-of-arts methods. The proposed scheme dominates the other methods in MSE and PSNR values, which proves that the proposed watermarking approach maintains good qualities of watermarked image and recovered image.

Chittagong University of Engineering and Technology (CUET)
Chittagong-4349, Bangladesh
pranabdhar81@gmail.com

Abstract— **This paper presents a blind audio watermarking method based on lifting wavelet transform (LWT) and QR decomposition (QRD) for audio copyright protection. In our proposed method, initially the original audio is segmented into non-overlapping frames. Watermark information is embedded into the largest element of the upper triangular matrix obtained from the low frequency LWT coefficients of each frame. A blind watermark detection technique is introduced to identify the embedded watermark under various attacks. Simulation results indicate that the proposed watermarking method is highly robust against different attacks. In addition, it has high data payload and provides good imperceptible watermarked sounds. Moreover, it shows superior performance than the state-of-the-art watermarking methods reported recently.**

Index Terms— **copyright protection; lifting wavelet transform; QR decomposition.**

I. Introduction

The recent development of digital world has greatly facilitated the transmission and manipulation of multimedia data such as text, image, audio, and video. Easy access and duplication of multimedia data have led to serious problem for copyright protection. Digital watermarking has drawn extensive attention for protecting multimedia data from unauthorized copying. Therefore, media owners can use this technique to insert some information into their digital contents to show authenticity and ownership. This technique has several applications such as content authentication, copyright protection, data indexing, broadcast monitoring, fingerprinting, medical safety, and so on. In recent years, a significant number of audio watermarking techniques have been reported. A comprehensive survey on audio watermarking can be found in [1]. Most audio watermarking methods utilize either a time domain [2]-[3] or a transform domain such as discrete wavelet transform (DWT) [4]-[5], discrete cosine transform (DCT) [6], fast Fourier transform (FFT) [7], and discrete fractional sine transform (DFST) [8]. Time domain methods are very efficient and easy to implement, however, transform domain methods can provide high robustness. Conventional wavelet transform provides good results for its multi resolution characteristics and perfect reconstruction. However, it is mainly calculated by convolution operation, resulting in high computation. In addition, the generated floating numbers increase storage requirements. As a result, the lifting wavelet transform (LWT) [9] is designed to increase the efficiency and it is now used in audio watermarking [10]. Moreover, some other techniques such singular value decomposition (SVD) [11]-[14], empirical mode decomposition (EMD) [15], patchwork algorithm [16], and audio histogram techniques [17]-[18] are becoming popular in audio watermarking field.

In this paper, a blind audio watermarking method based on LWT and QR decomposition (QRD) is proposed. The main features of the proposed method include (*i*) it utilizes the LWT and QRD jointly, (*ii*) it uses Bernoulli map, containing the chaotic characteristic to enhance the confidentiality of the proposed method, (*iii*) watermark extraction process is blind, (i*v*) subjective and objective evaluations reveal that the proposed method maintains a high audio quality, and (*v*) it achieves a good trade-off among imperceptibility, robustness, and data payload. Simulation results demonstrate that the proposed watermarking method shows high robustness against various attacks such as noise addition, cropping, re-sampling, re-quantization, and MP3 compression. Moreover, it outperforms the state-of-the-art methods [4]-[5], [7], [11], [13], [15]-[18] in terms of imperceptibility, robustness, and data payload. The data payload of the proposed method is 172.39 bps which is relatively higher than that of the state-of-the-art methods.

The rest of this paper is organized as follows. Section II discusses the background information including LWT and QRD. Section III introduces our proposed watermarking method including watermark pre-processing, watermark embedding and detection processes. Section IV presents the experimental results of the proposed method. Lastly, Section V concludes this paper.

II. Background Information

A. Lifting Wavelet Transform

The LWT is designed to reduce the computation time and memory requirement. It has several unique properties in comparison with traditional wavelet: (*i*) it allows an in-place implementation of the fast wavelet transform thus it can be calculated more efficiently and needs less memory space, (*ii*) it is particularly easy to build non-linear wavelet transforms, (*iii*) it has the frequency localization features which overcome the weakness of the traditional wavelet transform. The main principle of the lifting wavelet is to construct a new wavelet with better characteristics based on a simple wavelet. Lifting wavelet scheme consists of three steps: split/merge, prediction, and update. The detailed reasoning and proof of the lifting scheme is given in [9].

B. QR Decomposition

In QRD, the orthogonal-triangular decomposition of a matrix is performed with the following definition:

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

$$[Q,R]=qr(A) \tag{1}$$

where R is an $m\times m$ upper triangular matrix and Q is an $m\times m$ unitary matrix, so that $A=QR$. The columns of Q are obtained from the columns of A by Gram-Schmidt orthogonalization process. One of the good properties of R matrix is that when columns of A have correlation with each other, the absolute values of the elements in the first row of R matrix are probably greater than those in other rows. This property can be utilized for embedding watermark in audio signal.

III. Proposed Watermarking Method

Let $X=\{x(n),\ 1\le n\le L\}$ be an original audio signal with L samples, $W=\{w(i),\ 1\le i\le I\}$ be a binary watermark sequence to be embedded into the original audio signal.

A. Watermark Preprocessing

To enhance the security of the proposed method, watermark sequence should be preprocessed first. The proposed method utilizes a Gaussian map, containing the chaotic characteristics to encrypt the binary watermark sequence for enhancing the confidentiality of the proposed method. It can be defined as follows:

$$y(i+1)=\exp\left(-a(y(i))^2\right)+b \tag{2}$$

where $y(1)\in(0,1)$, a and b are real parameters (map's initial condition). Then $y(i)$ is mapped using the following rule:

$$z(i)=\begin{cases}1 & if\ y(i)>T\\ 0 & otherwise\end{cases} \tag{3}$$

where T is a predefined threshold. Finally $w(i)$ is encrypted by $z(i)$ with the following rule:

$$u(i)=z(i)\oplus w(i),\quad 1\le i\le I \tag{4}$$

where $\oplus$ is the exclusive-or (XOR) operation and $u(i)$ is the encrypted watermark sequence. After applying this chaotic encryption technique, the original watermark is encrypted and can not be found by random search. In this study, the value of $y(1)$, a, and b are used as secret key K.

B. Watermark Embedding Process

The proposed watermark embedding process is described as follows:

1) The original audio signal X is first segmented into non-overlapping frames $F=\{F_1, F_2, F_3,.....,F_I\}$.

2) A two-level LWT is performed on each frame F_i. This operation produces three sets of coefficients D_1, D_2, and A_2, where D_1, D_2 and A_2 represent the detailed and approximate coefficients, respectively.

3) The approximate coefficients A_2 of each frame F_i are rearranged into an $N\times N$ square matrix H_i. This is done by dividing the coefficient set into N segments with N coefficients.

4) QRD is performed to decompose each matrix H_i into two matrices: upper triangular matrix R_i and unitary matrix Q_i. The QRD operation is represented as follows:

$$[Q_i,R_i]=qr(H_i) \tag{5}$$

5) In order to guarantee the robustness and transparency, the proposed method embeds watermark bits into the largest element of each matrix R_i using a quantization function. Let $Y_i=round\left(\frac{R_{i(\max)}}{D}\right)$, where D is a predefined quantization coefficient and $R_{i(\max)}$ is the largest element of each R_i. The embedding equation is given as follows:

$$Y_i'=\begin{cases}Y_i+C-(Y_i \bmod M), & if\ u(i)=1\\ Y_i+C-((Y_i+C) \bmod M), & if\ u(i)=0\end{cases} \tag{6}$$

where $M=2C$, C is an integer, mod is the modulo operation.

6) The modified largest element $R'_{i(\max)}$ of each matrix R_i is calculated using the following equation:

$$R'_{i(\max)}=Y_i'D \tag{7}$$

where R'_i is the upper triangular matrix.

7) Reinsert each modified largest element $R'_{i(\max)}$ into each matrix R_i and inverse QRD is applied to obtain the modified matrix H_i' which is given by

$$H_i'=Q_iR_i' \tag{8}$$

Each matrix H_i' is then reshaped to create the modified approximate coefficients A'_2 of each frame F_i by performing the inverse operation of step 3.

8) After substituting the modified approximate coefficients A'_2 for A_2, a two-level inverse LWT is performed to obtain the watermarked audio frame F_i'.

9) Finally, all watermarked frames are concatenated to calculate the watermarked audio signal X'.

C. Watermark Detection Process

The proposed watermark detection process is described as follows which does not need the original audio signal to extract the watermark.

1) A two-level LWT is performed on each frame F_i^* of the attacked watermarked audio signal.

2) The approximate coefficients A_2^* of each frame F_i are rearranged into an $N\times N$ square matrix H_i^*.

3) QRD is performed on each R_i^* and select the largest element $R^*_{i(\max)}$ from each matrix R_i^* of the attacked watermarked audio frame.

4) Calculate Y_i^* of each $R^*_{i(\max)}$.

5) Encrypted watermark sequence is extracted as follows:

$$u^*(i)=\begin{cases}1 & if\ (Y_i^* \bmod M)=1\\ 0 & otherwise\end{cases} \tag{9}$$

6) Perform chaotic decryption using the secret key K to find the binary watermark sequence with the following rule:

$$w^*(i)=z(i)\oplus u^*(i) \tag{10}$$

IV. Simulation Results

In this section, several experiments were conducted on four different types of 16 bit mono audio signals (Pop, Jazz, Classical, and Speech) sampled at 44.1 kHz to demonstrate the performance of the proposed method. Each audio file contains 262,144 samples (duration 5.94 sec). Each audio signal is divided into frames of size 256 samples. Thus, the total number of frames is 1024. In each frame of audio signal, we embed one bit watermark data. In this study, the selected value for $y(1)$, a, b, T and M are 0.4, 5.90, -0.39, 0.25, and 1, respectively. These parameters have been selected in order to achieve a good trade-off among the conflicting requirements of imperceptibility, robustness, and data payload.

A. Imperceptibility Test

The imperceptibility of the watermarked audio signal is evaluated by using two ways: (*i*) subjective listening test (*ii*) objective test.

1) Subjective Listening Test

An informal subjective listening test was performed to evaluate the perceptual quality of the watermarked audio. Ten listener involved in this listening test and were asked to classify the differences between them, using a five point subjective difference grade (SDG) ranges from 5.0 to 1.0 (imperceptible to very annoying) as shown in Table I. The average SDG (i.e., mean opinion) scores for different watermarked sounds using the proposed method are shown in Table II. From the test results, we observed that the average mean opinion score (MOS) of all watermarked sound using the proposed method is 4.90, indicating that original and watermarked audio signals are perceptually similar.

TABLE I. SUBJECTIVE AND OBJECTIVE DIFFERENCE GRADES

SDG	ODG	Description	Quality
5	0	Imperceptible	Excellent
4	-1	Perceptible, but not annoying	Good
3	-2	Slightly annoying	Fair
2	-3	Annoying	Poor
1	-4	Very annoying	Bad

TABLE II. MOS, ODG AND SNR RESULTS FOR DIFFERENT WATERMARKED SOUNDS

Types of Signal	MOS	ODG	SNR
Pop	4.9	-0.74	34.65
Jazz	5.0	-0.56	35.48
Classical	4.9	-0.79	34.93
Speech	4.8	-0.83	33.26
Average	**4.9**	**-0.73**	**34.58**

2) Objective Test

Objective test was conducted using the objective difference grade (ODG) which is one of the output values obtained from the perceptual evaluation of audio quality (PEAQ) measurement technique specified in ITU-R BS.1387 (International Telecommunication Union-Radio-communication Sector) standard [19]. It corresponds to the subjective grade used in human based audio tests. The ODG ranges from 0.0 to -4.0 (imperceptible to very annoying) as shown in Table I. The objective quality of the watermarked audio signals is calculated in terms of ODG and shown in Table II. We observed that the average ODG value is -0.73, indicating that original and watermarked audio signals are perceptually indistinguishable.

Objective evaluation was also done by calculating the SNR which is given by

$$SNR = 10\log_{10}\frac{\sum_{i=1}^{L} x^2(n)}{\sum_{i=1}^{L}\left[x(n)-x^*(n)\right]^2} \quad (11)$$

where $x(n)$ and $x^*(n)$ are the original and watermarked audio signals in time domain, respectively. According to the International Federation of the Phonographic Industry (IFPI) standard [13], audio watermarking should be imperceptible when SNR is over 20 dB. After embedding watermark information, the SNRs of the watermarked audio signals using the proposed method are above 20 dB, shown in Table II, which satisfied the IFPI standard.

The proposed method was compared with the several recent methods in terms of the SNR and MOS. This comparison is based on the reported results in [4]-[5], [7], [11], [15]-[16] as shown in Table III. From the comparison of results, it is seen that our proposed method outperforms the recent watermarking methods in terms of SNR and MOS, indicating the high transparency of the watermarked audio signals.

TABLE III. SNR AND MOS COMPARISON BETWEEN THE PROPOSED AND SEVERAL RECENT METHODS

Reference	Algorithm	SNR	MOS
[5]	DWT-based energy proportion	17.95	4.15
[4]	Wavelet-based entropy	22.46	4.38
[15]	EMD	24.12	--
[16]	Patchwork	24.95	4.67
[7]	FFT amplitude modification	25.70	--
[11]	DCT-SVD	32.53	4.71
Proposed	**LWT-QRD**	**34.58**	**4.90**

B. Robustness Test

Various signal processing attacks summarized in Table IV were performed to assess the robustness of the proposed method.

TABLE IV. ATTACKS USED IN THIS STUDY FOR WATERMARKED SOUND

Attacks	Description
Noise addition	Additive white Gaussian noise (AWGN) is added to the watermarked audio signal.
Cropping	1000 samples are removed from the beginning of the watermarked signal and then these samples are replaced by the watermarked samples attacked with AWGN.
Re-sampling	The watermarked signal originally sampled at 44.1 kHz is re-sampled at 22.050 kHz and then restored by sampling again at 44.1 kHz.
Re-quantization	The 16 bit watermarked audio signal is quantized down to 8 bits/sample and again re-quantized back to 16 bits/sample.
MP3 Compression	MPEG-1 layer 3 compression with 128 kbps is applied to the watermarked audio signal.

TABLE V. NC AND BER OF THE EXTRACTED WATERMARK FOR DIFFERENT AUDIO SIGNALS

Audio Signal	Attack Type	NC	BER (%)
Pop	No attack	1	0
	Noise addition	0.9919	0.9766
	Cropping	0.9926	0.8789
	Re-sampling	0.9894	1.2695
	Re-quantization	1	0
	MP3 compression	0.9822	2.1484
Jazz	No attack	1	0
	Noise addition	0.9943	0.6836
	Cropping	0.9992	0.0977
	Re-sampling	0.9918	0.9766
	Re-quantization	1	0
	MP3 compression	0.9748	3.0303
Classical	No attack	1	0
	Noise addition	0.9959	0.4883
	Cropping	0.9984	0.1953
	Re-sampling	0.9910	1.0742
	Re-quantization	1	0
	MP3 Compression	0.9721	3.3203
Speech	No attack	1	0
	Noise addition	0.9951	0.5865
	Cropping	0.9976	0.2930
	Re-sampling	0.9902	1.1719
	Re-quantization	1	0
	MP3 Compression	0.9737	3.1250

Normalized correlation (NC) coefficient is used to compare the similarities between the original watermark W and the extracted watermark W^*, which is calculated as:

$$NC\,(W,W^*) = \frac{\sum_{i=1}^{I} w(i)\cdot w^*(i)}{\sqrt{\sum_{i=1}^{I} w(i)\cdot w(i)}\sqrt{\sum_{i=1}^{I} w^*(i)\cdot w^*(i)}} \quad (12)$$

The correlation between W and W^* is very high when NC (W, W^*) is close to 1. On the other hand, the correlation between W and W^* is very low when NC (W, W^*) is close to zero.

TABLE VI. A GENERAL COMPARISON BETWEEN THE PROPOSED AND SEVERAL RECENT METHODS SORTED BY DATA PAYLOAD

Reference	Algorithm	Payload (bps)	Re-sampling BER (%)	Re-quantization BER (%)	MP3 compression BER (%)
Proposed	**LWT-QRD**	**172.39**	**1.27 (22.05 kHz)**	**0 (8 bits/sample)**	**3.32 (128 kbps)**
[4]	Wavelet-based entropy	172.28-86.14	9.1 (22.05 kHz)	--	6.7 (128 kbps)
[5]	DWT-based energy proportion	114.82	6.92 (22.05 kHz)	--	5.71 (80 kbps)
[15]	EMD	46.9-50.3	3 (22.05 kHz)	0 (8 bits/sample)	1 (32 kbps)
[13]	DWT-SVD	45.90	2 (22.05 kHz)	0 (8 bits/sample)	1 (32 kbps)
[11]	DCT-SVD	43	0 (22.05 kHz)	0 (8 bits/sample)	3 (32 kbps)
[18]	Histogram	3	0 (--)	0 (8 bits/sample)	15 (128 kbps)
[19]	DWT-based Histogram	2	0 (16 kHz)	0 (8 bits/sample)	17.50 (64 kbps)
[10]	LWT	--	16.50 (36.750 kHz)	22.09 (8 bits/sample)	51.73 (128 kbps)

The bit error rate (BER) is used to measure the robustness of a watermarking method and is computed as:

$$BER(W,W^*) = \frac{\sum_{i=1}^{I} w(i) \oplus w^*(i)}{I} \tag{13}$$

where $\oplus$ is an exclusive or (XOR) operation.

The proposed method utilizes chaotic encryption to enhance the security. The proposed watermark embedding and detection processes depend on the quantization parameter D and the secret key K. Thus, it is impossible to maliciously detect the watermark without them. Table V shows the robustness results of the proposed method in terms of NC and BER against several attacks for the audio signal 'Pop', 'Jazz', 'Classical', and 'Speech'. The NC values are all above 0.97 and the BER values are below 4%. This clearly indicates a high robustness of the proposed method against different attacks. This is because watermark bits are embedded into the largest element of the upper triangular matrix obtained from the low frequency LWT coefficients of each frame.

Table VI shows a general comparison between the proposed and the several recent methods sorted by data payload, which is based on the reported result in the references [4]-[5], [10]-[11], [13], [15], [18]-[19]. Moreover, re-sampling, re-quantization, and MP3 compression are compared in Table VI. From this comparison, we observed that the proposed method provides higher data payload and lower BER values against several attacks compared with the recent watermarking methods.

V. CONCLUSION

A blind audio watermarking method based on LWT and QRD has been presented in this paper. The performance analysis of the proposed method indicates that it is highly robust against various attacks including noise addition, cropping, re-sampling, re-quantization, and MP3 compression. In addition, audio quality evaluation tests show high imperceptibility of the watermark in the audio signals. Moreover, it has high data payload and provides superior performance than the state-of-the-art audio watermarking methods. These results verify the effectiveness of the proposed watermarking method as a suitable candidate for audio copyright protection.

Abstract— **A good number of efforts have been made on design of ternary reversible combinational circuits, but no significant attempt has yet been made to design arbitrary ternary reversible sequential circuits. In this paper, we have proposed a novel design method of ternary reversible sequential circuit using direct feedback of the present state output. We have also shown the way of making the circuit falling-edge triggered and pre-settable using Fredkin gate. For this purpose, for the first time, we have shown realization of Fredkin gate on the top of M-S gates. We have shown design examples of an arbitrary two-trit sequential circuit, three-trit up/down counter, and three-trit universal register.**

Index Terms—**Reversible logic, ternary reversible gates, ternary reversible sequential circuit, TGFSOP expression.**

I. Introduction

Ternary circuit is more compact than binary circuit, since ternary encoded realization of a function requires 0.63 times input lines than binary realization [1]. Ternary reversible/quantum circuits are realizable using linear ion-trap technology [2]. The reversible gates proposed in [2] are commonly known as Muthukrishnan-Stroud (M-S) gates. A good number of design methods for ternary reversible combinational circuits are proposed in the literature [1], [3]-[13]. Among them, ternary Galois field sum of products (TGFSOP) expression based design method [1], [3] has become very promising and practical, since ternary logic function with any number of inputs can be easily represented as TGFSOP expression and any TGFSOP expression can be realized as cascade of ternary Feynman and Toffoli gates. Moreover, ternary Feynman and Toffoli gates can be realized on the top of M-S gates [14]. On the other hand, only one attempt has been made to design ternary reversible sequential circuit [15], where design of only D and T flip-flops are proposed and nothing is stated regarding design of arbitrary sequential circuits using these flip-flops.

In this paper, we have proposed a novel design method for ternary sequential circuits, where the present state outputs are directly fed-back to the next state determination circuit and that circuit is realized using TGFSOP expression as a cascade of ternary one-trit (ternary digit), Feynman and Toffoli gates. We have also developed methods for making the ternary reversible sequential circuit falling-edge triggered and pre-settable. As design example, we have presented designs of an arbitrary sequential circuit with two-trit state, one input, and one output; a three-trit up/down counter; and a three-trit universal register.

The rest of the paper is organized as follows. In section II, we have discussed preliminaries of TGFSOP expression and ternary reversible gates. We have discussed the proposed method of designing ternary reversible sequential circuit in section III. Finally, in section IV, we have concluded the paper.

II. Preliminaries

The basis of TGFSOP expression is the GF(3) operation, which has a set of values $T = \{0, 1, 2\}$ and two binary operations - addition (denoted by $\oplus$) and multiplication (denoted by $\cdot$ or juxtaposition). The GF(3) operations are mod 3 operations. The GF(3) operations are commutative. The multiplication operation is distributive over addition operation.

There are 3! = 6 possible permutations of 0, 1, and 2. Therefore, there are six possible reversible literals of a ternary variable that take the values as shown in Table I. The literal x^{+0} is often written as x.

TABLE I
Ternary Reversible Literals

Variable	Reversible Literal					
x	x^{+0}	x^{+1}	x^{+2}	x^{01}	x^{02}	x^{12}
0	0	1	2	1	2	0
1	1	2	0	0	1	2
2	2	0	1	2	0	1

In [3], we have developed 16 ternary Galois field expansions (TGFE), which are used to expand a ternary logic function $f(x_1, \ldots, x_n)$ on any of the n variables to generate the TGFSOP expression. In [3], Kronecker tree is constructed for TGFSOP minimization. In this paper, we have used pseudo Kronecker tree for TGFSOP minimization as discussed in section III. In general, pseudo Kronecker tree produces more minimization than Kronecker tree.

The one-trit gates are shown in Fig. 1(a), where the output P is the U-transform of the input A and U is any unitary transform from Table I. The cost of one-trit gate is assumed to be one. Ternary M-S gate is shown in Fig. 1(b). The output $P = A$. When $A = 2$, then the output Q is the U-transform of B, otherwise $Q = B$. The cost of M-S gate is assumed to be one. Ternary Feynman gate is shown in Fig. 1(c). The outputs are $P = A$ and $Q = A \oplus B$. Realization of Feynman gate on the top of M-S gate is proposed in [14] and its cost is four. Ternary multiple-controlled (n-trit with $n > 2$) Toffoli gate is shown in Fig. 1(d). Realization of multiple-controlled Toffoli gate on the top of M-S gate is proposed in [14] and its cost is 8 + 2×cost of (n - 1)-trit Toffoli gate. The cost of Toffoli gates for n = 2, 3, 4, 5, 6, 7, 8, 9, 10 are 4, 16, 40, 88, 184, 376, 760, 1528, 3064, respectively.

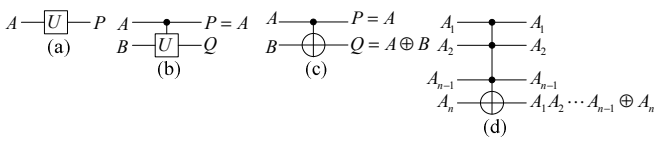

Fig. 1 Ternary (a) one-trit, (b) M-S, (c) Feynman, and (d) multiple-controlled Toffoli gates.

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

Ternary Fredkin gate is shown in Fig. 2(a). If $A \neq 2$ (i.e., $A^{02}A^{02} = 1$ and $AA^{01} = 0$), then $Q = B$ and $R = C$. If $A = 2$ (i. e., $A^{02}A^{02} = 0$ and $AA^{01} = 1$), then $Q = C$ and $R = B$. Thus, when $A \neq 2$, then the inputs B and C are passed directly to the outputs and when $A = 2$, then they are swapped at the output. The realization of Fredkin gate on the top of M-S gate is shown in Fig. 2(b) and its cost is 15.

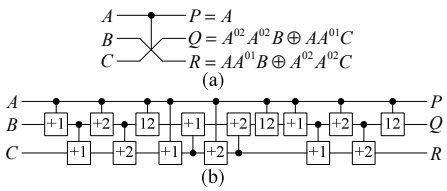

Fig. 2 Ternary (a) Fredkin gate and (b) its realization on the top of M-S gate.

III. Design of Ternary Reversible Sequential Circuit

The basic principle of sequential circuit is that the next state and the output are determined based on the present state and the input. So, if the present state output can be directly fed-back to the next state determination circuit, then ternary reversible sequential circuit can be designed. Let Q and Q^+ be the present state and the next state, respectively. Then Q^+ can be expressed as $Q^+ = Q \oplus Q \oplus Q \oplus Q^+ = Q \oplus Q^*$, where $Q^* = Q \oplus Q \oplus Q^+$ is the modified next state. Now, Q^* is determined as the function of the present state and the input. Let C be the clock. Then the next state is realized in the next state determination circuit as $Q^+ = Q \oplus CC^{01}Q^*$. When $C \neq 2$ (i. e., $CC^{01} = 0$), then $Q^+ = Q$, which provides the feedback of the present state through the next state determination circuit to maintain the present state. When $C = 2$ (i. e. $CC^{01} = 1$), then $Q^+ = Q \oplus Q^*$, which generates the next state in the "Next state determination" circuit. We express the next state function as TGFSOP expression. The TGFSOP expression is minimized using pseudo Kronecker tree, where one of the 16 TGFEs [3] is used for each of the $(3^n - 1)/2$ internal nodes of the tree. For this purpose, we have written a C program to construct pseudo Kronecker tree from the given output vector and to determine the corresponding minimized TGFSOP expression. We also implement the output of the sequential circuit in the "Output determination" circuit using TGFSOP expression of the output as function of present state and input.

The proposed design method is illustrated using an arbitrary sequential circuit with two-trit state $Q1Q0$, one input x, and one output z as shown in the state transition diagram of Fig. 3. The truth table representing the next states $Q1^+Q0^+$, the output z, and the modified next states $Q1^*Q0^*$ is shown in Table II. From the output vector of the modified next state $Q1^*$ of Table II, we have generated the pseudo Kronecker tree for $Q1^*$ as shown in Fig. 4. The number inside each circle is the selected TGFE for that node. The reversible literals corresponding to each of the cofactors of the selected TGFE are written along the edges. Each product term of the generated TGFSOP expression is determined by multiplying the literals along the path from the root to the non-zero constant leaf and the constant itself. Thus, the minimized TGFSOP expression for $Q1^*$ from the tree of Fig. 3 is

$$Q1^* = 2x^{+1}Q1^{+1}Q0^{+1} \oplus x^{12}Q1^{+2}Q0^{+2} \quad (1)$$

The corresponding next state equation for $Q1^+$ is determined from (1) using the formula $Q^+ = Q \oplus CC^{01}Q^*$ as follows. Readers should note that $2C^{01} = C^{+2}$.

$$Q1^+ = Q1 \oplus CC^{+2}x^{+1}Q1^{+1}Q0^{+1} \oplus CC^{01}x^{12}Q1^{+2}Q0^{+2} \quad (2)$$

Similarly, we have determined the equation for the next state $Q0^+$ as follows:

$$Q0^+ = Q0 \oplus CC^{01}Q1Q0 \oplus CC^{+2}xQ1^{+2} \quad (3)$$

From the output vector of the output z from Table II, we have determined the TGFSOP expression for the output z as follows:

$$z = Q0 \oplus xQ1^{01}Q0 \oplus xQ1Q0^{+1} \quad (4)$$

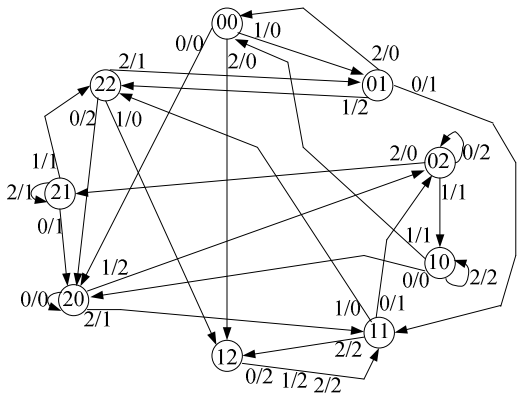

Fig. 3 State transition diagram of an arbitrary sequential circuit.

The reversible realization of the sequential circuit of Fig. 3 is shown in Fig. 5. Each of the five parts of Fig. 5 is discussed separately.

In the "Feedback" part, the two present states are copied using two Feynman gates and fed-back to the "Next state determination" part of the circuit.

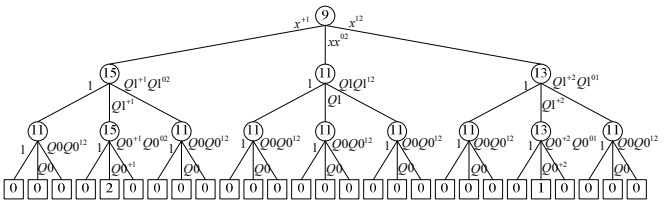

Fig. 4 Pseudo Kronecker tree for minimizing TGFSOP expression for $Q1^*$ of Table II.

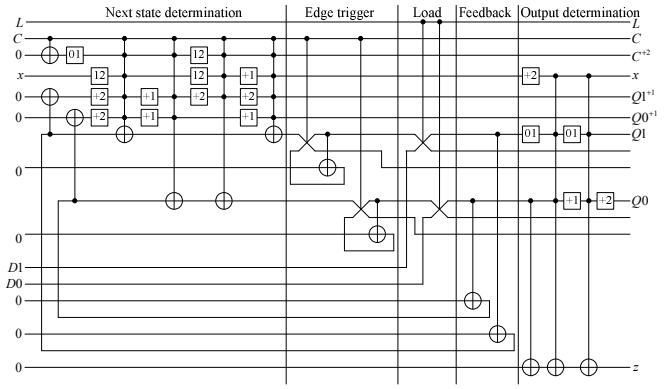

Fig. 5 Reversible realization of the sequential circuit represented by the state transition diagram of Fig. 3.

In the "Load" part, when $L = 2$, then $D1$ and $D0$ data inputs will be loaded to the state output $Q1$ and $Q0$, respectively, through the Fredkin gates and they will become the present state. Then these newly loaded output states will be fed-back to the "Next state determination" part by the "Feedback" part of the circuit. As discussed below, the "Next state determination" part determines the next state when the clock $C = 2$. So, the output state loading should me made asynchronously only when $C \neq 2$ so that the loaded states are fed-back before the next state determination starts. When $L \neq 2$, then the Fredkin gates will pass the two state values provided by the "Edge trigger" part to maintain the output states unchanged.

The next state equations of (2) and (3) are realized in the "Next state determination" part of Fig. 5 as function of the fed-back present states $Q1$ and $Q0$, the input x, and the clock C. When $C \neq 2$ (i. e., $CC^{01} = 0$), then $Q^+ = Q \oplus CC^{01}Q^* = Q$. In this case, the two outputs of the "Next state determination" part will simply be equal to the two fed-back present state values. When $C = 2$ (i. e., $CC^{01} = 1$), then $Q^+ = Q \oplus CC^{01}Q^* = Q \oplus Q^*$. In this case, the "Next state determination" part will determine the two next states.

In the "Edge trigger" part, when $C = 2$, then the Fredkin gate will provide the feedback to maintain the state output unchanged. At the same time, the "Next state determination" part will determine the next state. After that when the clock goes from $C = 2$ to $C \neq 2$, then the Fredkin gates will pass the outputs of the "Next state determination" part to the state outputs through the "Load" part provided $L \neq 2$ is maintained. Thus, the sequential circuit becomes a falling-edge triggered circuit.

In the "Output determination" part, the output z is realized using the TGFSOP expression of (4) as function of the present state $Q1Q0$ and the input x.

The circuit of Fig. 5 has 17 one-trit, eight Feynman, four Fredkin, two four-trit Toffoli, two five-trit Toffoli, and two six-trit Toffoli gates. Thus, its cost is 17×1 + 8×4 + 4×15 + 2×40 + 2×88 + 2×184 = 733. The useful outputs of the circuit are $Q1$, $Q0$, and z. Thus, the circuit has 10 garbage outputs. The state outputs from the "Next state determination" part are older version of the states and are not useful for further use. For this reason, they are considered as garbage outputs.

We have designed a three-trit up/down counter as shown in Fig. 6. The state outputs are $Q2$, $Q1$, and $Q0$. The mode selector input M determines the direction of count. When $M \neq 2$, then it counts in the up direction. When $M = 2$, then it counts in the down direction. The determined next state equations are given below:

$$Q2^+ = Q2 \oplus CC^{+2}Q1^{+1}Q1^{01}Q0^{+1}Q0^{01} \oplus CC^{+2}M^{+1}M^{02}Q1^{+1}Q1^{01}Q0^{+1}Q0^{01} \oplus CC^{+2}M^{+1}M^{02}Q1Q1^{01}Q0Q0^{01} \tag{5}$$

$$Q1^+ = Q1 \oplus CC^{+2}Q0^{+1}Q0^{01} \oplus CC^{01}M^{+1}M^{02}Q0^{+2}Q0^{01} \tag{6}$$

$$Q0^+ = Q0 \oplus CC^{+2} \oplus CC^{01}M^{+1}M^{02} \tag{7}$$

Based on the next state equations (5) to (7), reversible realization of three-trit up/down counter is shown in Fig. 6. The circuit of Fig. 6 has 11 one-trit, 12 Feynman, six Fredkin, one three-trit Toffoli, two five-trit Toffoli, two seven-trit Toffoli, and two nine-trit Toffoli gates. Thus, its cost is 11×1 + 12×4 + 6×15 + 1×16 + 2×88 + 2×376 + 2×1528 = 4149. The circuit has 15 garbage outputs. The state outputs from the "Next state determination" part are older version of the states and are not useful for further use. For this reason, they are considered as garbage outputs.

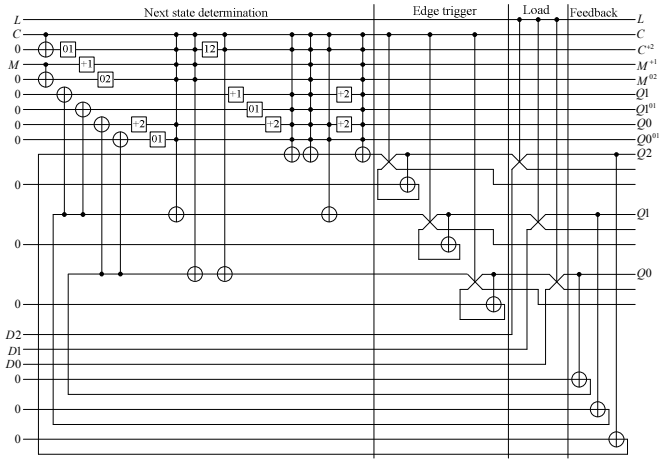

Fig. 6 Reversible realization of three-trit up/down counter.

We have designed a three-trit universal register as shown in Fig. 7. The state outputs are $Q2$, $Q1$, and $Q0$. The "Load" part of the circuit provides asynchronous load facility for parallel input. When $L = 2$, then the parallel input data $D2$, $D1$, and $D0$ are loaded to the state outputs $Q2$, $Q1$, and $Q0$, respectively. Parallel outputs are taken form $Q2$, $Q1$, and $Q0$. The mode selector input M determines the direction of shift. When $M \neq 2$, then the circuit shift the data in the right direction. In this case, the serial input is D_R and the serial output is $Q0$. When $M = 2$, then the circuit shifts the data in the left direction. In this case, the serial input is D_L and the serial output is $Q2$. Thus, the circuit is a three-trit universal register. The determined next state equations are given below:

$$Q2^{+} = Q2 \oplus CC^{01}Q2^{01}Q1 \oplus CC^{01}Q2Q1^{+2} \oplus CC^{01}M^{+1}M^{02}D_R^{01}Q1 \oplus CC^{01}M^{+1}M^{02}D_RQ1^{+2} \quad (8)$$

$$Q1^{+} = Q1 \oplus CC^{01}Q1^{01}Q0 \oplus CC^{01}Q1Q0^{+2} \oplus CC^{01}M^{+1}M^{02}Q2^{01}Q0 \oplus CC^{01}M^{+1}M^{02}Q2Q0^{+2} \quad (9)$$

$$Q0^{+} = Q0 \oplus CC^{01}Q0^{01}D_L \oplus CC^{01}Q0D_L^{+2} \oplus CC^{01}M^{+1}M^{02}Q1^{01}D_L \oplus CC^{01}M^{+1}M^{02}Q1D_L^{+2} \quad (10)$$

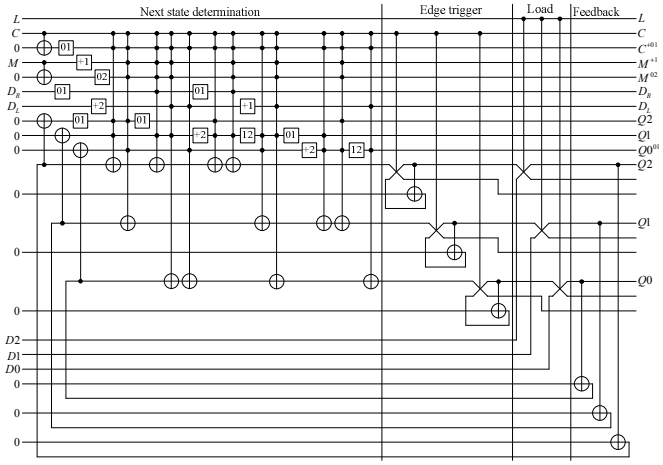

Fig. 7 Reversible realization of three-trit universal register.

Based on the next state equations (8) to (10), reversible realization of three-trit universal register is shown in Fig. 7. The circuit of Fig. 7 has 14 one-trit, 11 Feynman, six Fredkin, six five-trit Toffoli, and six seven-trit Toffoli gates. Thus, its cost is 14×1 + 11×4 + 6×15 + 6×88 + 6×376 = 2932. The circuit has 16 garbage outputs. The state outputs from the "Next state determination" part are older version of the states and are not useful for further use. For this reason, they are considered as garbage outputs.

IV. Conclusions

Ternary circuits are more compact than corresponding binary circuits. Though a good number of efforts have been made in designing ternary reversible combinational circuits, no significant effort has been reported on designing ternary reversible sequential circuits. In this paper, for the first time, we have proposed a novel technique for designing ternary reversible sequential circuit. For this purpose, we have provided direct feedback of the present state output to the next state determination circuit. To accommodate the direct feedback of the present state to the next state determination circuit, a special technique has been developed for determining modified next state. Actual next state is then determined using the fed-back present state and the modified next state equation. Asynchronous load facility and falling-edge triggering is provided using ternary Fredkin gate. For determining the next state equation and the output equation, we have used TGFSOP expression. In the earlier effort [3], TGFSOP expression was minimized using Kronecker tree. As the pseudo Kronecker tree produces more minimized TGFSOP expression, in this paper, we have minimized the TGFSOP expression using pseudo Kronecker tree.

***Abstract*—Single Electron Transistor (SET) is an ultra small device which can be used as a possible replacement of a MOSFET. Like CMOS technology, CSET (Complementary SET) models can be used to build same digital circuits. Apart from the drawbacks (which have been discussed at the end of this paper), these digital circuits work fine. One of the main advantages of a SET based digital circuit over a MOSFET based digital circuit is its low power consumption. In this paper we have focused on this issue. For an example, we have presented the circuits of NAND gate and NOR gate made up of both MOSFETs and SETs. The PSPICE simulations of these circuits show that the SET built digital circuits consume much less power than those of MOSFETs.**

***Index Terms*—Moore's law, low power consumption, NAND gate, NOR gate, orthodox theory, background charge**

I. Introduction

According to International Technology Roadmap for Semiconductors (ITRS), CMOS technology may be obsolete by 2018 due to its reaching of minimum feature size which is not compatible with the Moore's law. Besides the reduction of power consumption of different electrical and electronic appliances has already been a major issue. Single electron transistor (SET) is a new device which can solve both the problems. This paper emphasized on the low power consumption of SET.

II. MOSFET Based Nand gate and simulated results

Fig. 1 shows the circuit diagram a MOSFET based 2-input NAND gate. Here the supply voltage is taken to be 3.5 V.

All the simulations of MOSFET based circuits (both NAND gate and NOR gate) were done in PSPICE. Plotting of the wave shapes and power consumption calculation were done in MATLAB. The equations which were used in PSPICE can be found in [1]

Fig. 2 shows the PSPICE simulation result of transient analysis of a CMOS NAND gate. Fig. 3 shows the power consumptions across MPU1 and MPU2 at different times respectively and Fig. 4 shows the power consumption across MPD1 and MPD2 at different times respectively.

Average power consumptions across MPU1, MPU2, MPD1 and MPD2 are 9.4545×10^{-6} Watts, 5.4681×10^{-6} Watts, 5.9826×10^{-6} Watts and 3.9908×10^{-6} Watts respectively.

Total average power consumption across the whole circuit = 2.4896×10^{-5} Watts.

III. SET Based Nand gate and simulated results

Fig. 5 shows the circuit diagram a SET based 2-input NAND gate. Here the supply voltage is taken to be 35mV. The red and blue colored islands of the circuit indicate that the background charges [2] of them are positive and negative respectively. The background charges may have different signs but the absolute values of them are considered same throughout the whole simulation.

The switching characteristics of SET is described in [3]. All the simulations of SET based circuits (both NAND gate and NOR gate) were done in PSPICE. Plotting of the wave shapes and power consumption calculation were done in MATLAB. The equations which were used in PSPICE can be found in [4].

Fig. 6 shows the PSPICE simulation result of transient analysis of a SET based NAND gate. Fig. 7 shows the power consumptions across SETPU1 and SETPU 2 at different times respectively and Fig. 8 shows the power consumption across SETPD 1 and SETPD 2 at different times respectively.

Average power consumptions across SETPU1, SETPU2, SETPD1 and SETPD2 are 2.7457×10^{-12} Watts, 2.8335×10^{-12} Watts, 4.6971×10^{-12} Watts and 2.0068×10^{-12} Watts respectively.

Total average power consumption across the whole circuit = 1.2283×10^{-11} Watts.

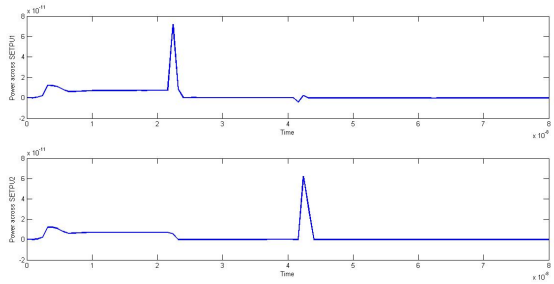

Fig. 7. Power consumptions across SETPU1 and SETPU2 of a NAND gate

IV. MOSFET Based Nor gate and simulated results

Fig. 9 shows the circuit diagram of a MOSFET based 2-input NOR gate. Here the supply voltage is 3.5V as usual for a MOSFET based digital circuit.

Fig. 10 shows the PSPICE simulation results of transient analysis of a CMOS NOR gate. Fig. 11 shows the power consumptions across MPU1 and MPU2 at different times respectively and Fig. 12 shows the power consumption across MPD1 and MPD2 at different times respectively.

Average power consumptions across MPU1, MPU2, MPD1 and MPD2 are 9.4953×10^{-6} Watts, 5.0227×10^{-6} Watts, 4.8594×10^{-6} Watts and 3.5093×10^{-6} Watts respectively.

Total average power consumption across the whole circuit = 2.2887×10^{-5} Watts.

V. SET Based Nor gate and simulated results

Fig. 13 shows the circuit diagram of a SET based 2-input NOR gate. Here the supply voltage is 35mV as usual for a

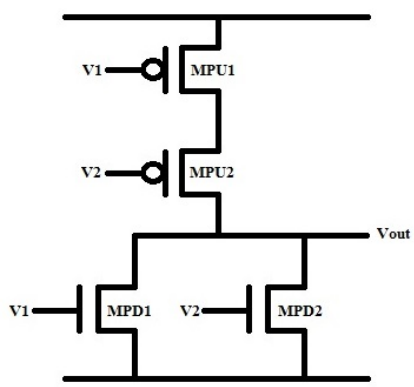

Fig. 9. Circuit diagram of a MOSFET based NOR Gate

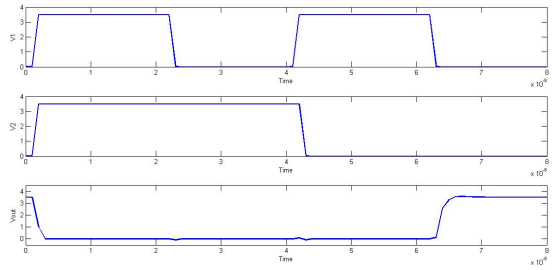

Fig. 10. Transient analysis of a MOSFET based NOR gate

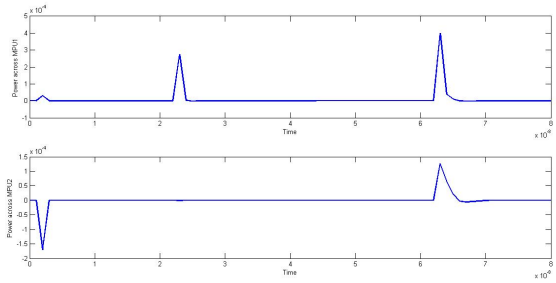

Fig. 11. Power consumptions across MPU1 and MPU2 of a NOR gate

SET based digital circuit.

Fig. 14 shows the PSPICE simulation result of transient analysis of a SET based NOR gate. Fig. 15 shows the power consumptions across SETPU1 and SETPU2 at different times respectively and Fig. 16 shows the power consumption across SETPD1 and SETPD2 at different times respectively.

Average power consumptions across SETPU1, SETPU2, SETPD1 and SETPD2 are 1.7578×10^{-12} Watts, 4.7476×10^{-12} Watts, 2.5310×10^{-12} Watts and 2.3184×10^{-12} Watts respectively.

Total average power consumption across the whole circuit = 1.1355×10^{-11} Watts.

VI. Comparisons of MOSFET and SET based Circuits

From the simulation results it is clear that SET shows almost the same results in transient analysis as the MOSFET does. The main advantage of SET based circuits focused here over MOSFET based circuits is the consumption of less power. The simulation results show that both SET based NAND and NOR gates consume almost **1 million** times less power than those of CMOS circuits.

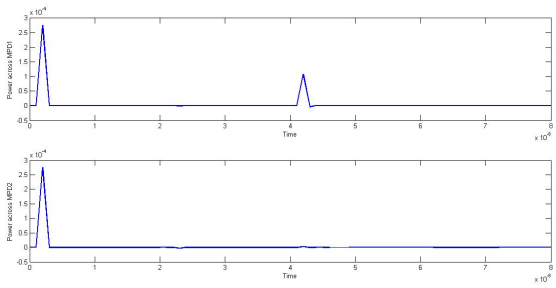

Fig. 12. Power consumptions across MPD1 and MPD2 of a NOR gate

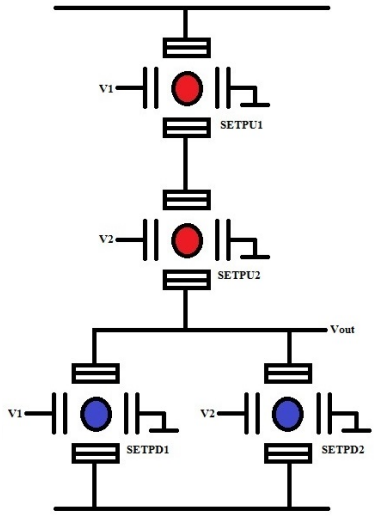

Fig. 13. Circuit diagram of a SET based NOR Gate

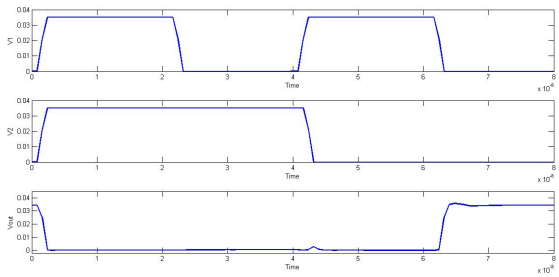

Fig. 14. Transient analysis of a SET based NOR gate

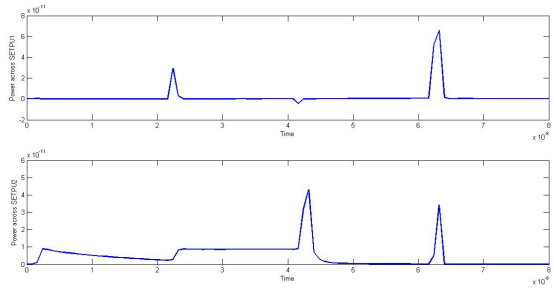

Fig. 15. Power consumptions across SETPU1 and SETPU2 of a NOR gate

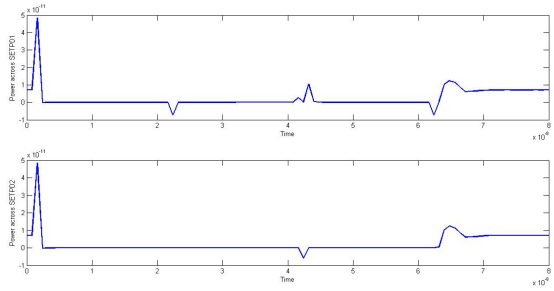

Fig. 16. Power consumptions across SETPD1 and SETPD2 of a NOR gate

VII. Limitations and conclusion

There are some limitations of SET based circuits. In these simulations orthodox theory [5] of single electron tunneling was used where co-tunneling was not considered. The simulations were done assuming the temperature at 27k. In room temperature these simulations do not work. Moreover, SET is very sensitive on background charge issue. We have assumed the background charge of all the SETs in a circuit constant and equal (absolute value). Background charges barely behave like this way. But still SET can be important in coming days' VLSI technologies if these limitations can be recovered.

Abstract— **Currently, the demand of memories has been increasing due to its higher speed, lower cost and lower power consumption. The complexity of instructions to control the memory devices increases with the increase in technology. DDR4 is the latest generation family of DDR SDRAM. This memory device provides higher reliability, availability and serviceability than other DDR memories. In this paper, the overall architecture of the DDR4 SDRAM controller is proposed .The detailed design and operation of its individual sub blocks is described. Also the advantages of DDR4 over DDR3 SDRAM are discussed.**

***Index Terms*—DDR4, SDRAM Controller, Rank.**

I. Introduction

DDR4 SDRAM, an abbreviation for Double Data Rate type 4 Synchronous Dynamic Random Access Memory is the latest member of DDR family of technologies mostly for the computing, server, biomedical and embedded applications. Recently DDR3 SDRAM is widely used in PC, Smart phones, Tablets, High-end servers and micro server systems. DDR4 is focusing on data reliability. A large number of server systems are required for increasing high-bandwidth and high capacity of multimedia contents [1]. Hence, a main memory of server systems is one of the vital components, so it should definitely have high performance feature [2]. The increasing demand of faster operating systems as well as big size applications created the need of using high capacity memory. Due to the use of high capacity memory, power consumption is also increased immensely which is one of the major concerns for memory market. DDR4 not only increased its volume but also reduced the power consumption.

The main changes of DDR4 SDRAM are supply voltage, higher data rate, higher densities, more banks, faster bursts access and higher system reliability compared with DDR3 SDRAM.

Figure 1 shows the new features which is introduced in DDR4 SDRAM such as : CRC, C/A parity, data bus inversion (DBI), Command address latency (CAL), per-DRAM addressability , CAL (command address latency), MPR (multi-purpose registers), gear-down mode, FGREF (fine granularity refresh) and temperature controlled refresh. Among these, CRC, C/A parity, data bus inversion (DBI) for solving the data reliability issue. Using Per DRAM addressability mode only selected DRAM programmed is possible in a single Rank.

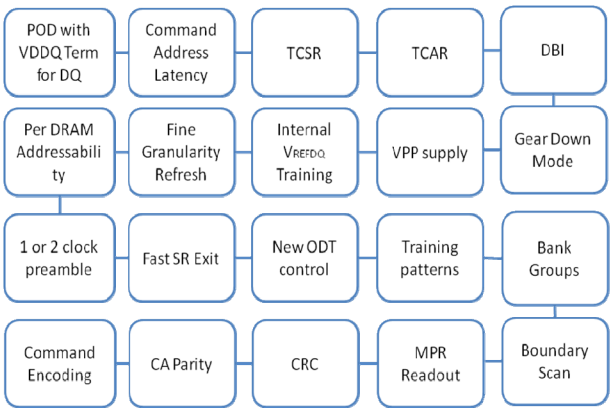

Fig.1 New Features of DDR4 SDRAM

Now Table 1 shows the comparison of DDR4 SDRAM than others.

TABLE 1
COMPARISON TABLE OF DDR3 AND DDR4 SDRAM

Feature	DDR3	DDR4	DDR4 Advantage
Voltage (core and I/O)	1.5V	1.2V	Reduces memory power demand
Prefetch	8n	8n	DDR4 also have 8n prefetch but parallel bank group
Densities	512Mb–8Gb	2Gb–16Gb	Better enablement for large-capacity memory subsystems
Data rate (MT/s)	800, 1066, 1333, 1600, 1866, 2133	1600, 1866, 2133, 2400, 2667, 3200	Migration to higher data bandwidth
Internal banks	8	16	More Banks
Bank groups (BG)	0	4	Faster burst accesses

DDR4 SDRAM controller is used as a bridge to interface with SDRAM memory devices and processors subsystem. It manages bi-directional data flow of memory. The main function of controller is data read and write. It also assists the DRAM to retain the data such as periodic refresh, precharge etc. Data transfer is accomplished with the bi-directional differential data strobe (DQS, DQS#). The DDR4 SDRAM memory device transmits data strobe (DQS) for read operation and controller device transmits DQS for write operation.

This paper is divided by following sectors: sector 1 is introduction. Sector 2 is discussed the functional description of DDR4 SDRAM. Sector 3 is described the overall architecture of DDR4 SDRAM controller and finally the conclusion sector.

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

II. FUCNTIONAL DESCRIPTION OF DDR4 SDRAM

DDR4 SDRAM has 8n prefetch with parallel bank for higher data transfer rate. The memory internally configured as 16 banks, 4 bank group with 4 banks for each bank group [4]. Bank is independent memory array. The row and column address is used to locate the requested address of bank in memory. And Page is unique address comprise of bank group, bank and row address. A page size is a total number of columns in a row. Rank architecture is very important to enhance data rate without increasing burst length [3]. Figure 2 shows the organization of memory.

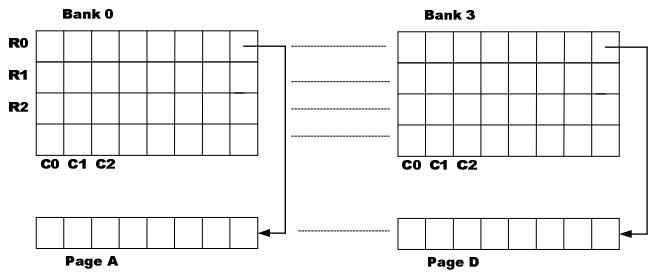

Fig. 2 RAM organization

DDR4 SDRAM read and writes operation is burst oriented. It begins at a specific selected location, and continues for a burst length of eight in a programmed sequence. The memory starts operation begins with an ACTIVATE Command, which is then followed by a Read or Write command. To select the bank and row to be activated, address bits registered is used with the ACTIVATE Command. Also to select the starting column location for the burst operation, address bits registered is used with the Read or Write command [4].

The following state diagram shows in figure 3 is described the possible state transitions and commands to control DDR4 SDRAM [4].

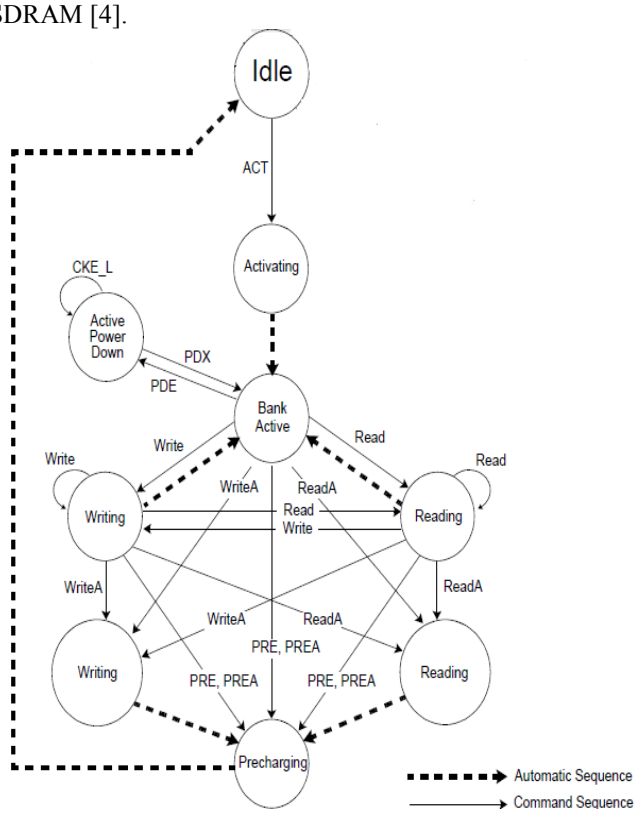

Fig. 3 State diagram of DDR4 SDRAM

III. ARCHITECTURE OF DDR4 SDRAM CONTROLLER

Fig. 4 shows the proposed overall architecture of DDR4 SDRAM controller.

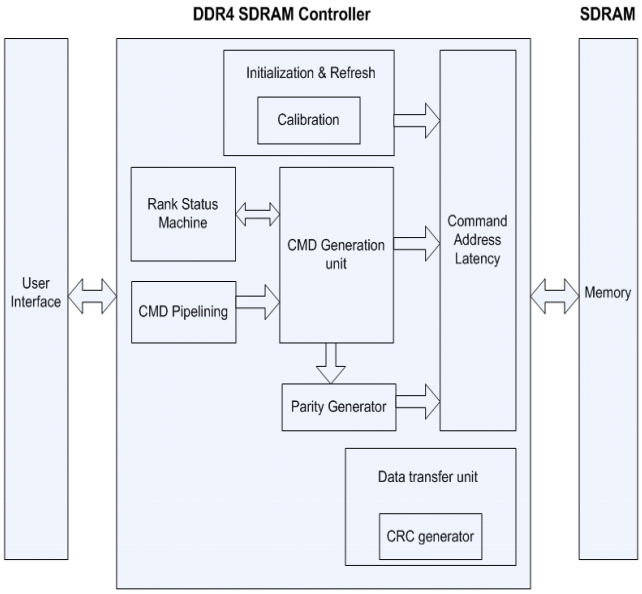

Fig. 4 Architecture of DDR4 SDRAM Controller

A. *Rank status machine*

In the controller we propose a Bank management unit (we called Rank status machine) which tracks the present state of each memory bank in the original DRAM. This provides greater flexibility to perform parallel read write command processing. The rank status machine architecture is shown in Fig.5.

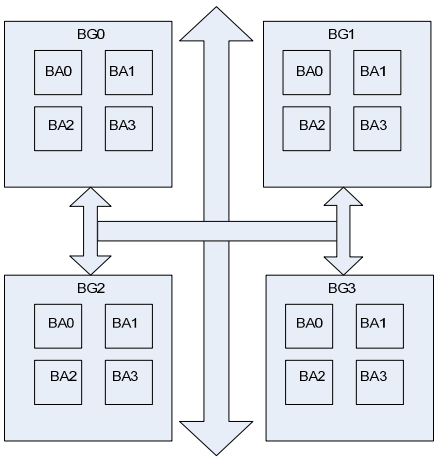

Fig. 5 Rank architecture

There are 4 Bank groups status processor and each Bank group contains 4 banks status processor, so total 16 banks can be managed at one time. Each status processor contains specific timing counter such as tCCD, tRRD, tFAW etc. The status is: bank active, readable, writeable, prechagable and row address. This ensures read-to-write and write-to-read bus turnaround time; active-to-precharge, activate delay between different banks and bank groups. When a command is sent to DDR4; timing constraint's counters corresponding to that command start to count and updated the status upon counting. For an example if a bank "x" in DDR4 is in idle state and a activate command is issued to the DDR4. The timing constraints related to activate command are tRRD (active-to-active command delay), tRCD (active-to-read/write delay),

tRAS (active-to-precharge delay) etc. In rank status machine corresponding bank "x" status processor starts counting of these times i.e. tRRD, tRCD, tRAS etc. after issuing activate command. At beginning the bank "x" status was bank active =0, readable =0, writeable =0, prechagable =0. After the tRCD time counts bank "x" status updated as bank active =1, readable =1, writeable =1, prechagable =0.

DDR4 introduces new specifications for read to read or write to write delay which are called tCCD_S and tCCD_L time for read or writes to banks of different Bank group and same Bank groups respectively.

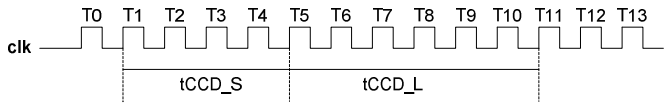

Fig. 6 tCCD variation of rank operation

The full bandwidth of DDR4 cannot be used, until Bank group interleaving access is not employed [5]. To achieve the better performance the controller can performs the bank interleaving operations by monitoring rank status.

B. CMD pipelining

Today's most of system shares the common RAM (Such as multiple processor, GPU, GPIO shares the DRAM). So the controller queues up multiple commands from different peripherals using command pipeline. The command pipeline is used for optimal bandwidth utilization. Command pipeline is used by the Command generation unit to pre-process the target bank for read or write operation such as active and precharge.

C. Command address latency

Command-to-Address Latency (CAL) function offers by DDR4 memory that can be used to save power. Basically, CAL is the delay between enable a Chip select and command/Address in clock cycles which is defined by mode register. Before issuing a command, it provides the DRAM time to active the CMD/ADDR receivers. The receivers can be latched, whenever the command and the address are latched. In case of providing consecutive commands, the receiver will have enabled by DRAM for the period of command sequence [4].

D. Calibration Unit

Calibration Unit performs write leveling, read leveling and ZQ calibration. DDR4 memory used fly-by topology for better signal integrity. To reduce the number of stubs and their length this topology is used. Despite benefiting, it causes skew problem between clock and strobe at every DRAM on the DIMM module. Hence, to solve the skew problem memory controller uses the 'write leveling' feature and feedback from the DDR4 SDRAM to adjust the data strobe to clock relationship [4]. This feature can compensate for unbalanced loading on the board for write and read operations. Calibration unit put the DDR4 into write leveling state by writing mode register MR1 of DDR4. The write strobe DQS is repeatedly delayed in small increments by the Delay Locked Loop (DLL). DDR4 samples the CLK with the rising edge of DQS and provide feedback on DQ. During this protocol, each set of DQ is output with a "0" until the rising edge is detected by the DQS at which time the DQ will be output with a "1". The calibration unit will detect these "1" on the DQ bus and then knows the correct DQS compensation to align the DQS and CLK on the write path. Once all DQS have been adjusted, these compensation values of DLL stored for each DQS for future usage. Then the memory controller sends another MRS command to exit the write level mode.

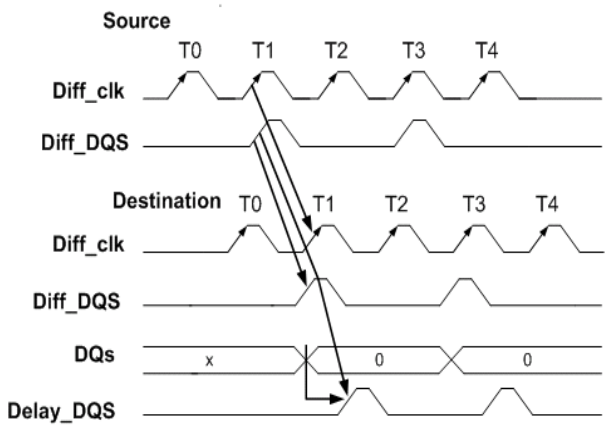

Fig. 7 Write Leveling

As DDR4 write leveling manages the DQS/DQ on write data, the DDR4 read leveling manages the DQS/DQ on read data. DDR4 read leveling is to compensate the imbalanced loading on the read path. First the memory controller puts the DDR4 memory devices into MPR mode by writing to the MR3 register. This puts the DDR4 memory devices into the read leveling mode which outputs a training pattern of consecutive "01" on each memory read command. Since the memory controller knows that data stream, so it will adjust the internal DQS delay to capture the DQ using DQS. Memory controller repeats these calibration reads until read data capture at memory controller is optimized.

ZQ Calibration command is used to calibrate DRAM Ron & ODT values. The ZQ calibration accounts the voltage and temperature variation on DRAM output driver.

E. Command Generation Unit

The command generator accepts user commands from the CMD pipelining unit. When the unit receives a single request, from pipelining unit request is processed immediately. For specified read or write request, Command Generation Unit lookup in the rank status to ensure the timing constraints for each previous memory transaction is met up before start new transaction. It also checks for availability of target bank for read or write operation from the rank status. Bank availability means the requested row in corresponding bank is active. If the requested bank is not active then it generates the necessary precharge and active command to activate the bank in DDR4. The command generation unit halt itself from throwing next command until the timing requirements of DDR4 are met. Upon availability of the bank; the requested read or write command is send to the DDR4 and internal rank status machine so that rank can update itself each time when a new command is throwing to the DDR4. If there are outstanding requests from two or more queues, the Command generation unit process the requests in look-ahead way. While processing

the active request from pipeline if there are any unsatisfied timing constraints which lead the controller to stall the transaction, controller then check the next upcoming request from queue. Command generation unit check the next requests bank address to find out the upcoming requests bank whether it is in active and activated row does match with the requested row address or not. If the condition does not met then command generation unit perform necessary precharge activate sequence to active that bank, so that when the request will be active the request will incur minimum stall time. Such deliberately bank active of future requests utilize the active requests stall time. This opportunistically look-ahead activates improve overall throughput.

F. Data Transfer Unit

Data transfer unit consist a read FIFO and a write FIFO. The read FIFO receives data from the DDR4 and passes that data to the user. The write FIFO receives write data from the user interface and passes that data to the DDR4. Read data from DDR4 arrive at the controller at both positive and negative edge of clock. The burst length of DDR4 is 8. Read FIFO captures these data in 4 clock cycles and provides the user read data in a single clock cycle on next positive edge of clock. Similarly write FIFO loads the user write data in a single clock and send to the DDR4 in next 4 clocks both at positive and negative edge. During the write data transfer to DDR4 it also added up CRC code at trail of each burst.

G. CRC Generator

As speed increased data prone to error. To solve Data reliability issue during WRITE operations, DDR4 included Cyclic Redundancy Check (CRC) along with DBI. DDR4 uses an 8-bit CRC header error control. The CRC polynomial used by DDR4 is the ATM-8 HEC, X^8+X^2+X^1+1.

Figure 8 shows CRC generator. DRAM generates checksum in each write burst per Data Strobe lane. CRC use 72 bits of data and all unallocated bits are 1s. DRAM compares the checksum. If two checksums do not match then DRAM flags an error.

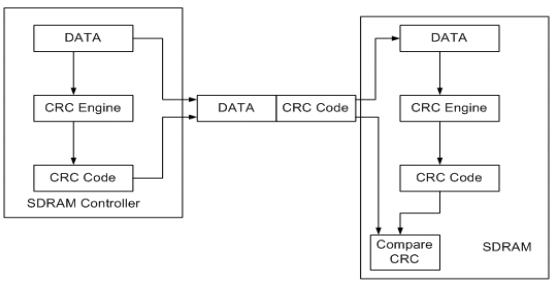

Fig. 8 CRC Generator

H. Initialization and Refresh Unit

Initialization and Refresh Unit performs the power up initialization and periodic refresh. After power up or reset the DDR4 must be initialized before start read or write transaction. The reset pin of DDR4 is kept low by the controller for 100ns to begin the initialization process. To active DDR4 clock, reset pin set to high and CKE pin set to low for 5100us. Then CKE pin drive to high. After tXPR period of time when DRAM is initialized Mode Register Set commands are issued for proper mode of operation such as burst length, additive latency, cas latency etc. After setting the mode register the Initialization and refresh unit switch on the calibration unit to perform the read and write leveling. Upon completion of coalition the DDR4 is ready for normal operation. It has a tREFI counter, which counts DDR4 refresh interval. On each tREFI count the controller issues refresh command to DDR4.

IV. CONCLUSIONS

The proposed architecture is designed and implemented according to DDR4 SDRAM JEDEC specification. DDR4 has reduced power consumption whereas it transfer rate is more above of its predecessor i.e. DDR3, DDR2, DDR. Its application will be more widely used from low power mobile computing device to high density servers. To enhance the throughput and reliability the controller should be aware of both parallel bank operation and error detection. For that reason we proposed parallel bank group and bank status machine co-ordinated by rank and separate data transfer unit with CRC generator. For better performance upon notifying error status from DDR4 the controller should be able to handle the ongoing transaction and suspended transaction traffic. This is the upcoming challenge for DDR4 controller which we will try in future.

A Graph Rewriting Approach to Replace Asynchronous RAMs in Circuits with Cycles for FPGAs

Md. Nazrul Islam Mondal[1*] Md. Shahid Uz Zaman[2] and Biprodip Pal[3]
[1,2,3] Dept. of Computer Science and Engineering, Rajshahi University of Engineering and Technology, Bangladesh
*nimbd@yahoo.com

***Abstract*—Circuit design that minimizes the number of clock cycles is easy if we use asynchronous read operations. However, most of FPGAs support synchronous read operations, but do not support asynchronous read operations. It is one of the main difficulties for users to implement parallel and hardware algorithms in FPGAs. The main contribution of this paper is to provide one of the potent approaches to resolve this problem. We assume that a circuit which includes cycles using asynchronous RAMs designed by a non-expert or quickly designed by an expert is given. Our goal is to convert this circuit with asynchronous RAMs into an equivalent synchronous ones. The resulting circuit with synchronous RAMs can be embedded into the FPGAs.**

***Index Terms*—FPGA, Block RAMs, asynchronous read operations, rewriting algorithm.**

I. Introduction

An *FPGA*is a programmable VLSI (Very Large Scale Integration) in which a hardware designed by users can be embedded quickly. Typical FPGAs consist of an array of programmable logic blocks (slices), memory blocks, and programmable interconnects between them. Some circuit implementations using FPGAs are described in the papers [4], [5], [6], [7] to accelerate computation.

In our previous paper [1], we have presented a circuit rewriting approach for circuits represented by a directed acyclic graph (DAG), which has no directed cycle. More specifically, presented approach presented in the paper [1] has a strict restriction in terms of input circuits. It works only for a circuit whose underlying graph is a DAG. Although most of practical circuits have cycles, it can not handle such circuits.

To resolve this problem, this paper modifies the circuit rewriting algorithm in the paper [1] to process practical circuits with cycles. More specifically, our new circuit rewriting algorithm can convert any circuit represented by a directed reachable graph (DRG) having cycles.

The main contribution of this paper is to present a circuit rewriting approach that converts *an asynchronous circuit* consisting

> *Combinational Circuits (CCs), Registers (Rs), and RAMs with asynchronous read operations (ARAMs)*

into *an equivalent synchronous circuit* consisting

> *Combinational circuits (CCs), Registers (Rs), and RAMs with synchronous read operations (SRAMs).*

The outlines of our work are as follows:

1) We use *a negative register* (NR) which is originally introduced in our previous paper [2].
2) We define simple *six rules* that rewrite a circuit.
3) The rewriting algorithm just repeats applying these rules until no more rules can be applied. When the rewriting algorithm terminates, we have an equivalent ARAM-free circuit to the original circuit.

The paper organization is described to the following Sections.

II. Random Access Memory (RAM)

A RAM is an array of memory where information can be stored until power is switched off. It has b-bit data input D, e-bit address input A and c-bit data output Q, it can store 2^e words such as $M[0]$, $M[1]$, ..., $M[2^e - 1]$ with c bits each, shown in Fig 1.

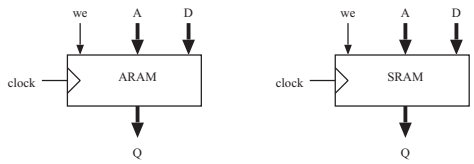

Fig. 1. An ARAM and an SRAM.

A RAM can support Asynchronous read, Synchronous read and Synchronous write operations as illustrated details in our previous paper [1].

For the reader's benefit, we need to describe two types of RAM. However, we refer readers to our previous paper [1] for the page limitation.

In this work, we consider Write After Read (WAR) mode for data handling of the memory blocks. The Fig 2 for the illustrations of the WAR and RAW. The Fig. 2 shows a timing diagram of the ARAM, SRAM, Register (R) and Negative Register (NR). Initially global reset is 1 and it drops to 0 just before time 0. We assume that write enable *we* is high for the first several clock cycles from the beginning (initially *we* is 1 and drops to 0 before the fourth rising clock edge). Data 11, 12, 13, −, −, − and 1, 2, 3, 1, 2, 3 are given to the input data port D and address port A respectively. The dash (-) line represents any data which is not necessary in our case. For simplicity, we have used the written data values of $M[1]$, $M[2]$, $M[3]$ for an SRAM to read again at the latest rising clock edge at time 3, 4, 5 respectively. Note that, M[1], M[2] and M[3] represent data value of memory location 1, 2 and 3 respectively. We have also used the written data values of $M[1]$, $M[2]$, $M[3]$ for an ARAM to read immediately at time 3, 4, 5 respectively. The edges at time 0, 1, 2 of the clock represent the latest rising edges for the stored data values of $M[1]$, $M[2]$, $M[3]$ respectively of an SRAM and ARAM. On

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

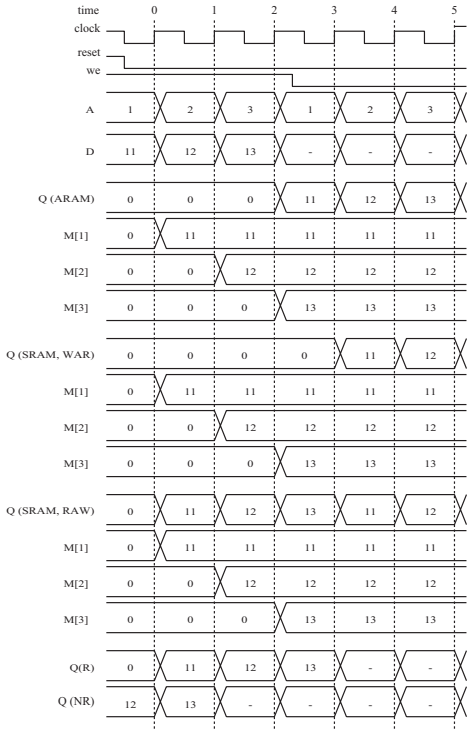

Fig. 2. A timing chart of an ARAM, an SRAM, a register (R) and a negative register (NR).

the other hand, the edges at time 0, 1, 2, 3, 4 of the clock represent the latest rising edges for the output data sequence of 0, 0, 0, 11, 12 respectively of an SRAM when it follows WAR. We assume that the stored values of M[a] are initialized by 0 of an SRAM and an ARAM. For the case of an ARAM, the data values of $M[1]$, $M[2]$, $M[3]$, $M[1]$, $M[2]$, $M[3]$ correspond to 0, 0, 0, 11, 12, 13 are taken respectively at time 0, 1, 2, 3, 4, 5 from the output port Q immediately due to the asynchronous read operations. Therefore, the output sequence of an ARAM, $[Q(ARAM)]$ is: 0, 0, 0, 11, 12, 13. According to the WAR, the output sequence of an SRAM, $[Q(SRAM, WAR)]$ is: 0, 0, 0, 0, 11, 12 at time 0, 1, 2, 3, 4, 5 respectively. On the other hand, according to the RAW, the output sequence of an SRAM, $[Q(SRAM, RAW)]$ is: 0, 11, 12, 13, 11, 12 at time 0, 1, 2, 3, 4, 5 respectively. Note that the output value of an SRAM at time 0 is initialized by 0. The stored data of $M[1]$, $M[2]$ and $M[3]$ of the time 0, 1, 2, 3, 4, 5 are the same for an ARAM and an SRAM which are $M[1]$: 0, 11, 11, 11, 11, 11; $M[2]$: 0, 0, 12, 12, 12, 12 and $M[3]$: 0, 0, 0, 13, 13, 13. The output of R is 0 at time 0. Also at time 1, 2, 3, 4, 5; the value of output R is 11, 12, 13, -, - respectively. The value of output NR is: 12, 13, $-$,$-$, $-$, $-$ of the time 0, 1, 2, 3, 4, 5 respectively.

III. Circuits and Their Equivalence

Let us consider a synchronous sequential circuit that consists of input ports, output ports, combinational circuits (CCs), registers (Rs), Random Access Memories (RAMs), a global clock input (clock), a global reset input (reset) and a write enable input (we).

Since there is a page limitation, we refer readers to our previous paper [2], [1] for details about the behavior of combinational circuits (CCs) and Registers (Rs), SRAM, ARAM and circuit equivalence.

In this paper, we assume that a fully synchronous circuit as illustrated in Fig. 3. We also assume that a circuit has loop or cycle.

Now we are in position to describe the equivalence of two circuits. Because of page limitation, we refer readers to our previous paper [1] for details about it.

Suppose that a circuit X with ARAMs is given. The main contribution of this paper is to show

- a necessary condition such that an ARAM-free circuit, Y can be generated, which is equivalent to X, and
- an algorithm to derive Y if the necessary condition is satisfied.

IV. Circuit Graph and Rewriting Rules

We simply use a directed graph to denote the interconnections of a fully synchronous circuit. We call such graph *as a circuit graph*. A circuit graph consists of a set of nodes and a set of directed edges connecting two nodes. Each node is labeled by either I (Input port), O (Output port), CC (Combinational Circuit), R (Register), NR (Negative Register), ARAM, or SRAM. The Fig. 3 illustrates an example of a directed graph.

Let us define rules to rewrite a circuit graph. The readers should refer to Fig 4 for illustrating the rules, where P and S denote predecessor and successor nodes respectively. The nodes between predecessor and successor nodes are rewritten as follows:

Rule 0 ARAM node is rewritten into SRAM+NR.

Rule 1 Adjacent R and NR nodes are rewritten into NULL circuit, that is, they are removed.

Rule 2 R+SRAM is rewritten into SRAM+R. More specifically, if each incoming edge of an SRAM node is connected to a R node, then all the Rs are removed to the outgoing edge of the SRAM node.

Rule 3 If all the incoming edges of a CC node are connected to a R node, then all the Rs are removed to all the outgoing edges of the CC node.

Rule 4 NR+SRAM is rewritten into SRAM+NR. More specifically, if one of the incoming edges of an SRAM node is connected to an NR node, then the NR node is removed, a R node is added to all other incoming edges, and the NR node is moved to the outgoing edge of the SRAM node.

Rule 5 If one of the incoming edges of a CC node is connected to an NR node, then the NR node is removed, a R node is added to all the other incoming edges, and the NR node is moved to all the outgoing edges of the CC node.

Let us confirm that, after applying one of the rewriting rules, an original circuit and the resulting circuit are an equivalent. Let a_i, b_i, c_i, d_i, a_i (address data) and *we* ($i \geq 0$) denote inputs given from the predecessor node at time i.

Rule 0 Both ARAM and SRAM+NR have the same output sequences and stored data.
ARAM/SRAM+NR(output sequence): $\langle 0, 0, 0, 11, 12, 13, \rangle$
ARAM/SRAM+NR (stored data of M[1], M[2] and M[3]):

- **M[1]:** $\langle 0, 11, 11, 11, 11, 11, \rangle$
- **M[2]:** $\langle 0, 0, 12, 12, 12, 12, \rangle$ and

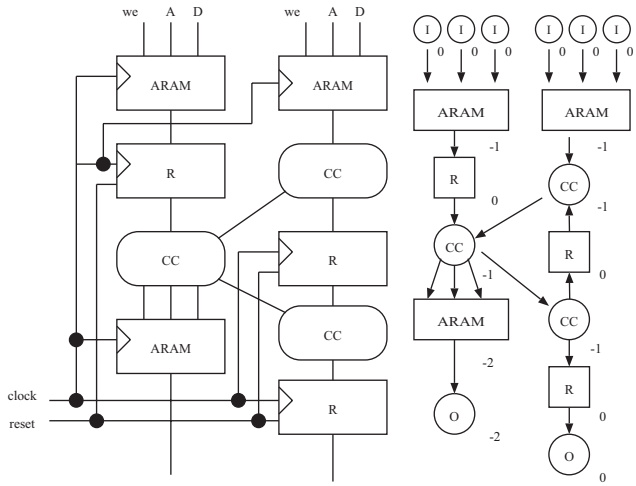

Fig. 3. An example of a fully synchronous circuit and the corresponding circuit graph with potentiality.

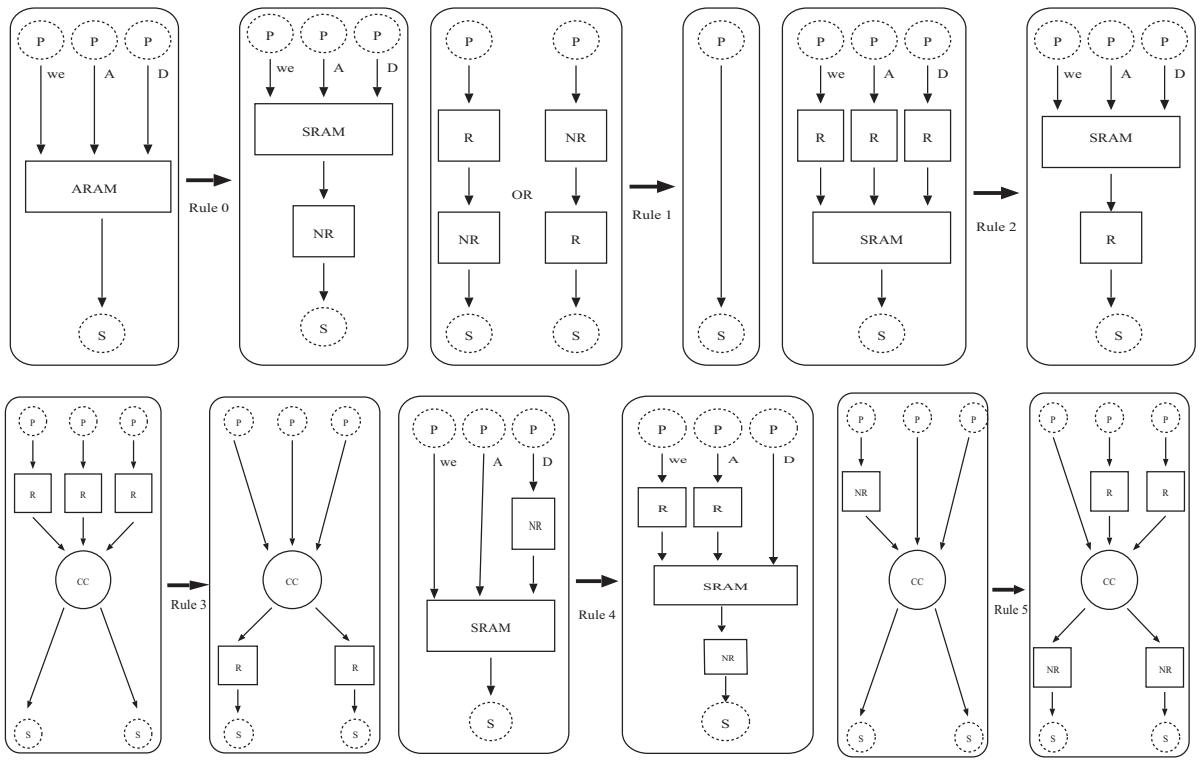

Fig. 4. Rules to rewrite a circuit graph.

- **M[3]:** $\langle 0, 0, 0, 13, 13, 13, \rangle$.

Thus they are an equivalent.

Rule 1 R+NR and NR+R have the following output sequences $\langle 11, 12, 13, -, -, -, \rangle$ and $\langle 0, 12, 13, -, -, -, \rangle$, respectively. Also, NULL circuit has the following output sequence $\langle 11, 12, 13, -, -, -, \rangle$. Thus, they are an equivalent.

Rule 2 R+SRAM has the following output sequence and stored data.

R+SRAM(output sequence): $\langle 0, 0, 0, 0, 0, 11, \rangle$

R+SRAM(stored data of M[1], M[2] and M[3]):

- **M[1]:** $\langle 0, 0, 11, 11, 11, 11, \rangle$
- **M[2]:** $\langle 0, 0, 0, 12, 12, 12, \rangle$ and
- **M[3]:** $\langle 0, 0, 0, 0, 13, 13, \rangle$.

SRAM+R has the following output sequence and stored data.

SRAM+R(output sequence): $\langle 0, 0, 0, 0, 0, 11, \rangle$

SRAM+R(stored data of M[1], M[2] and M[3]):

- **M[1]:** $\langle 0, 11, 11, 11, 11, 11, \rangle$
- **M[2]:** $\langle 0, 0, 12, 12, 12, 12, \rangle$ and
- **M[3]:** $\langle 0, 0, 0, 13, 13, 13, \rangle$.

Thus they are an equivalent.

Rule 3 The output sequences of the left-hand side of the rule are $\langle f(a_1, b_0, c_0),\ f(a_2, b_1, c_1),\ f(a_3, b_2, c_2),\ \ldots \rangle$ and $\langle g(a_1, b_0, c_0),\ g(a_2, b_1, c_1),\ g(a_3, b_2, c_2),\ \ldots \rangle$. Those of the right-hand side are $\langle f(a_1, b_0, c_0),\ f(a_2, b_1, c_1),\ f(a_3, b_2, c_2),\ \ldots \rangle$ and $\langle g(a_1, b_0, c_0),\ g(a_2, b_1, c_1),\ g(a_3, b_2, c_2),\ \ldots \rangle$. Thus, they are an equivalent.

Rule 4 NR+SRAM has the following output sequence and

stored data.
NR+SRAM(output sequence): $\langle 0,0,0,0,12,13,\rangle$
NR+SRAM(stored data of M[1], M[2] and M[3]):

- **M[1]:** $\langle 0,12,12,12,12,12,\rangle$
- **M[2]:** $\langle 0,0,13,13,13,13,\rangle$ and
- **M[3]:** $\langle 0,0,0,-,-,-,\rangle$.

SRAM+NR has the following output sequence and stored data.
SRAM+NR(output sequence): $\langle 0,0,0,0,12,13,\rangle$
SRAM+NR(stored data of M[1], M[2] and M[3]):

- **M[1]:** $\langle 0,0,12,12,12,12,\rangle$
- **M[2]:** $\langle 0,0,0,13,13,13,\rangle$ and
- **M[3]:** $\langle 0,0,0,0,-,-,\rangle$.

Thus they are an equivalent.
For the Rule 4, we consider that an NR is connected to data input port, *D* only. If an NR is connected to the address input port, A or write enable input, *we*, an equivalency of the Rule 4 can be shown in the similar way.

Rule 5 The output sequences of the left-hand side of the rule are $\langle f(0,0,0),\ f(a_0,b_0,c_0),\ f(a_1,b_1,c_1),\ \ldots\rangle$ and $\langle g(0,0,0),\ g(a_0,b_0,c_0),\ g(a_1,b_1,c_1),\ \ldots\rangle$. Those of the right-hand side are $\langle 0,\ f(a_0,b_0,c_0),\ f(a_1,b_1,c_1),\ \ldots\rangle$ and $\langle 0,\ g(a_0,b_0,c_0),\ g(a_1,b_1,c_1),\ \ldots\rangle$. Thus, they are an equivalent.

We are now in position to describe the rewriting algorithm. Suppose that an input circuit graph has nodes with labels *I*, *O*, *R*, *ARAM*, *SRAM*, and *CC*. The following rewriting algorithm generates a circuit graph equivalent to the original circuit graph.

> *Find a minimum i such that Rule i can be applied to the current circuit graph. Rewrite the circuit graph using such Rule i. This rewriting procedure is repeated until no more rewriting is possible.*

V. Behavior of Our Circuit Rewriting Algorithm

Let us observe the behavior of the rewriting algorithm.

- First, the rewriting algorithm repeats the applying Rule 0 to all ARAM nodes until all ARAM nodes are rewritten into SRAM+NR. After that, Rule 0 is never be applied.
- Rule 1 is applied and adjacent R and NR nodes are removed whenever possible.
- R or NR node is moved toward the output nodes using Rule 2, Rule 3, Rule 4 and Rule 5 whenever possible.

In our previous paper [1], we have shown one of the applications of our rewriting algorithm. Since application example is similar for rewriting algorithm, presented in this paper, hence we are not incorporating it.

For the purpose of clarifying the condition such that the rewriting algorithm can generate NR-free circuit graph. We define *the potentiality of the nodes* in a circuit graph. Suppose that a node v of a circuit graph has k (≥ 0) incoming edges such as $(u_1,v),(u_2,v),\ldots,(u_k,v)$. Let us define *the potentiality* $p(v)$ of a node v as follows:

- If v is I, then $p(v)=0$.
- If v is O, then $p(v)=p(u_1)$.
- If v is SRAM, then $p(v)=\min(p(u_1),p(u_2),p(u_3))$
- If v is ARAM, then $p(v)=\min(p(u_1),p(u_2),p(u_3))-1$.
- If v is NR ,then $p(v)=p(u_1)-1$.
- If v is R then $p(v)=p(u_1)+1$.
- If v is CC, then $p(v)=\min(p(u_1),p(u_2),\ldots,p(u_k))$.

The Fig 3 shows the potentiality of each node. We have the following theorem.

Theorem 1: All O nodes and all cycles of a circuit graph have non-negative potentiality, if and only if our rewriting algorithm generates an ARAM-free and NR-free circuit graph, equivalent to the original circuit graph.

In other words, we can determine a fully synchronous circuit that can be converted into an ARAM-free circuit by evaluating the potentiality of all O nodes and all cycles of the corresponding circuit graph. Also, the potentiality of all O nodes and all cycles are non-negative, our rewriting algorithm generates an ARAM-free and NR-free circuit graph, and the corresponding fully synchronous circuit is ARAM-free and equivalent to the original fully synchronous circuit.

VI. Proof of Theorem 1

The main purpose of this section is to show a proof of Theorem 1. Hence, we need to show several lemmas for a proof of Theorem 1. However, we are not incorporating the proof of Theorem 1 in this paper because of the page limitation. The reader may think that this paper is useless without proof of Theorem 1. In this case, we refer the readers to the proof part of our previous papers [3], [1] which is the similar for this paper.

VII. Conclusions

In this paper, we have presented a rewriting algorithm and six rewriting rules to obtain the equivalent circuits with Synchronous RAMs (SRAMs) for the circuits with Asynchronous RAMs (ARAMs) including cycles. Using our rewriting algorithm, any sequential circuit with ARAMs represented by a directed reachable graph (DRG) can be converted into an equivalent fully synchronous sequential circuit with no ARAMs to support the current FPGA architecture. Note that, rewriting algorithm presented in our previous paper [1] was only capable to convert DAG circuits (no cycle) with ARAMs into an equivalent circuit with SRAMs for implementing in modern FPGAs. Hence, there was a strict limitation to handle practical circuits with cycles. However, our algorithm presented in this paper can do it automatically.

Abstract—**Graphene nanoribbons (GNRs) are widely used as a channel of nanoscale based transistor. Now it is investigated in very large scale integration (VLSI) based interconnect system because of its higher degree of conductivity. It is seen that the RLC (resistor inductor and capacitor) equivalent circuit of GNR interconnect system has four important parameters like classical capacitance, quantum capacitance, magnetic inductance and kinetic inductance. These parameters have an important relation with the structure (here width) of GNR. Another important parameter is the resonant frequency which is normally calculated from the RLC model of a system. In this paper we have analyzed these four parameters for varying width of GNR. Then the resonant frequency response of GNR based interconnect system has been observed by varying width of GNR. Moreover, we have analyzed our work on resonant frequency by considering the two degeneracy factors of quantum capacitance.**

Keywords—Graphene nanoribbon, classical capacitance, quantum capacitanc, magnetic inductance , kinetic inductance.

I. INTRODUCTION

Graphene is a flat monolayer of carbon atoms tightly packed into two dimensional honeycomb lattice [1], has appeared as one of the most potential candidate in fundamental research [2].When it is patterned into a nanoscale ribbon then it is called graphene nanoribbon (GNRs) have been studied for interconnects [3]-[5]. It is showed that traditional copper based interconnect suffers serious problems due to increased resistivity and susceptibility to electro-migration [6]. Otherwise GNRs have larger mean free path and higher amount of thermal conductivity it lags the earlier Cu based interconnect [7].

Depending on the geometrical structure GNRs can be either semiconducting or metallic [8]. Here the basic geometrical parameter is number of dimerline (N) which is also called number of hexagonal ring in GNR. And from the equivalent circuit model of GNRs structure, it is observed that an RLC model and interconnect system is formed. It is also seen that RLC model can be splitted into some important parameters like classical capacitance, quantum capacitance, magnetic inductance and kinetic inductance Upon this GNR based interconnect the resonant frequency can be observed which will be useful hint of GNR based VLSI technology also in microprocessor.

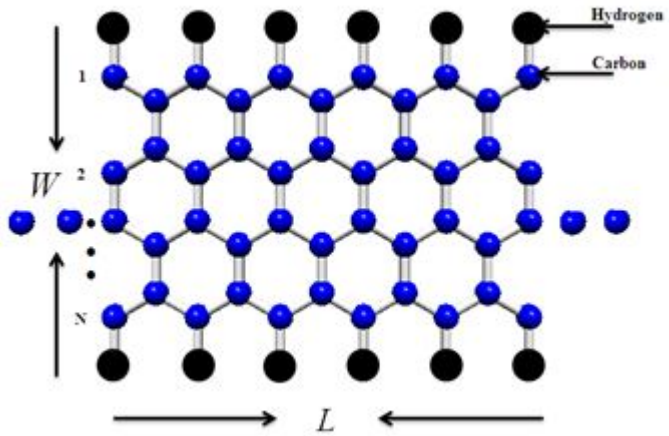

Figure 1. Schematic of a GNR. The blue circles denote carbon atoms termintaing by black circle hydrogen atoms. The number of dimmer line, width and length of GNR are represented by N , W and L respectively.

In this paper we will calculate some parameter of RLC interconnect system like resonant frequency, classical capacitance, quantum capacitance for two degeneracy factors, magnetic inductance and kinetic inductance for varying width of GNR from corresponding number of dimer line N.

II. THEORY

As stated earlier the geometrical structure which is width of GNR can be found from N. And sample which is made by this geometry shows semiconducting property in one condition and metallic property for other. Now the width of semiconducting GNR which is usually called as armchair GNR is-

$$W_{ac} = (N-1)\frac{\sqrt{3}}{2}a \qquad (1)$$

where $a = 1.42$ A^0 is the nearest neighbor distance.

The simple electrical circuit model of monolayer Graphene Nanoribbon is like RLC circuit which is the first concern in Graphene Nanoribbon based interconnect system.

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

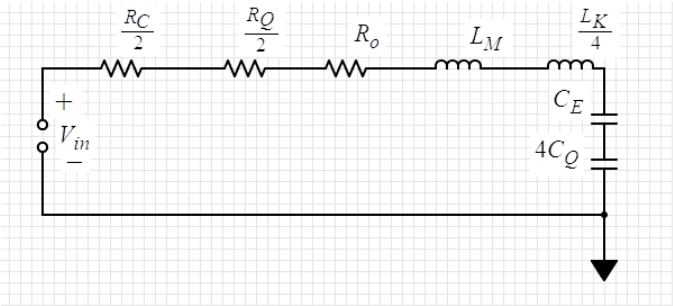

Figure 2. Schematic of a RLC model of monolayer GNR interconnect system.

In Fig. 2, R_C , R_Q and R_o denotes respectively the imperfect contact resistance quantum resistance and ohmic resistance. Also L_M , L_K denotes respectively magnetic inductance and kinetic inductance and C_E , C_Q denotes classical capacitance and quantum capacitance.

The frequency at which a system here in RLC circuit, the system or electric signal of the system oscillates with greater amplitude than that frequency is called resonant frequency of that system. From the above Fig. 2, we can calculate the resonant frequency excluding only ($\frac{R_C}{2}$, $\frac{R_Q}{2}$ and R_o) resistive part-

$$2\pi f_r L_M + 2\pi f_r \frac{L_K}{4} - \frac{1}{2\pi f_r C_E} - \frac{4}{2\pi f_r C_Q} = 0 \tag{2}$$

So

$$f_r = \frac{1}{2\pi} \frac{\sqrt{\left(\frac{1}{C_E} + \frac{4}{C_Q}\right)}}{\sqrt{L_M + \frac{L_K}{4}}} \tag{3}$$

For calculating other paprameter we have used their established relation with the width of GNR.

The classical capacitance is calculated from the device geometry like width of GNR, dielectric constant of insulator etc. Now the classical capacitance become-

$$C_E = N_G \varepsilon_o k \left(\frac{W_{ac}}{t_{ox}} + \alpha \right) \tag{4}$$

where N_G is the number of gates, k is the relative dielectric constant of the gate insulator, ε_0 is the permittivity of air, t_{ox} represents the gate insulator (oxide) thickness and $\alpha = 1$ is a dimensionless fitting parameter[9].

As the device is controlled by a source voltage the classical capacitance cannot be well enough to investigate the electronic behavior of GNR based device. So another capacitance must be included for better understanding of observing the device behavior like quantum capacitance which is [10]

$$C_Q = \frac{e^2}{3ta\pi} \left(\frac{x + \frac{E_G}{2k_B T}}{\sqrt{x + x\frac{E_G}{k_B T}}} \right) f(E) \tag{5}$$

Where

$$x = E - \frac{E_G}{2}$$

$$E_G = -\frac{2\pi(\gamma_1 - 2\gamma_3)}{\sqrt{3}(\frac{2}{\sqrt{3}}\frac{W_{ac}}{a} + 2)} + \frac{6(\gamma_3 + \Delta_{\gamma_1})}{\left(\frac{2}{\sqrt{3}}\frac{W_{ac}}{a} + 2\right)} \tag{6}$$

where γ_1 = - 3.2 eV is the first nearest neighbor hopping parameter, γ_3 = - 0.3 eV is the third nearest neighbor hopping parameter, Δ_{γ_1} = - 0.2 eV is the correction of γ_1 [11]. $k_B = 1.38 \times 10^{-23} J/K$ (Boltzmann constant), $e = 1.6 \times 10^{-19}$ Columb, T = Room temperature, t = 2.7 eV, hopping integral of perfect GNR.

$$f(E) = \frac{1}{\exp\left(\frac{E - E_F}{k_B T}\right) + 1}$$

If GNR based device is tuned by a supply voltage, degeneracy can be determined from the position of Fermi level. In degenerate regime, the Fermi level is located within or close to the conduction band so for this condition becomes $E - E_F < 3k_B T$ and therefore, the Fermi function can be approximated as $f(E)$ = 1. On the other hand, for a nondegenerate condition when the Fermi level is located inside the GNR bandgap, the condition is given by $E - E_F > 3k_B T$. So Fermi function becomes $f(E) = \exp[(E_F - E)/k_B T]$.

Now the quantum capacitance in degenerate regime can be written as-

$$C_{Q(\deg)} = \frac{e^2}{3ta\pi} \left(\frac{x + \frac{E_G}{2k_B T}}{\sqrt{x + x\frac{E_G}{k_B T}}} \right) \tag{7}$$

Another the quantum capacitance in nondegenerate regime can be written as-

$$C_{Q(non\deg)} = \frac{e^2}{3ta\pi} \left(\frac{x + \frac{E_G}{2k_B T}}{\sqrt{x + x\frac{E_G}{k_B T}}} \right) \exp(\eta) \tag{8}$$

where $$\eta = \frac{E_C - E_F}{k_B T} \quad (9)$$

Kinetic inductance arise from the energy stored in the magnetic field due to a current. Now to compute the kinetic inductance of GNR by extending the derivation of kinetic inductance of carbon nanotubes [12].The kinetic inductance in relation with GNR width is [13]-

$$L_K = \frac{\pi^3 \hbar^2 L}{E_F e^2 W_{ac}} \quad (10)$$

Where L is the length of a monolayer GNR

Otherwise magnetic inductance arises from the energy stored in the motion of the charge carriers. And for one layer of GNR the magnetic inductance becomes [7]-

$$L_M = \frac{\mu d}{W_{ac}} \quad (11)$$

Where $\mu = \mu_o = 4nH\,cm^{-1}$ is the permeability of GNR, d=5nm distance of another materials.

III. Results and Discussion

The width of the GNRs is derived from the number of dimer lines N which is obtained from equation (1) .If we look into the equation (1) it can be said easily that there is a linear relation between the dimer line and width of GNR. From this calculated width we can also measure the bandgap energy using the equation (6).Here also it can be said that there will be inverse relation between the width of GNR and bandgap energy.

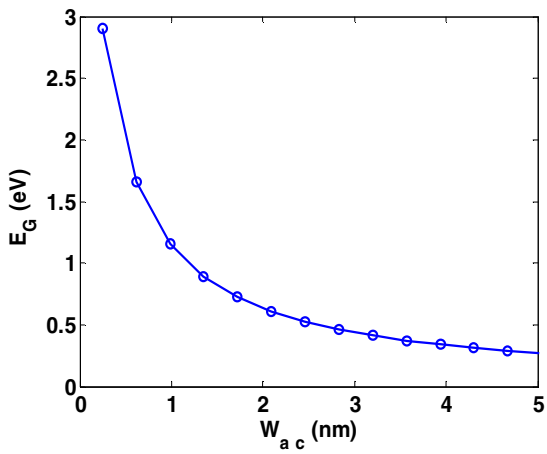

Figure 3. Bandgap Energy (E_G) vs. width (W_{ac}) of GNR .

Here, at first we can observe the band gap energy for the above calculated width of GNR which will be useful in calculating the quantum capacitance. From the above Fig.3 it is seen that there is an inverse relation between the band gap energy and width of GNR. As the width is increased the band gap is decreased.

Now we will observe the classical capacitance. From the equation (4) it can be also said that there will be a linear relation between width of GNR and classical capacitance which will be not sufficient. So we will observe the response of classical capacitance along with quantum capacitance in i)degenerate regime and ii) nondegenerate regime for corresponding changing the width of GNR.

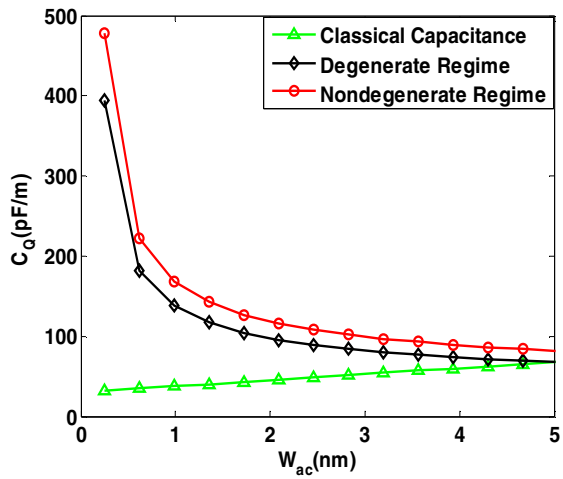

Figure 4.Quantum capacitance in two regimes vs. width (W_{ac}) of GNR.

From the Fig.4 it is seen that classical capacitance gives linear response with width of GNR and the values are varied from 31 pF/m to 73 pF/m. Also it is seen that there is an inverse relation between quantum capacitance in degenerate, nondegenerate regime and width of A-GNR. Here we have analyzed that the quantum capacitance value for a fixed Fermi energy which is close to conduction (for this two regime works simultaneously). As the Fermi level close to conduction band and it is seen from equation (9) that there is a relation of conduction band energy in nondegenerate regime. So quantum capacitance in this regime will be greater value than in degenerate regime. Quantum capacitance in degenerate regime is calculated as 394.09 pF/m to 64.57pF/m. And quantum capacitance in nondegenerate regime is calculated as 478.36 pF/m to 78.38 pF/m.

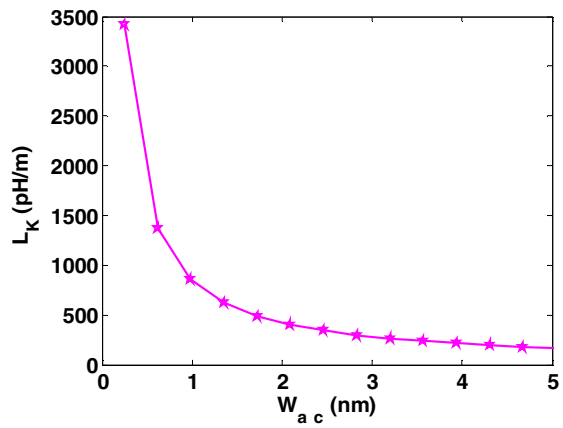

Figure 5. Kinetic inductance (L_K) vs. width (W_{ac}) of GNR

Now we will observe the kinetic inductance for varying width of GNR. From the Fig.5 it is seen the kinetic inductance is decreasing for increasing width of GNR width. It means enlargement of width of GNR reduces kinetic energy of charge carrier. Here it is calculated for 3415 pH/m to 1453 pH/m.

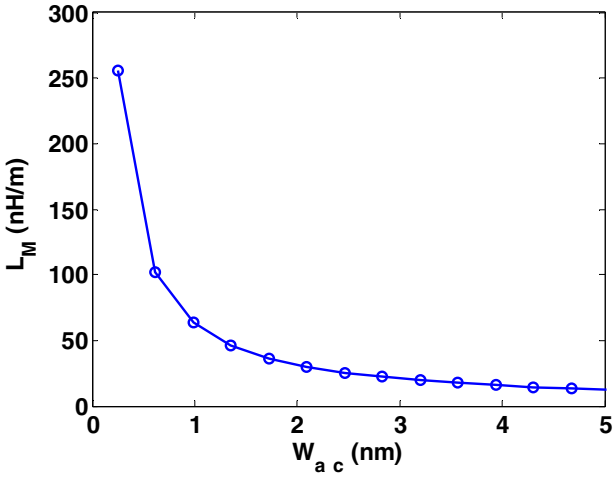

Figure 6.Magnetic inductance (L_M)vs. width (W_{ac}) of GNR

From the Fig.6 it is also observed that increasing the width of GNR reduces the energy stored as magnetic field. It is due to the current through the GNR channel. For this magnetic inductance is greater than kinetic inductance. Because we know that current in a device is formed from integer number of charge carrier (electron) movements. Here this inductance is calculated for 255.46 nH/m to 10.87 nH/m.

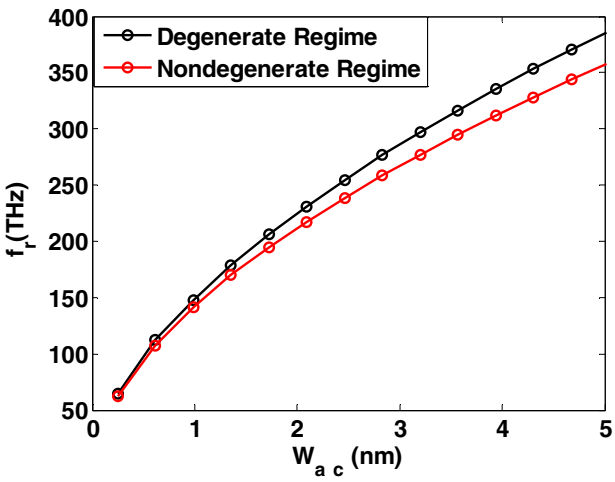

Figure 7. Resonant frequency (f_r)vs. width (W_{ac}) of A-GNR

From Fig.7 we have seen that the resonant frequency in two regime works in two ways. It can be described when the device structure is decreasing, the resonant frequency traces 387.38 THz to 62.60 THz. After that the frequency traces 63.99 THz to 418.81 THz when the device structure is increased.

IV. Conclusion

The RLC interconnect system is one of the important phenomena in microchip, microprocessor, VLSI technology. In this paper we have first observed equivalent circuit of monolayer GNR. Then we have seen that the system can be splitted into some other important parameter like classical capacitance, quantum capacitance, magnetic inductance, kinetic inductance. Then we have analyzed these parameters for varying the structure (here width) of GNR. Quantum capacitance, magnetic inductance, kinetic inductance parameter shows inverse relation with the width of GNR. At last we have observed that the resonant frequency of the system for considering the two regime of quantum capacitance by varying width of GNR. Here we have seen that resonant frequency is larger in degenerate regime than in nondegenerate regime. So in the fabrication it will be fruitful if there is a compromising between width of GNR and resonant frequency of GNR based interconnect system.

Abstract— **In this paper we propose a digital logic inverter based on Graphene Nanoribbon Field Effect Transistor (GNR-FET) using ratioed circuit topology. Different types of GNR-FET architectures have been analysed through their current-voltage characteristics to find their probable applications like interconnect, on-chip resistance etc. Here electronic transport calculation is based on NEGF approach which is coupled with Poisson's equation to incorporate the effects of self-consistent field. Our all-graphene inverter shows output voltage swing of ~0.8V for an input voltage swing of 1V having a noise margin of 0.2V with a rise time of ~14.4ps and fall time of ~1.78ps. When it operates in 10GHz and 80% duty cycle the total power consumption is ~100nW which seems promising for low power logic design.**

Index Terms—**Graphene nanoribbon (GNR), Logic inverter, GNR-FET, Non-equilibrium Green's Function (NEGF), Low power, Noise margin.**

I. Introduction

Following Moore's law [1], semiconductor based electronics gone through a very dynamic evolution over decades. Key to this success was the continuous scaling of silicon Metal Oxide Semiconductor Field Effect Transistor (Si MOSFET). Today Si MOSFETs with 20nm gates are in mass production, and for the year 2020, the International Technology Roadmap for Semiconductor (ITRS) requires 10nm MOSFETs [2]. Unfortunately it becomes more and more difficult to further scale the Si MOSFET and simultaneously achieve the needed device performance.

Recently, Graphene, a 2-D carbon-based material, has attracted a lot of attention due to its unique electronic transport properties such as a high Fermi velocity, outstanding carrier mobility, and a high carrier saturation velocity [3]. These characteristics make graphene an excellent candidate for advanced application in future electronics. But due to the zero bandgap nature of unpatterned graphene sheets Graphene-FET (GFETs) suffer from a high off current which makes it unsuitable for digital logic circuit application whereas analog applications of GFETs is potentially emerging [4]-[5]. However lateral confinement of graphene sheet following some particular pattern (chirality) opens up a bandgap (E^g <1.4eV), called graphene nanoribbon (GNR). GNRs have opened a prospect for GNR based FETs as their energy gap is inversely proportional to their width [6] and depending on this width they can be semiconducting or metallic. The ultrathin structure of GNRs leads to perfect electrostatic control of gate over channel which is a key advantage over conventional semiconductors. Extensive research is now going on for fabricating GNRs with narrow width and smooth edges. Patterned GNRs have been exhibited experimentally with ~10nm width [7]-[8]. So, computer simulations can be very useful to provide physical insights and determine performance of GNR-FETs with ultrathin (~1nm) width.

In this paper we have analyzed different GNR-FET architectures where electronic transport is modeled by Non-equilibrium Green's Function (NEGF) formalism which incorporates electron-electron interaction through self-consistent field. Taking accounts the analysis of transmission spectrums and *I-V* characteristics of the devices in a specified voltage range (0V to 1V) suitable applications of different GNR-FETs are proposed. Finally we design a digital logic inverter with necessary optimization and analyzed its different performance parameters such as transfer characteristics, power consumption, noise margin and then operated by a 10GHz, 80% duty cycle input to observe rise time and fall time.

II. Device Configuration and Types

Graphene nanoribbon can be Armchair (A-GNR) or Zig-zag (Z-GNR) depending on the chirality. Depending on the number of carbon atoms along its width Armchair GNR and Zig-zag GNR show semiconducting or metallic behaviour [9]. Taking the variation of bandgap with the width of armchair GNR into consideration we propose four types of GNR-FETs that can be made from only Armchair GNRs.

Fig. 1 shows channel and source-drain regions of four types of GNR-FETs proposed in this paper. For Type-I device in Fig. 1(a), N=7 (E^g = 1.35eV) semiconducting armchair nanoribbon of 3.5nm length is used in the channel region, where N is the number of carbon atoms along the width of armchair GNR. This region is then connected with two N=8 ($E^g \approx$ 0eV) metallic armchair nanoribbons, considered as electrodes. Width of this device is ~0.74nm. This proposed structure provides excellent interface matching between channel and electrode regions thus eliminating the possibility of interface defects, reducing the possibility of impurity scattering. While a contact metal would introduce large contact resistance to the device [10], contact with the metallic armchair GNR makes smoother metal-semiconductor interface with minimum contact resistance. Fig. 1(b), 1(c), 1(d) shows other combinations of GNRs considered in this paper. Type-II and Type-III devices are solely made of metallic GNR (N=11) and semiconducting GNR (N=7) respectively. In Type-IV device top-gated channel is a cascade of metallic (N=8)-semiconducting (N=7)-metallic (N=8) GNR. The detailed behaviour of all types of devices under potential will be discussed in the subsequent sections.

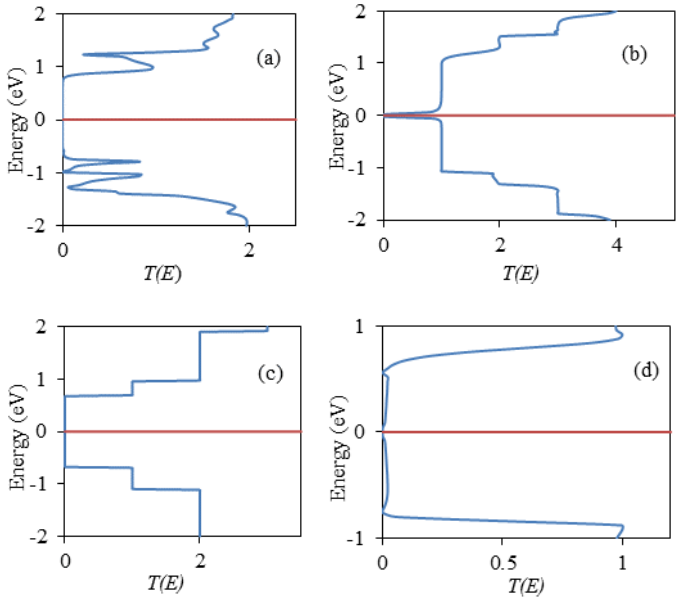

Fig. 2 Transmission Spectrum, *T(E)* of (a) Type-I device (b) Type-II device (c) Type-III device (d) Type-IV device at zero gate bias.

III. Simulation and Results

In this paper we have used non-equilibrium Green's functions (NEGF) approach coupled with Poisson's equation to calculate electronic transport in GNR-FET. Here the NEGF formalism [11] is based on tight binding P_Z orbital which incorporates 3rd nearest neighborhood calibrated through a first-principle calculated *ab-initio* model [12]. The charge distribution described by NEGF is self-consistently coupled with electrostatics to incorporate the effect of self-consistent field and solved by multi-grid finite difference method. The edge atoms are considered as hydrogen passivated (σ bond) and HfO_2 ($\kappa \approx 25$) is used as gate oxide with oxide thickness of ~0.4nm for minimized gate leakage.

A. Transmission Spectrum

Transmission spectrum for Type-I device is shown in Fig. 2(a). In the bandgap (1.35eV) energy range it has zero transmission coefficient, *T(E)*.

On the other hand Type-II device in Fig. 2(b) shows zero bandgap ensuring metallic behaviour where a small bias voltage can produce very high current but having less impact of top-gate voltage upon this current. Whereas in Type-III device transmission spectrum may seem as 2D semi-conductor like as shown in Fig. 2(c), but current may degrade a lot due to very high contact resistance and schottkey barrier due its relatively high bandgap.

Type -IV device is in general sense a cascade of Type-III and Type-II device. Its channel is formed by both semiconducting (N=7) and metallic (N=8) GNR, where for metallic region transmission coefficient is non-zero in the bandgap region of semiconducting GNR as shown in Fig. 2(d), which may give rise to piecewise linear resistance behaviour and this resistance is controllable by top-gate voltage. By varying the relative length of semiconducting and metallic GNR it is possible to construct different resistance (in mega ohm range) at fixed gate potential.

So we can come in a decision that Type-I device may be chosen for better performance as FET, Type-II for interconnect, Type-IV for on-chip resistance.

B. I-V Characteristics

From the transmission spectrums it is evident that gate voltage and drain-source bias voltage will have larger impact on the current in the channel region for Type-I device than any other three types of devices. When a positive gate potential is applied, minimum energy for non-zero electron transmission coefficient comes closer to Fermi energy level which in turns gives rise to current, I_{ds}. The current-voltage characteristics, I_{ds}-V_{ds} curve for Type-I device for different gate potential is shown in Fig. 3. The current-voltage characteristics of Type-II device is shown in Fig. 4. This device shows resistor like behaviour (almost linear *I-V* characteristics) with resistance in kilo-ohm (KΩ) range.

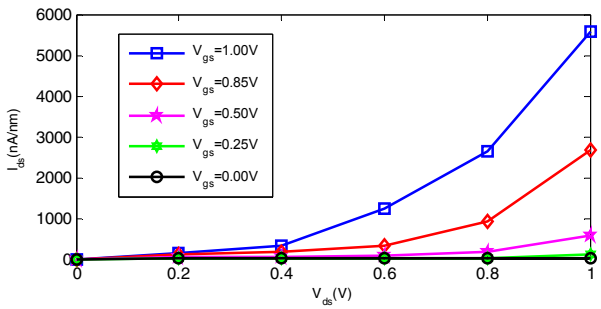

Fig. 3 I-V_{ds} curve at different gate voltage for Type-I device.

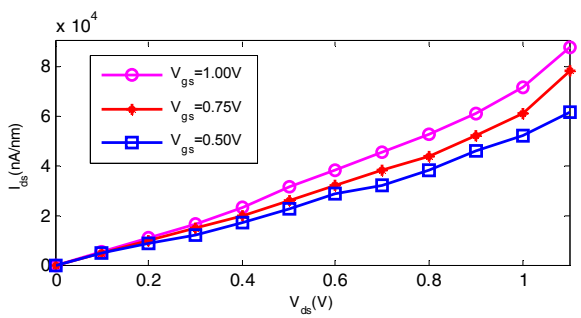

Fig. 4 I-V_{ds} curve at different gate voltage for Type-II device.

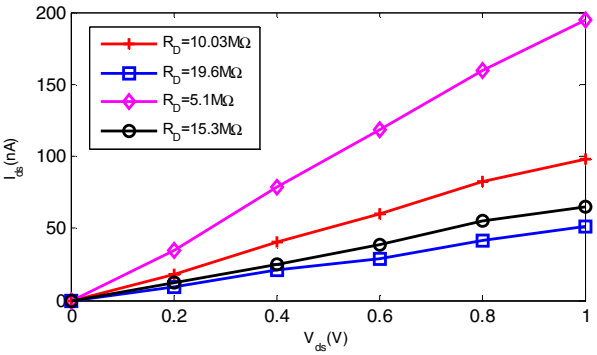

Fig. 5 *I-V*$_{ds}$ curve of Type-IV device at V_{gs}=0V.

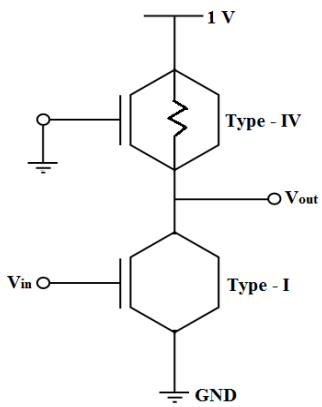
Fig. 5 shows I_{ds}-V_{ds} curves of Type-IV device. This device also shows linear resistor like *I-V* characteristics in a specified voltage range (0V to 1V) with resistance in the mega-ohm (MΩ) range. Using this property on-chip resistance can be modelled. In this paper, relative length of semiconducting and metallic GNR in the channel region was varied to construct different values of resistance.

IV. Digital Logic Inverter Design

Implementation of digital logic inverter or switching circuit using GNR-FET is somewhat challenging due to its unconventional behaviour (absence of current saturation) with respect to MOSFET. Due to absence of complementary GNR-FET pairs, the logic architecture proposed here is based on ratioed circuit topology. From the previous discussions it is evident that Type-I GNR-FET is suitable as pull-down network. Whereas pull up network is made by Type-IV GNR-FET because of its high resistance, R_D and Type-III GNR-FET is used as interconnect between pull-up and pull-down network. To obtain desired inverter transfer characteristics an optimum value of R_D is required. A schematic diagram and its layout diagram of our designed logic inverter are shown in Fig. 6 and Fig. 7 respectively.



V_{in}	0V	1V
V_{out}	0.90V	0.11V
I_{static}	8.63nA	88.6nA
P_{static}	8.63nW	88.6nW

Fig. 6 Inverter using Type-I and Type-IV GNR-FETs.

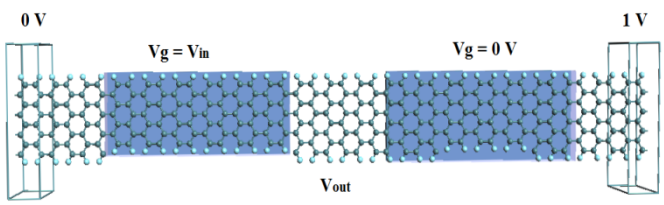


Fig. 7 Layout diagram of a GNR inverter.

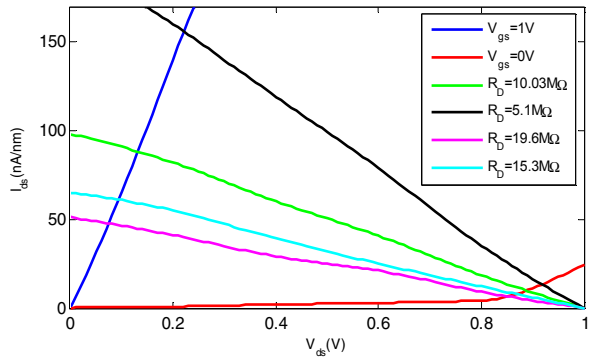

Fig. 8 I_{ds}-V_{ds} curve of Type-IV device with different load, R_D lines.

A. Optimization of R_D

The model of logic inverter proposed in this paper is based on the I_{ds}-V_{ds} curves of Type-I device and Type-IV device. In Fig. 8, *I-V* characteristics for both devices are shown in the same plot. From the figure we can see that variation of resistance, R_D of the pull up network would cause significant alteration in the output logic level of the inverter. When R_D is ~10MΩ, output voltage, V_{out} =0.9V and V_{out}=0.11V for input voltage, V_{in} =0V (Logic 0) and V_{in}=1V (Logic 1) respectively. Decreasing R_D (i.e. R_D~5.1MΩ) would improve inverter performance in Logic 0 input but degrade the performance in case of Logic 1 input. On the other hand if R_D is increased (i.e. R_D~15.3MΩ or R_D~19.6MΩ), performance in Logic 1 input would improve but performance in Logic 0 input would fall. For this reason, we selected the value of R_D at which the difference of output voltage logic levels is maximum. In our simulation optimum value of R_D was found to be ~10MΩ.

B. Power Dissipation and Delay

Static power dissipation in the designed inverter can be found by first calculating the static current, I_{static} of the device during different input logic level. As listed in Fig. 6 I_{static}=88.61nA for input Logic 1 and I_{static}=8.63nA for input Logic 0. So, static power dissipation is ~88.61nW for input Logic 1 and ~8.63nW for input Logic 0. Compared to other available technology these values are very low. Therefore, this device may become a viable option to the circuit design where power dissipation poses major headache.

If V_{out} is fed to operate a second inverter stage then the gate capacitance of the second stage will imposes a rise/fall time delay upon V_{out}. From the device configuration, gate capacitance, C_g of Type-I device is found to be 4.14×10^{-10} F/m. Using RC delay model rise time and fall time of the inverter is found to be ~14.4ps and ~1.78ps. The big difference between the rise and the fall time is due to the ratioed circuit topology where a large current flows during fall time enabling faster discharge of capacitor whereas very little current flows during rise time resulting in slower capacitor charging. Equal rise time and fall time for the device can be achieved by sacrificing the optimized value of R_D causing output logic voltage degradation.

C. Transfer Characteristics

Output input voltage relationship is summarized by voltage transfer characteristics shown in Fig. 9. This curve gives steady-state value of V_{out} for each value of V_{in}. When V_{in}=0V very small current (~8.63nA) flows through pull down transistor. As a result V_{out} is slightly less than to V_{DD} (1V). This voltage is referred as V_{OH} and its value is 0.9V.When V_{in}

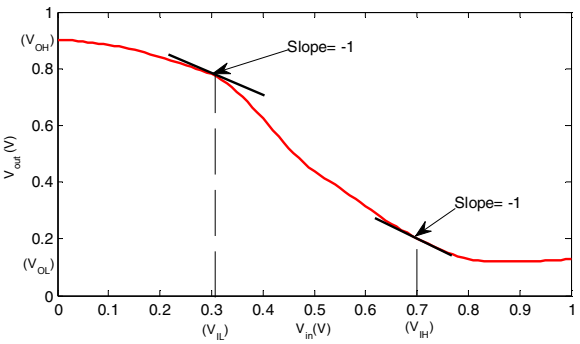

Fig. 9 Voltage transfer characteristics of the inverter.

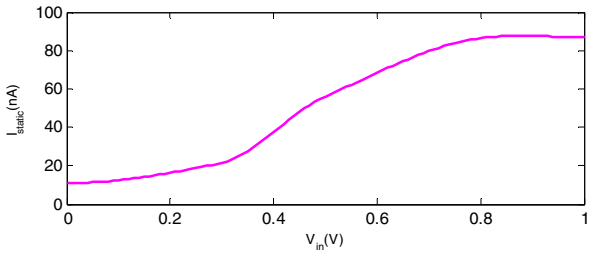

Fig. 10 I_{static}-V_{in} curve of the inverter.

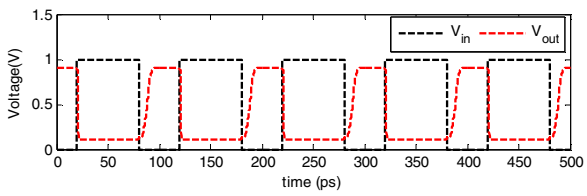

Fig. 11 Output voltage of the inverter when simulated with a 10GHz, 80% duty cycle input voltage signal.

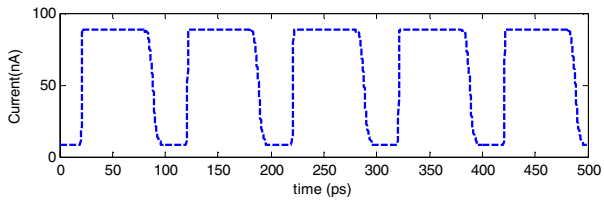

Fig. 12 Current through the inverter.

is 1V, current through pull down transistor increases significantly but still there is some voltage drop across the device. As a result V_{out} is slightly greater than to *GND* (0V). This voltage is referred as V_{OL} and its value is 0.11V.

Fig. 9 also shows the points where V_{out} begins to change from high to low and vice versa. The voltage V_{IL} indicates the points where V_{out} is high and slope of the curve is -1. This is the maximum input voltage level that inverter will interpret as low. Similarly V_{IH} is the minimum input voltage level that inverter will interpret as high. In the curve it indicates the points where V_{out} is low and slope of the curve is also -1.In our simulation we found V_{IL}=0.31V and V_{IH}=0.7V.

Variation of static current due to V_{in} is plotted in Fig. 10. Fig.11 shows the simulated output voltage of the inverter circuit when a sample input signal of 10GHz with 80% duty cycle is given at V_{in}. Current through this device is plotted in Fig. 12. From this figure we found that total power dissipation in the device for the above input signal is ~100nW. This result is very promising compared to complementary graphene inverter [13], where a static power dissipation is found to be ~0.77mW with maximum allowable operating frequency ~4.5GHz.

D. Noise Margin

Noise margin is defined as the ability to tolerate noise without altering the correct operation of the circuit. It is an important design parameter for logic circuits. Low noise margin, NM_L and high noise margin, NM_H are defined by the following equations

$$NM_L = V_{IL} - V_{OL} \quad (1)$$

$$NM_H = V_{OH} - V_{IH} \quad (2)$$

Using equations (1) and (2) values of noise margin were found to be NM_L=0.2V and NM_H=0.2V which is low compared to existing CMOS technology.

V. Conclusions

In this paper, we have performed NEGF simulation to demonstrate the intrinsic current-voltage characteristics of ultra-thin GNR-FETs. Different scattering phenomenon (phonon scattering, lattice mismatch with dielectric) are treated ideally because of its low voltage application. These results are used to design an all graphene digital logic inverter. Then we derived different performance parameters for ultra-fast logical operation which shows sufficient low power consumption (~100nW) even at high operating frequency (10GHz). In conclusion, our work may lay the basis for establishing the realistic operating range of GNR-FET based nanoelectronic logic circuit design, providing useful guidelines for future experimental exploration.

Abstract— **This paper shows a new methodology to design hardware of 32-bit unsigned pipelined multiplier. The proposed hardware design is based on Finite State Machine (FSM) for reducing hardware resources and proliferating maximum frequency. Our suggested pipelined multiplier design contains only four 40-bit full adders to complete 64-bit 32 partial products addition. The synthesis report of the 32-bit pipelined multiplier shows that the usage of the logical resources of FPGA is significantly less than the earlier 32-bit multiplier design. Moreover, the proposed pipelined multiplier hardware doesn't use any DSP or dedicated multiplier block of FPGA for the multiplication process. So, our proposed design is technology independent and it gives uttermost performance both in FPGA and ASIC. The maximum frequency achieved for operation latency of 9-clock cycle is 326.243 MHz for computing 32-bit×32-bit unsigned multiplication and the pipelined multiplier hardware design is tested on Xilinx Virtex-6 XC6VLX75T-3-FF484 FPGA.**

Index Terms— **FSM, Maximum frequency, Pipeline, FPGA and ASIC.**

I. INTRODUCTION

Multiplier circuit is an important block in digital system design such as Digital Signal Processing (DSP) block, Microprocessor, Microcontroller, floating point multiplier, sign multiplier, Multiply-Accumulator (MAC) block etc. The main challenge to design 32-bit multiplier is the addition of large number of partial product. So, efficient hardware design of multiplier has been developed frequently in order to decrease hardware resources and increase maximum frequency. [1-2, 5]

There are mainly two types of hardware implementation method of multiplier, combinational and pipelined implementation method. In combinational implementation, multiplier uses adder tree to add the partial products. As a result combinational multiplier increases both hardware resources and critical path delay. So, in large multiplier implementation combinational method is almost obsolete in digital circuit design. On the other hand, pipelined multiplier is reduced hardware resources and increase maximum frequency by using different pipelined stage. Although, pipelined multiplier reduces hardware resources, but it doesn't use the hardware evenly to complete the multiplication process due to lack of pipelined controller. As a result, the hardware implementations of this multiplier have less maximum frequency, higher clock cycle and higher usage of hardware resources.

Various techniques on implementing 32-bit unsigned multiplier based on pipelined architecture and combinational architecture can be found in the literature. A 32-bit unsigned multiplier is implemented in FPGA using Vedic algorithm and maximum combinational path delay achieved was 22.829 ns. [6] Moreover, the synthesis report shows that the design uses 1188 slices, 2054 4-input LUT and 128 IO buffer of the FPGA. Another implementation of unsigned multiplier uses 659.292 ns to complete the multiplication process. A pipelined multiplier implementation was proposed to reduce the usage of hardware resources and increase maximum frequency for implementing in FPGA and the designed FPGA based 32-bit multiplier's maximum frequency was 319.488 MHz (critical path delay 3.13 ns) [5] with operation latency of 16 clock cycle. The usage of hardware resources ware less compared to that of the counterpart at that time. At the same time, many designer uses DSP block or dedicated multiplier blocks to implement multiplier in FPGA to increase maximum frequency. Altera have Library Parameterized Module (LPM) multiplier where a 32-bit multiplier uses only four 18-bit DSP block for implementing the multiplier and maximum frequency achieved was 454 MHz at 3 output latency [7]. But this multiplier design is useless in implementing in ASIC because ASIC synthesis library does not have such DSP or dedicated multiplier block. So we need an efficient design to implement multiplier in ASIC. [4-5]

In this paper, we have proposed a new novel approach to efficiently design hardware of 32-bit unsigned pipelined multiplier. For the testing purpose we have tested our design in FPGA. The result of the synthesizing report supersedes previously proposed hardware design's synthesize report in terms of less clock cycle, maximum operating frequency and less usage of hardware resources. We have used shift and add algorithm for multiplication process. Our proposed multiplier design uses only four 40-bit adders (four 36-bit adder and four 4-bit adder), Mux (four 9-to-1 Mux and four 8-to-1 Mux) and Demux (two 1-to-9 Demux and two 1-to-8 Demux) for

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

partial product addition. For controlling the Mux and Demux we have used simple Finite State Machine (FSM) which has nine stages to complete the multiplication. Our design ensures maximum usage of the hardware resources in every clock cycle. Pipelining hazard, formation of combinational loops and unwanted latches are completely removed during the hardware design process.

II. Proposed Hardware Design Methodology and Architecture for 32-bit Pipelined Multiplier

A. Design Method

In this paper, we have applied simple shift and add algorithm for the multiplication process. In this process n-bit multiplicand and n-bit multiplier will generate 2n-bit product. To complete this process, it will generate n number of partial product and each partial product will shift left to one bit. Now, 2n-bit product will be generated by adding n number of partial product. Let's illustrate this method using a 4-bit multiplication.

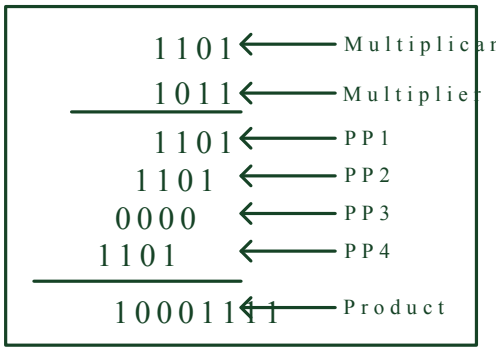

Fig. 1 Multiplication example using shifts and add algorithm.

This direct partial product addition process is useful for small multiplier but for larger multiplier this asynchronous addition process is futile in digital circuit. For example, a 32-bit multiplier will generate 32 partial products and each partial product will be 64-bit. So, 32 64-bit asynchronous additions will raise the critical path delay as well as hardware resources. To solve this problem we have designed FSM based pipelined multiplier.

B. Architecture Operation

In our proposed multiplier circuit, we have reduced adder number and added the partial product sequentially to increase maximum operating frequency and reduce hardware resources. To begin with, we have 32 32-bit partial products. So, we can add the adjacent partial products to reduce to adder width. At first stage, we have to change the 32-bit partial product to 34-bit partial product. So there are 16 34-bit additions and that will generate 16 34-bit partial products for second stage. In second stage, we have to change the 34-bit partial product to 36-bit partial product. So there are 8 36-bit additions and that will generate 8 36-bit partial products for third stage. In third stage, we have to again change the 36-bit partial product to 40-bit partial product. So there are 4 40-bit additions and that will generate 4 40-bit partial products for forth stage. In forth stage, we have to modify 40-bit partial product to 48-bit partial product. So there are 2 48-bit additions and that will generate 2 48-bit partial products for fifth stage. In final stage, we have to modify 48-bit partial product to 64-bit partial product. This two 64-bit partial product addition will give 64-bit product. Our proposed multiplier design can be divided into three major parts and these are partial product generator block, Datapath block and FSM block.

1) *Partial Product generator block*: This block generate partial product from multiplicand and multiplier. As we have seen that there are 31 different additions process among them 24 additions (16 34-bit additions and 8 36 bit additions) can be done by 36 bit adder. So we have generate the partial product in 36-bit to reduce the partial product modification process in verilog coding.

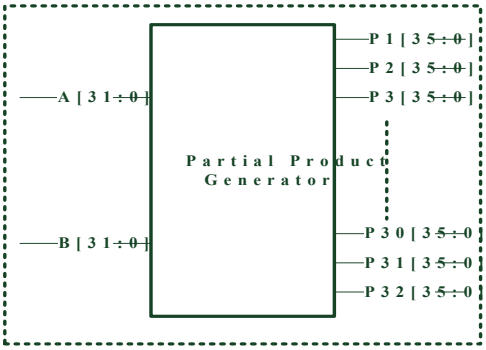

Fig. 2 Partial Product Generator block diagram

2) *Datapath block:* This block handles all the addition of the partial products. This block contains 4 40-bit adders (4 36-bit adder and 4 4-bit adder), 4 9-to-1 Mux and 4 8-to-1 Mux, 2 1-to-9 Demux and 2 1-to-8 Demux.

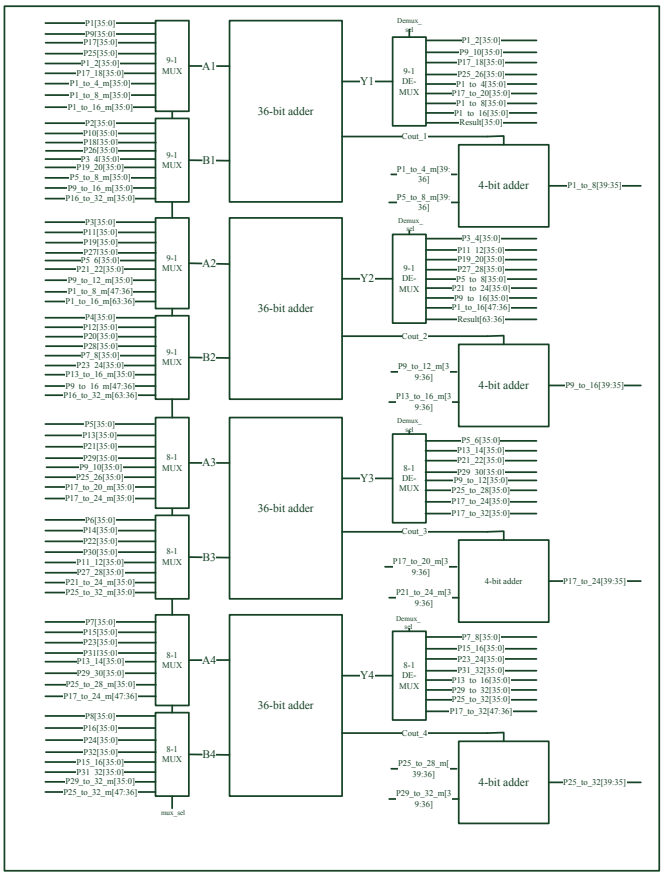

Fig. 3 Datapath block diagram

All the outputs of partial product generator block are assigned as inputs in the Datapath block. There are 32 36-bit partial products and 16 36-bit additions. So it needs 4 clock cycles to complete these 16 additions. And, these 16 36-bit partial products are stored in a register. Then, there are 16 36-bit partial products need 8 36-bit additions. So it needs 2 clock cycles to complete these 8 additions. This 8 addition will generate 8 36-bit partial products. After that, these 8 36-bit partial products (P1_to_4, P5_to_8, P9_to_12, P13_to_16, P17_to_20, P21_to_24, P25_to_28, and P29_to_32) are modified into 40-bit partial product (P1_to_4m, P5_to_8m, P9_to_12m, P13_to_16m, P17_to_20m, P21_to_24m, P25_to_28m, and P29_to_32m). Now, there are 8 40-bit partial products need 4 40-bit additions. And it can be done in one clock cycle where LSB 36 bits are assigned in 36-bit adder and MSB 4 bits are assigned in the 4-bit adder. If any carry generated in the 36-bit adder that will propagate to the 4-bit adder and 40-bit result will be concatenated from the two adder output. Then, there are 4 40-bit partial products (P1_to_8, P9_to_16, P17_to_24, and P25_to_32) and they are modified into 48-bit partial product (P1_to_8m, P9_to_16m, P17_to_24m, and P25_to_32m). Then first 2 48-bit partial products are assigned in the first 2 adder. In first adder LSB 36-bits are assigned and in second adder MSB 12 bits are assigned. If any carry generated in the first adder that will propagate to the second adder and 48-bit result will be concatenated from the two adder output. Same process will be followed for the last two partial products. Then, there are two 48-bit partial products (P1_to_16, P17_to_32) and they are modified into 64-bit partial product (P1_to_16m, P17_to_32m). First 36 bits are assigned in the first adder and remained 28 bits are assigned in the second adder. The result will be concatenated output of the two adders.

```

Fig. 4 Verilog code for partial product modification

3) *Finite State Machine (FSM) block:* This block generates Mux_sel and Demux_sel input for the Datapath block. This block can be divided into 2 parts Present State Register (PSR) and Next State Output Logic (NOSL). PSR is a sequential logic and it gives output in the positive edge clock. NOSL is a combinational circuit it gives the output of the FSM. This FSM contains 9 state and gives Mux_sel [3:0] and Demux_sel [3:0] outputs.

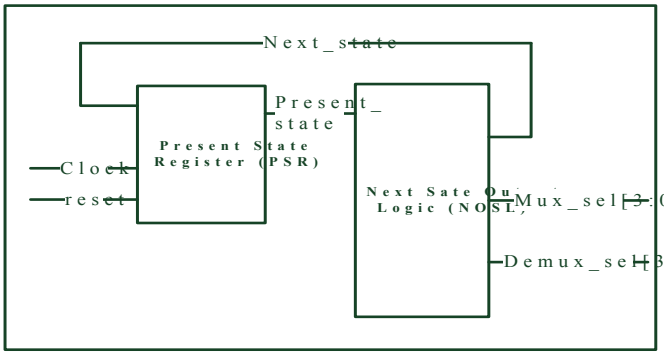

Fig. 5 Finite State Machine (FSM) block diagram

III. Result and Discussion

A. *Synthesis report of pipelined multiplier*

The proposed 32-bit unsigned pipelined multiplier is implemented on Xilinx Virtex-6 XC6VLX75T-3-FF484 FPGA. The results of the synthesizing reports of pipelined multiplier are shown in the Table I and Table I. Table II shows the advance level HDL synthesis report and Table II shows Low level HDL synthesis report.

TABLE I
Advance HDL Level synthesis report for 32-bit pipelined multiplier in Xilinx Virtex-6 XC6VLX75T-3-FF484 FPGA

37-bit adder	4-bit adder	Number of Flip-Flop	Number of Multiplexer	Number of FSM
4	4	1132	1005	1

There are 1005 different types of multiplexers among them 72 are 1-bit 12-to-1 multiplexer, 781 are 1-bit 2-to-1 multiplexer, 72 are 1-bit 8-to-1 multiplexer, 2 are 36-bit 12-to-1 multiplexer, 71 are 36-bit 2-to-1 multiplexer, 2 are 36-bit 8-to-1 multiplexer, 4 are 48-bit 2-to-1 multiplexer, and one 64-bit 2-to-1 multiplexer.

TABLE II
Low Level synthesis report for 32-bit pipelined multiplier in Xilinx Virtex-6 XC6VLX75T-3-FF484 FPGA

Clock Cycle	Maximum Frequency (MHz)	No. of Slice Registers	No. of LUT FF Pairs	No. of occupied slices	No. of Slice LUTs
9	326.243	1061	1790	1059	1788

Synthesis report shows that multiplier can support maximum 326.243 MHz and the multiplier circuit used only 1059 slices among 1790 slices.

B. *Simulation result:*

Simulation is done in Modelsim Simulator 10.0c. The following figure 6 shows the functional simulation of pipelined multiplier. It shows that after assigned inputs, it takes nine clock cycles for the result. At first reset input is high for one clock cycle and after that it takes nine clock cycles for getting the result.

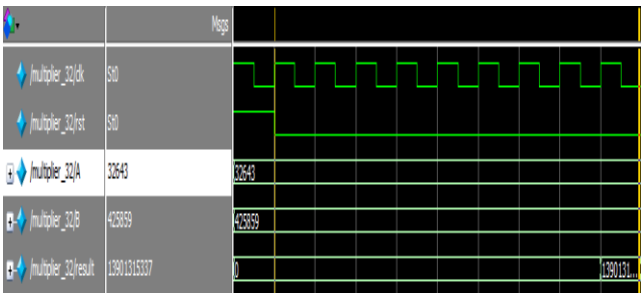

Fig. 5 Timing Diagram of Functional Simulation of 32-bit pipelined multiplier

C. *Compare the result with other design:*

Our proposed FSM based Pipelined design gives better output latency and lower critical path delay or lower minimum period than other previous design. Table III shows the comparison of critical path delay and output latency with other design. It clearly shows that our proposed design gives improved result than other design.

TABLE III
COMPARISON OF CRITICAL PATH DELAY AND OUTPUT LATENCY WITH PROPOSED PIPELINED DESIGN AND OTHER DESIGN

32-bit Multiplier Design	Output latency (Clock Cycle)	Critical Path Delay (ns)
Paper-5	32	3.13
Paper-6	16	22.829
Proposed Multiplier design	**9**	**3.065**

IV. CONCLUSIONS

In the presented paper, we have designed a pipelined multiplier which gives better performance than other pipelined design. The main advantage of this design is it used less output latency to calculate the result than other design. We can increase the output latency by adding more adders. Similarly, we could increase maximum frequency of the multiplier by designing the adder in gate level. Another benefit of this design is that it technology independent. This design gives maximum performance both in FPGA and ASIC.

Abstract—**Ternary Content Addressable Memory (TCAM) compares a stored word in its memory with a search word and returns the address of the stored word. In this paper we have proposed a memristor based TCAM cell which has only 8 transistors and 4 memristors whereas a conventional transistor based TCAM cell consists of 16 transistors. The average search energy per bit of the proposed Memristor based TCAM cell is almost 70.9% smaller and the search time in the proposed cell is almost 71% smaller than the corresponding quantities in a 16T TCAM cell. The voltage margin of our proposed cell is 138.9% higher than that in a 16T cell. Moreover, the required area for layout design of the proposed cell is almost 64% smaller than that of the 16T cell. Hence, our proposed Transistor-memristor hybrid structure shows superior performance in terms of speed, energy consumption, voltage margin and area occupancy.**

Index Terms—**TCAM, Memristor, Hysteresis.**

I. Introduction

There are three fundamental passive circuit elements: the resistor, the capacitor and the inductor. But Leon Chua predicted the existence of a fourth fundamental device, which he called a memristor[1]. Memristor has a non-volatile nature which means it can store data even when no power supply is applied to the circuit. Because of its long-term memory and suitability for nanoscale design, memristor can be used as a non-volatile memory device in future semiconductor memory chips. Memristor is basically a two terminal device. It can be formed from a thin semiconductor film [2], [3] with one layer of insulating TiO_2 and one layer of oxygen deficient TiO_{2-x}. The film resides between two metal contacts. The resistance of the doped layer of TiO_{2-x} is lower compared to the resistance of undoped layer of TiO_2.The ionic motion of oxygen vacancies (+2) [4] results in this resistance change. Fig. 1 shows the doped and undoped layers of a memristor. The memristor has a size D. The lengths of doped and undoped regions are *w* and (D-w) respectively.

As a linear circuit element, Memristance M is constant and memristor behaves like a resistor. The most basic mathematical definition of a current-controlled memristor for circuit analysis is the differential form

$$v = R(w)i \tag{1}$$

$$\frac{dw}{dt} = i \tag{2}$$

Here w is the length of doped region and R(w) is memristance as a function of w.

The application of an external bias v(t) across the device moves the boundary between the two regions by causing the

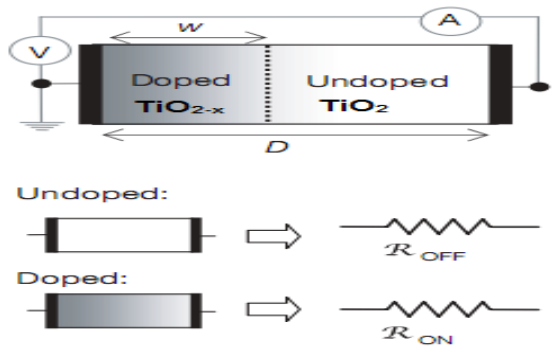

Fig. 1 A single memristor

charged dopants to drift. The total resistance of the memristor is a sum of the resistances of the doped and undoped regions,

$$R_{MEM}\left(\frac{w(t)}{D}\right) = R_{ON}\left(\frac{w(t)}{D}\right) + R_{OFF}\left(1-\frac{w(t)}{D}\right) \tag{3}$$

Here R_{ON} is the resistance of the memristor when it is completely doped and R_{OFF} is the resistance of the memristor when it is completely undoped.

When a positive voltage is applied to the left platinum wire, oxygen vacancies move from the TiO_{2-x} layer to the TiO_2 layer. As a result the length of doped region increases. This situation is termed as "ON" state which is characterized by a decrease in the memristance. When the positive voltage is applied for a long time, at a certain point in time no change in memristance takes place. The device then enters a hysteresis region. If a voltage with opposite polarity is now applied across the memristor, the boundary separating the doped and undoped region moves in the opposite direction, that is towards TiO_{2-x} layer. Therefore, the length of doped layer now decreases and memristance increases. This situation corresponds to "OFF" state. The hysteresis curve of a memristor is shown in Fig. 2 below. The simulation has been performed using the parameters: R_{ON}=100 R_{OFF}=10K R_{INIT}=5K D=8N μ_v=1f p=10

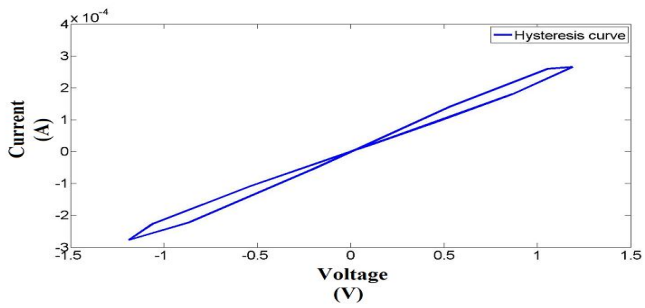

Fig. 2 Hysteresis curve of memristor

TCAM [5] is a specialized type of high-speed memory that searches its entire contents in a single clock cycle. Data stored on a TCAM can be accessed by comparing the input search data against a table of stored data and returning the address [6] of the matching data. TCAMs deal with three states (high, low and mask states). The third state i.e. the mask state can be used to search a portion of the word when necessary, instead of searching the whole word. Thus this includes greater flexibility in the search operation.

II. Proposed 8 Transistor 4 Memristor TCAM Cell

We have designed a TCAM cell with a reduced number of transistors compared with the conventional TCAM cell. We have designed a hybrid structure that contains 8 transistors and 4 memrisors whereas a conventional TCAM cell contains 16 transistors.

A. Basic Cell

The proposed cell is shown in Fig. 3. Each cell can store three states namely high, low and mask states. The high, low and mask states are denoted by DATA1 DATA2= 10, DATA1 DATA2= 01 and DATA1 DATA2= 11 respectively. The two Memristors MEM3 and MEM4 are connected in such a way that their memristance is high when current flows through them. For simulation purpose we have used R_{OFF}=100k for MEM3 and MEM4; R_{ON}=100 and R_{OFF}=100k for MEM1 and MEM2. Let us consider the case when DATA1 DATA2 =01, then DT1 DT2 =10. Since, DATA1 DATA2 = 01 is written, resistance of MEM1 goes high e.g. R_{OFF}=100k and resistance of MEM2 goes low e.g. R_{ON}=100.

During search cycle, R_{MEM3}=100k and R_{MEM4}=100k, R_{MEM1}=100k and R_{MEM2}=100

Voltage at DT1 will be,

$$V_{DT1} = \frac{R_{MEM1}}{R_{MEM1} + R_{MEM3}} V_{DD} \tag{4}$$

which is 1.65V, a high voltage.

Voltage at DT2 will be,

$$V_{DT2} = \frac{R_{MEM2}}{R_{MEM2} + R_{MEM4}} V_{DD} \tag{5}$$

which is 0.00329V, low voltage. Thus 2 bits are stored.

B. Precharge Unit

The proposed precharge unit (Fig. 4) charges the ML line to VDD prior to search operation. Hence, any mismatch will discharge the matchline to ground voltage and any match will keep the matchline charged to VDD.

C. Sense Amplifier Unit

The proposed Sense Amplifier unit contains a NOT gate and a pass transistor. The sense amplifier detects the state of ML line during search. The pass transistor holds its output value when search operation is not performed. A single row of our proposed TCAM array is shown in Fig. 4. Each row consists of 64 TCAM cells, a precharge unit and a sense amplifier unit.

III. Circuit Operation

The circuit operates in two phases, write and search. These phases are described as follows.

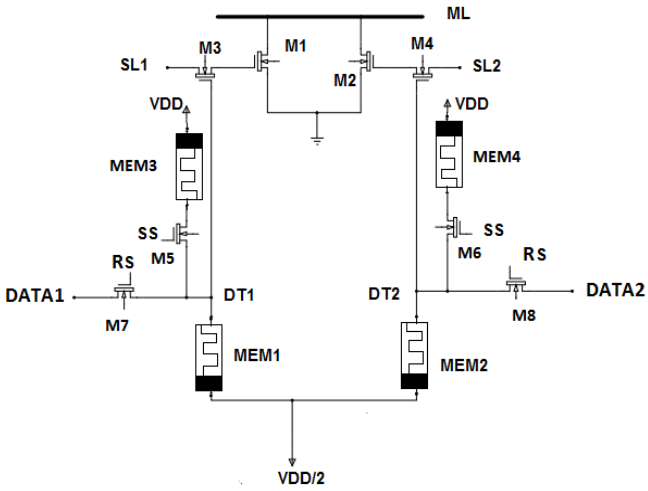

Fig. 3 Eight transistor-four memristor proposed TCAM cell.

A. Write

We have designed a 64 bit TCAM array. The Row Select (RS) signal is used to select a particular row where we want to write a 64 bit data. During write operation, Search Select (SS) signal is set to low state while RS is set to high state (Fig. 3). When a high voltage is applied to data line, the memristance connected to that line goes low and voltage across it is also low. However, a low voltage in the data line causes the memristance and hence the voltage drop across it to go high. The circuit that results during write is shown in Fig. 5(a).

When for example, DATA1 DATA2=10, the memristance 1 and memristance 2 will be low and high respectively. Hence DT1=0 and DT2=1. When DATA1 DATA2=01, DT1=1 and DT2=0.

B. Search

During search the Search Select (SS) signal (Fig. 3) is set to HI state and RS is set to low. Hence the write signals DATA1 and DATA2 are cut off from the rest of the circuit and only search occurs. Then, we get the circuit configuration as in Fig. 5(b).

The search data are placed on search lines SL1 and SL2. These values are compared with the stored data in TCAM cell. A match is denoted by the condition DATA1 DATA2= SL1 SL2. This will keep the match line ML charged to V_{DD}. This is sensed at the sense amplifier output as a low voltage. When a mismatch occurs i.e. DATA1 DATA2 ≠ SL1 SL2, the ML line is discharged to ground voltage. This is detected as a high voltage at the sense amplifier output.

IV. Simulation Results For 64 Bit TCAM Array

The simulation is performed for 64 bit array. The applied Write Select (WS) signal is of 3n duration. SS is of 2n duration. VDD/2 is 1.65 volt during write operation. As soon as write is finished, VDD/2 becomes zero.

For the purpose of analysis the graphs for cell 22 is plotted. A mismatch occurs during the second cycle of search signal in cell 22.

A. Match

During the first cycle of write, DATA1 DATA2=01 is written to cell 22. This is shown in Fig. 6. As a result, R_{MEM1} goes high and R_{MEM2} goes low. During the search cycle SL1 SL2=01. Hence a match occurs and the matchline remains at high voltage. This is indicated in the plot of ML in Fig. 7.

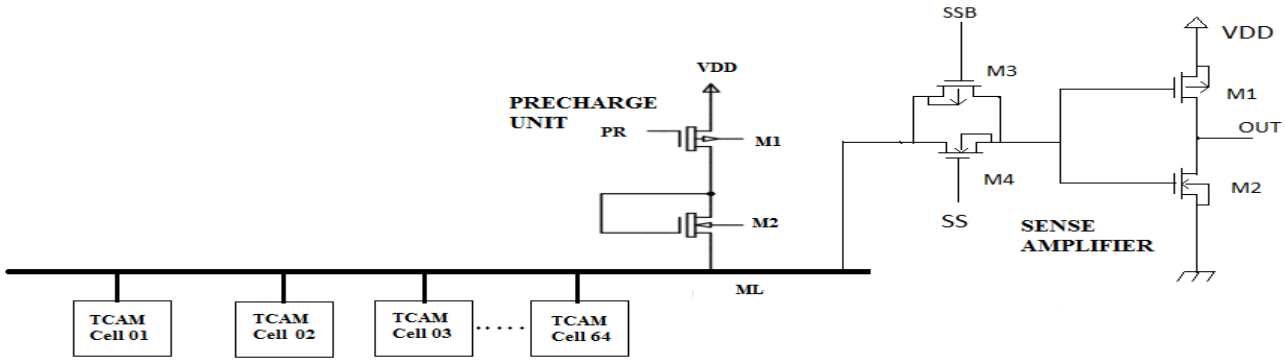

Fig. 4 Block Diagram of the proposed 64 bit TCAM array.

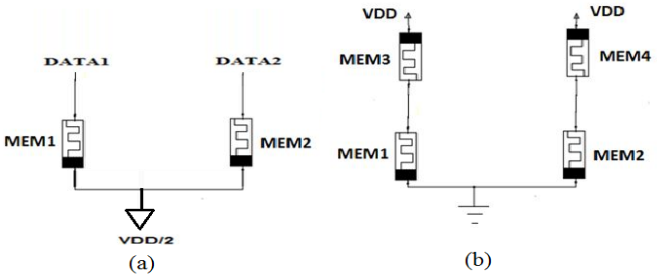

Fig. 5 (a) Circuit when SS=0, RS=1 (b) Circuit when SS=1, RS=0.

Since ML is high, the sense amplifier output OUT goes low.

B. Mismatch

During the second cycle of write, DATA1 DATA2 =10 is written to the TCAM cell 22 (Fig. 6). Hence, R_{MEM1} goes low and R_{MEM2} goes high. But during the search cycle SL1 SL2=01. Hence a mismatch occurs and ML is discharged to ground voltage. At the same time the sense amplifier output goes high (Fig. 7).

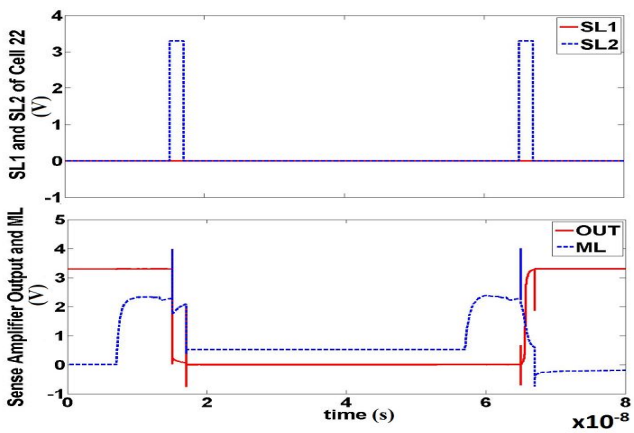

Fig. 7 Search operation in a 64 bit TCAM array

V. Three Simulation Corners

Our proposed design is compared with the conventional design with respect to speed, energy per bit and voltage margin. All these criteria are tested for three design corners i.e. typical, fast and slow. The process parameters are given below.

TABLE I.
Design Parameters for Three Corner Simulations

		Typical	Fast	Slow
VTH0	**NMOS**	0.366247V	0.329622V	0.402872V
	PMOS	-0.390601V	-0.351541V	-0.429661V
Temperature		27 ºC	0ºC	100 ºC
Supply voltage		3.3V,1.65V	3.63V,1.815V	2.97V,1.485V

VI. Comparison of Performance Parameters

A. Speed and Energy Per Bit

Search time during full-match is calculated by taking the time difference between 50% rise time of Search Enable (SE) signal and 50% fall time of the sense amplifier output (OUT).

TABLE II.
Comparison of Performance Characteristics
(For Search Cycles)

		16T NOR Type (Conventional design)	8T 4M NOR Type (Proposed design)
TYPICAL MODE			
Charging (full match)	Time	0.626 ns	0.026 ns
	Energy per bit	374.8 fJ	7.7 fJ
Discharging (1-bit mismatch)	Time	1.06 ns	0.94 ns
	Energy per bit	573.66 fJ	268 fJ
FAST MODE			
Charging (full match)	Time	0.495 ns	0.024 ns
	Energy per bit	417 fJ	165 fJ
Discharging (1-bit mismatch)	Time	0.892 ns	0.65 ns
	Energy per bit	615.92 fJ	1.1 pJ
SLOW MODE			
Charging (full match)	Time	0.776 ns	0.031 ns
	Energy per bit	325.75 fJ	120fJ
Discharging (1-bit mismatch)	Time	1.13 ns	1.3 ns
	Energy per bit	426.32 fJ	1.1 pJ

The time needed for changing the voltage level during write cycle is very low. However for this voltage to be stored even after the power supply is turned off, it is necessary to change the states of the memristors according to the data. So we have kept the write signal (RS) enabled for a longer time (irrespective of data). As we have defined the write time to be the entire write enable period, the write time for different data combination is considered to be the same. Though, this fact causes our design to require more time and energy for write operation compared to the conventional design, it is expected that these criteria can be improved by using memristors with better model parameters.

TABLE III.
COMPARISON OF PERFORMANCE CHARACTERISTICS (FOR WRITE CYCLES)

Data		16T NOR Type (Conventional design)	8T 4M NOR Type (Proposed design)
TYPICAL MODE			
0 1	Time	0.145 ns	1.75 ns
	Energy per bit	0.873 pJ	1.2 fJ
1 0	Time	0.143 ns	1.75 ns
	Energy per bit	0.901 pJ	1.1 fJ
1 1	Time	0.159 ns	1.75 ns
	Energy per bit	0.657 pJ	0.81 fJ
FAST MODE			
0 1	Time	0.135 ns	2 ns
	Energy per bit	1.178 pJ	1.77 fJ
1 0	Time	0.134 ns	2 ns
	Energy per bit	1.181 pJ	1.75 fJ
1 1	Time	0.14 ns	2 ns
	Energy per bit	0.855 pJ	1.56 fJ
SLOW MODE			
0 1	Time	0.158 ns	4 ns
	Energy per bit	0.662 pJ	1.54 fJ
1 0	Time	0.161 ns	4 ns
	Energy per bit	0.65 pJ	1.54 fJ
1 1	Time	0.164 ns	4 ns
	Energy per bit	0.438 pJ	1.42 fJ

B. *Voltage Margin*

Voltage margin is determined by taking the difference of the ML voltage level for full-match and for worst case (1 bit) mismatch. The match line is more prone to be detected erroneously in case of 1-bit mismatch. So, the higher the voltage margin, the better the design.

TABLE IV.
COMPARISON OF VOLTAGE MARGIN

	16T NOR Type (Conventional design)	8T 4M NOR Type (Proposed design)
TYPICAL MODE		
Voltage Margin	0.314 V	0.75 V
FAST MODE		
Voltage Margin	0.276 V	0.86 V
SLOW MODE		
Voltage Margin	0.326 V	0.72V

VII. PHYSICAL LAYOUT AND AREA ESTIMATION

The layout of our proposed design is drawn in Microwind 2.0 layout design and simulation software using lambda (λ) based rules at TSMC 180nm technology.

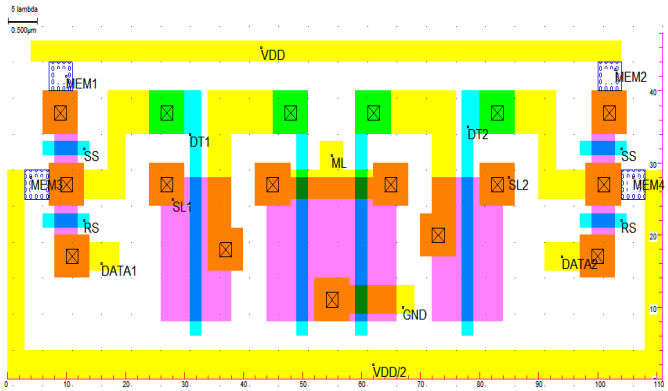

Fig. 8 Layout implementation of proposed TCAM cell.

Total area of our proposed design is found to be 48.4 μm^2. Each memristor requires an area of 0.002 X 0.002 μm^2 = 0.000004 μm^2, which is negligible with respect to the total area of the design. However, for clarifying the position of the memristors we have not drawn the memristors up to scale. Memristors are drawn somewhat larger to make them noticeable in the layout.

TABLE V.
AREA OF BASIC CELL

Parameter	**16T NOR Type (Transistor based)**	**12T NOR Type (Memristor based)**
Area	134.7675um^2	48.4μm^2

VIII. CONCLUSION

In this paper we have proposed a hybrid architecture of Ternary Content Addressable Memory (TCAM) with 8 transistors and 4 memristors. After extensive simulation it is shown that our proposed design offers greater speed, lower energy consumption, higher voltage margin and smaller area requirement than conventional TCAM design. From this observation it can be delineated that, our proposed design has the perspective of being a promising alternative for future memory based applications.

Abstract— **In this contribution, we have proposed a robust technique to achieve tetra-band performance in both conventional dielectric (elliptical shape) and also metamaterial loaded (rectangular shape) patch antennas. Incorporation of symmetric slots over the patch in both type of antennas have been shown here by using the concept of additional modified modes and perturbation approach. At first, we have shown that if and only if, elliptical shape patch antenna is properly optimized along with symmetrical slots over metallic patch, it is possible to achieve satisfactory four- band performance without the aid of any complex procedure currently present in literature. Later, we have reported a compact metamaterial loaded tetra band rectangular patch antenna to achieve extremely high gain and directivity performances for all the four bands, which may not be possible with conventional dielectric antennas.**

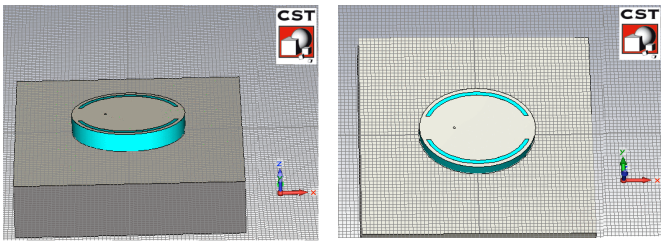
Index Terms— **Elliptical and rectangular patch antenna, Broadside radiation, metamaterial, tetra band antenna.**

I. Introduction

Multi-band performance, high directivity and size reduction are desirable for radar, satellite and in many other important communication systems such as mobile cellular and Wi-fi communications [1-5]. It would be interesting if all these qualities were achieved in a unique radiator. As huge size reduction of patch antennas is not possible with conventional ways, Alu et al. [6-9] has proposed design method to obtain electrically small patch antennas using DPS (Double Positive)-MM (metamaterial) juxtaposed-layer. But we have shown [1-5] such patches give broadside null radiation pattern at sub wavelength regime. Finally, it was predicted that all these electrically small rectangular antennas loaded with metamaterial can only be good resonators but may not be good radiators [1-5], [10]. Later, in [1] we proposed the idea of additional modified modes to design successful dual band radiators according to designers' will. Although theoretically maximum 35% size reduction is possible [2,3], electrically small patch antenna may not be possible with any shape using juxtaposed layer of MM [10]. So, the question arises: is there any real practical benefit with these metamaterial based small antennas [11]? A probable solution of this problem is using multi-band (or multi-functional) antennas instead of reduced size antennas. In literature, there are several designs of multi-band patch antennas with conventional size. However, a notable fact is that many of them [12, 13] do not fulfil the criteria of -10 dB S-parameter performance to consider it a real frequency band among some of their multi bands [12]. Moreover, any cavity that does not radiate at broadside direction with gain performance more than '0' dB and also with not maximum directivity at broadside may not be considered as a successful microstrip patch antenna (i.e. see [13]). As a result, only few 'successful' designs of tetra band PIFA antennas with complex designs have been demonstrated in literature [14], [15] so far. But as per we know, for such four-band performance, conventional dielectric filled microstrip patch antennas have not been demonstrated in literature. In this article, at first we have demonstrated a tetra band elliptical microstrip patch antenna with quite satisfactory gain & directivity, broadside radiation and S-parameter performance. Notable fact is that our proposed design is extremely simple and probably will be very useful for commercial designs. As per we know, due to the use of conventional material, the gain and directivity performance are not extremely high of the antennas present in current literature. As a result, here we have also demonstrated a rectangular patch antenna with ENG MM to achieve extremely high broadside radiation performance (directivity and gain). Moreover, in metamaterial loaded 2nd antenna, designers can choose the resonant frequency according to their own will [1-5]. Such degrees of freedom for getting desired four-band performance 'according to the designers will' may not be available in literature. Here we have also analysed the robustness of such antennas by varying some important antenna parameters.

II. Tetra Band Elliptical Patch Antenna Filled With Conventional Dielectric Material

This antenna is a simple tetra band antenna that needs no other materials than the substrate itself which is of single layer and composed of normal dielectric material found in nature. It needs only symmetrical slots to obtain higher order modes over the metallic patch. It shows tetra band characteristics with quite acceptable radiation performance. The geometry and parameters of that antenna are given below:



(a) (b)

Fig 1: Geometry of the elliptical microstrip patch antenna (a) side view (b) top view.

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

TABLE I
ELLIPTICAL MICROSTRIP PATCH ANTENNA MEASUREMENTS FOR DESIGNING TETRA BAND

Ground plane	Elliptical patch & substrate	Substrate height	Substrate's relative permittivity, ε_R	Substrate's relative permeability, μ_R	Feed position	Probe radius
60mm×60mm	Major axis= 15mm Minor axis= 12 mm	5 mm	9.8	1	x=-6, y=0	0.3 mm

From $|S_{11}|$ Parameter analysis (Fig 2) it has been observed that microstrip antenna with elliptical patch giving tetra band resonance frequency at 2.2 GHz, 5.22 GHz, 6.22 GHz & 6.77 GHz.

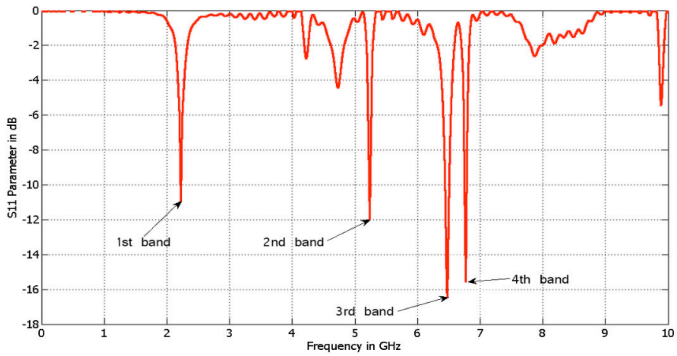


Fig 2: S-parameter performance of proposed elliptical tetra band microstrip patch antenna.

The radiation patterns found from the full wave simulation (Fig 3-6) is describing that at broadside the antenna shows maximum radiation. From both the 3D and polar plot, they provide satisfactory radiation performance at all bands without adding any complexities to the design. For a simple dielectric elliptical antenna, the expressions for the TE^z and TM^z modes can be written as (before the incorporation of the slots):

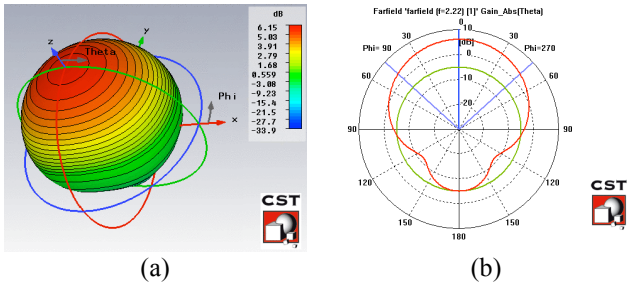
TE^z modes:

$$H_z(\xi,\eta,z)=\sum_{n=0}^{\infty}\sum_{m=0}^{\infty}\sum_{p=0}^{\infty}\{A^{TE}_{e_{nmp}}R^{TE}_{e_{nm}}(q^{TE}_{mn},\xi)S^{TE}_{e_{nm}}(q^{TE}_{mn},\eta)+A^{TE}_{o_{nmp}}R^{TE}_{o_{nm}}(q^{TE}_{mn},\xi)S^{TE}_{o_{nm}}(q^{TE}_{mn},\eta)\}\sin(k_{z_p}z) \quad (1)$$

TM^z modes:

$$E_z(\xi,\eta,z)=\sum_{n=0}^{\infty}\sum_{m=0}^{\infty}\sum_{p=0}^{\infty}\{A^{TM}_{e_{nmp}}R^{TM}_{e_{nm}}(q^{TM}_{mn},\xi)S^{TM}_{e_{nm}}(q^{TM}_{mn},\eta)+A^{TM}_{o_{nmp}}R^{TM}_{o_{nm}}(q^{TM}_{mn},\xi)S^{TM}_{o_{nm}}(q^{TM}_{mn},\eta)\}\sin(k_{z_p}z) \quad (2)$$

where, A^{TE}_{onmp}, A^{TE}_{enmp}, A^{TM}_{onmp} and, A^{TM}_{enmp} are unknown expansion coefficients and the subscript e and o are used to refer even and odd mode respectively [16]. Except the first harmonic (n=0), all modes can be even or odd. The elliptical shape (θ and φ being different) is one of the reasons, which gives rise to different even and odd mode. Even mode and odd mode come from the horizontal and vertical polarisation of the antenna which are not same in case of elliptical shape. When they are seperated by a sufficient distance, they act like individual mode.



(a) (b)

Fig 3: (a) 3-D radiation pattern (b) Polar plot at 2.22 GHz

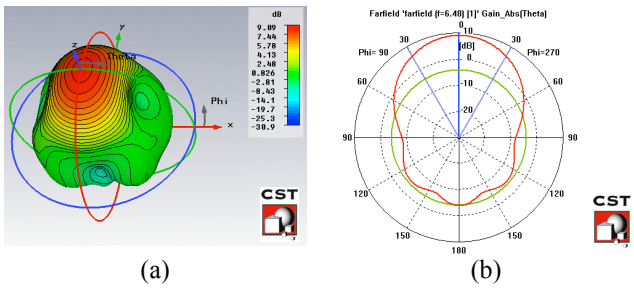
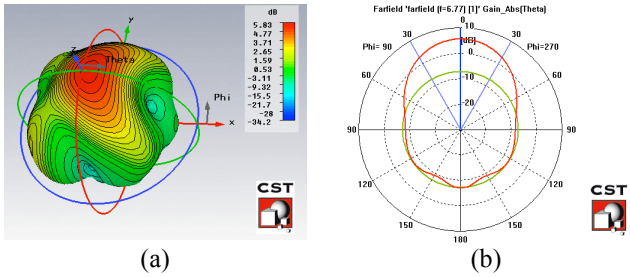
Fig 4: (a) 3-D radiation pattern (b) Polar plot at 5.24 GHz



(a) (b)

Fig 5: (a) 3-D radiation pattern (b) Polar plot at 6.48 GHz



(a) (b)

Fig 6: (a) 3-D radiation pattern (b) Polar plot at 6.77 GHz

In addition, we have found that the impedance matching performance of elleptical shaped antennas is better than other shaped [1-5] patch antennas if the feed position is properly optimized. Thus dual band performance is obtained just due to the elliptical shape. Using boundary conditions in [16], the resonant frequencies can be written before adding slots:

$$f_{e_{nmp}/o_{nmp}}^{\binom{TE}{TM}} = \frac{c}{2\pi\varepsilon_r}\sqrt{k_{c_{enm/onm}}^{\binom{TE}{TM}2} + k_{zp}^{\ 2}} \qquad (3)$$

which can also be expressed in the following form:

$$f_{e_{nmp}/o_{nmp}}^{\binom{TE}{TM}} = \frac{c}{2\pi\varepsilon_r}\sqrt{\frac{4q_{mn}^{\binom{TE}{TM}}}{f_o^{\ 2}} + k_{zp}^{\ 2}} \qquad (4)$$

The additional arc shaped parallel slits are responsible for further additional modified modes [2-4]. Maci et al. [17] showed that two parallel slots close to the radiating edges can cause mode modification and by effective current path elongation, it is possible to get multiband performance. In elliptical patch antennas, similar concept to get mode modification will be found in our previous work [18]. Here, we have used that idea to get further mode modification to obtain tetra band performance. The idea of splitted modes proposed by Alu et al. [8,9] is observed in our proposed simple elleptical antenna for 3rd and 4th band due to the additional slots. The generalized perturbation equation can be applied to model the slight frequency shifts for the 1st and 2nd band due to those slots:

$$\frac{\Delta k}{k_0} \approx \frac{\Delta W_e - \Delta W_h}{\Delta W_e + \Delta W_h} = \frac{(\frac{1}{2}\int_{\Delta v}\varepsilon|E|^2 dv) - (\frac{1}{2}\int_{\Delta v}\mu|H|^2 dv)}{(\frac{1}{2}\int_{\Delta v}\varepsilon|E|^2 dv) + (\frac{1}{2}\int_{\Delta v}\mu|H|^2 dv)}$$

The left most term indicates the frequency shifts criteria [19]. *Kzp* written in Eq (1) - (4) can be recalculated using above equation after the incorporation of the symmetric slots.

III. TETRA BAND RECTANGULAR PATCH ANTENNA PARTIALLY LOADED WITH ENG MM FOR HIGH GAIN AND DIRECTIVITY

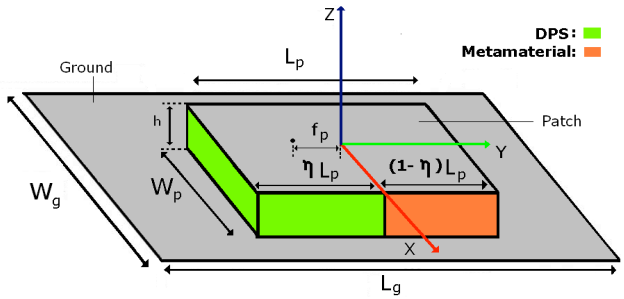


Fig. 7: Geometry of a un-slotted rectangular microstrip patch antenna partially loaded with metamaterial (ENG, MNG or DNG) [1]. f_p= feed position from DPS and metamaterial interface. The filling ratio of the DPS is η (i.e. the length of DPS block under the patch is ηL). The underneath substrate (which is $L_p \times W_p \times h$ in volume) is inhomogeneous, filled with two isotropic and homogeneous materials with permittivity and permeability ε_1, μ_1 and ε_2, μ_2. Substrate height is h.

According to J.Xiong et al. [20], any etched slot in the metallic patch may deteriorate the performance of a rectangular patch antenna loaded with metamaterial. But here we have used two symmetrical etched slots like [17] to introduce the concept of additional higher modified $TM_{0\delta0}$ (3<δ<4) mode(s). On the other hand, if we use such symmetric slots for MNG MM loaded dual band antennas [1]; we fail to get Tetra band performance from them. However, to get tetra band performance with ENG Metamaterial loaded antennas, we follow similar procedure followed by us in [5].

A very important fact is that the parameters of this tetra band design should be optimized very carefully. If the positions of f_0 and f_r are changed, it may behave like a triple band antenna proposed in [5]. Actually if f_r and f_0 are not far away from TM_{030} mode; bulk resonance & effective high value of permittivity of ENG MM may destroy the modified TM_{030} mode radiation performance and the antenna behaves like a triple band antenna proposed by us in [5]. Here, the detailed design procedure is given of this highly directive antenna:

(i) Firstly, we have adopted a conventional 40mm × 35mm patch to design such an antenna (not MM loaded). Using proposed idea of Maci et al. [17] and taking ε_r= 2.2, we find dual band performance with conventional TM_{010} & TM_{030} mode (modified like TM_{010} mode) at 2.37 GHz, 3.54 GHz and respectively. We get TM_{040} mode at 5.64 GHz (having broadside null rad. pattern). (ii) Now, to introduce an additional modified mode we have to use metamaterial. As we are targeting to get our desired mode over modified TM_{030} mode (behaves like conventional TM_{010} mode [1]), we have to use ENG MM. This is because in [1], we have shown that if we want to get any additional mode higher than conventional TM_{010} mode, we have to use ENG MM (Fig. 2 of [1]). So, we have chosen f_r= 4.5 GHz here (far from TM_{030} mode found in 3.54 GHz). Then using our proposed idea [1] & algorithm [21], we have derived necessary design parameters (given in the caption of Fig. 8). Lorentz dispersive lossy model [2],[4] has been used for ENG metamaterial loading with parameter values: ε_∞ = 1.0, ε_s= 1.1355, ω_0= 2670 rad/s, δ = 50MHz; when: relative permittivity, $\varepsilon_{2r}(\omega) = \varepsilon_\infty + \frac{(\varepsilon_s - \varepsilon_\infty)\omega_0^{\ 2}}{\omega_0^{\ 2} - \omega^2 + j\omega\delta}$ (iii)

Then, by using full wave analysis [22]; we have found two 'interface resonance' modes at 4.5 GHz and 4.75 GHz.

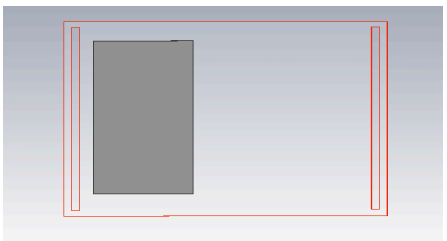

Fig. 8: proposed 40mm × 35mm ENG metamaterial loaded microstrip patch antenna with symmetrical slots and parasitic patch (Top view).Parasitic patch is underneath the DPS substrate. Parasitic patch dimension: 28.66 mm (parallel to slots or x-axis) × 14.32 mm × 0.1 mm . Distance between main and parasitic patch: 0.2 mm. Dimension of both slots: 33mm × 1 mm . Design parameters: Lp = 40 mm, Wp = 35 mm, Lg = 75 mm, Wg = 75 mm , fp = 15.272 mm, h = 1 mm, η = 0.5818 , ε_{1r} = 2.2, μ_{1r} = 1, μ_{2r} = 1 and ε_{2r} (at fr) = -0.1182 in case of ENG loading, fr = chosen resonant frequency = 4.5 GHz.

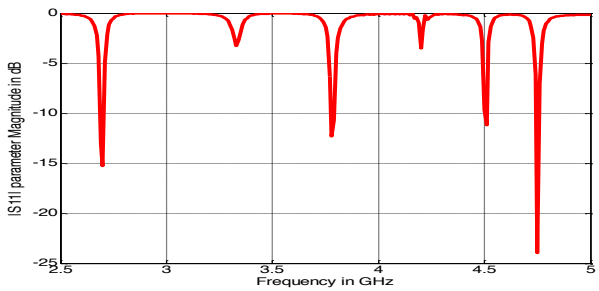

Fig. 9: $|S_{11}|$ performance of proposed antenna with parasitic patch

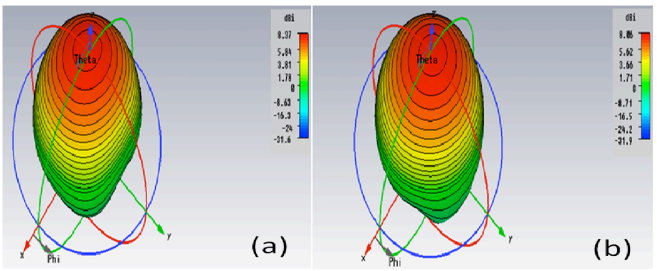

Fig. 10: 3-D radiation pattern radiation of proposed antenna (Fig. 2) (a) Conventional TM_{010} mode (at 2.7GHz); rad. efficiency 97.89% and (b) TM_{030} mode (at 3.78 GHz) ; rad. efficiency 77.678%.

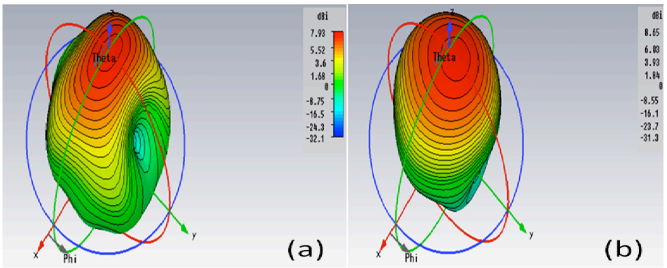

Fig. 11: 3-D pattern of proposed antenna (Fig. 2) (a) Unconventional $TM_{0\delta 0}$-^{1}mode (at 4.51GHz); rad. efficiency 67.67% and (b) $TM_{0\delta 0}{}^{2}$mode (at 4.75GHz); rad. efficiency 73.60%.

To solve the problem of bandwidth enhancement and impedance matching, we have applied the concept of parasitic patch [5] in this contribution to minimize the inductive effect caused by probe, ENG medium and mutual coupling between probe and patch. In this case, the parasitic patch must have larger dimension parallel to symmetrical slots (Fig. 8). Satisfactory $|S_{11}|$ Parameter performance of this antenna with this additional parasitic patch is shown in Fig. 9.

It is a noticeable fact of ENG loaded tetra band antenna that TM_{030} mode was in 3.54 GHz without metamaterial loading (using normal DPS with symmetric slots). After the loading of ENG metamaterial, the two modified modes are found at 4.51 GHz and 4.75 GHz. Both modes are quite far from 3.54 GHz. We are tagging these modes as $TM_{0\delta 0}{}^{1}$ mode and $TM_{0\delta 0}{}^{2}$ mode. The directivities at 2.7 GHz, 3.78 GHz, 4.51 GHz and 4.75 GHz are 8.374 dBi, 8.057 dBi, 7.925 dBi and 8.655 dBi respectively at broadside (Fig. 10 and 11). These extremely high directivities at broadside for all the four bands are the most important features of this compact sized antenna. Last but not the least, the practical implementation of such multi-band designs ([5] & this article) can be investigated with the MM inclusions proposed in [23], [24].

IV. CONCLUSION

In this article, we have shown one conventional and one metamaterial loaded design of 'successful' tetra band patch antenna. Although we have made only theoretical investigation; full wave analysis based simulations [22] and robustness analysis strongly bear the possibility of practical implementation of such antennas. In contrast, our proposed elliptical shaped conventional dielectric filled patch antenna can be considered very convenient for commercial designs because of its extremely simple design along with satisfactory four-band performance.

[1,2,3]Department of Electrical and Electronic Engineering, American International University-Bangladesh (AIUB)
Banani, Dhaka-1213, Bangladesh.
[*]Shahriar.hasan.shehab@gmail.com

Abstract— **In this paper a novel Ultra Wide Band textile antenna is designed which operates from 2.6–14 GHz, covering entire Ultra Wide Band frequency range of 3.1–10.6 GHz, as approved by FCC. The proposed antenna consists of a octagonal patch and a partial ground plane with a square notch. The substrate of the designed antenna is made of Dacron fabric (ε_r=3) while patch and ground is made of copper tape. The dimension of the substrate is 43×34 mm^2. Simulated results of different antenna parameters such as return loss (S11), gain and radiation patterns are presented. This antenna performance are also analysed at four different bending angles. The characteristics, low profile and compact size of the proposed antenna depicts as a potential candidate for UWB applications. The antenna design details and simulated results are presented by CST microwave studio.**

Index Terms—**Ultra Wide Band, Textile Antenna, Octagonal patch, Partial ground.**

I. Introduction

In recent years, the rapid development of wearable intelligent textile systems has increased the necessity for WBAN (Wireless Body area Network) system to provide standalone outfit. WBAN is a network where its nodes are placed close to the body which enables wearable computer devices to exchange digital information with each other using the electric conductivity of human body as a data network [1].

The antenna plays a very basic part of Wireless Body Area Network. In this modern era, body worn antenna is one of the most popular and cutting edge research areas. Body worn antennas may be made from textile materials [2] and fixed on body, into clothing or may be worn as a button antenna [3]. It can even be implanted inside a human body [4]. Textile antenna system has a wide variety of applications. It is used for detecting motion on the body during exercise, monitoring heart rate and blood pressure, emergency services such as fire fighters, detective and police [5]. It also helps to communicate among the soldiers of the modern battle field including unmanned vehicles [6]. Many researchers have reported single frequency band wearable antennas [7] and later dual frequency band wearable antennas [8]. In the recent researches Ultra Wide Band technology is one of the most favourable choices for WBAN applications. The Ultra Wide Band (UWB) system covers the frequency range from 3.1 – 10.6 GHz, which is based on narrow pulses, low power consumption and looks similar to random noise to conventional radio systems. The transmitter and receiver have simple structure because there is no carrier frequency instead UWB emits timed pulses of electromagnetic energy which is necessary for portable devices.

However, in case of wearable antennas it is quite difficult to obtain large bandwidth with smaller size and a very low thickness. As the antenna is mounted on textile material it is also difficult to operate the antenna when it is bent frequently.

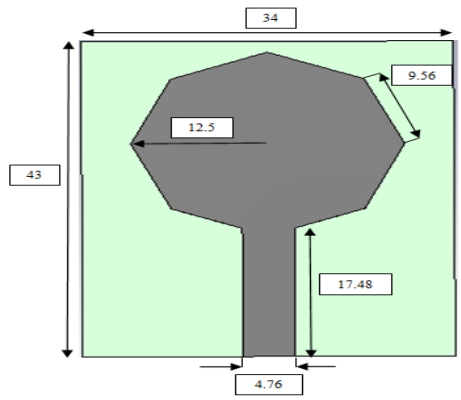
In this paper a novel design of compact octagonal UWB textile antenna is proposed. Also bending of the antenna for different angles is focused. The outline of the paper is structured as followings. In section 2 describes the antenna geometry. Bending of the proposed is shown in section 3. The antenna performances are evaluated in section 4 and compared the performances under several angles of bending in section 5. A conclusion is given is section 6. The antenna structures are designed and analysed using CST Microwave Studio package.

II. Antenna Design

The proposed octagonal UWB textile antenna operates from the frequency of 2.6 GHz to 14 GHz. The antenna is designed on hypalon coated Dacron fabric substrate with thickness of 1.68 mm. Selected textile material has high tensile strength, high resistance to stretching, durability, outstanding electric property. The specification of the substrate for dielectric permittivity, ε_r is 3 and tangent loss is 0.002. The octagonal patch of the antenna is fed by a 50 ohm microstrip feed line with a width of 4.76 mm. The radius of the patch is calculated using equation (1),

$$a = {87.94}/{f_r\sqrt{r}}\ , \quad \text{in mm } (f_r \text{ in GHz}) \qquad (1)\ [9]$$

Fig. 1 shows the front view (a) and back view (b) of the proposed antenna.



(a) Front View.

(b) Back View

Fig. 1: Geometry of the proposed UWB antenna.

The conductive octagonal plane and partial ground plane are made of copper tape. A partial ground plane is placed at the back of the substrate and the dimension is 18×34 mm^2. In addition, the partial ground has a square notch and the dimension of the slot is 4×4 mm^2. The area of the substrate is 43×34 mm^2. In Table I the antenna measurements are shown.

TABLE I
MEASUREMENTS OF OCTAGONAL UWB TEXTILE ANTENNA

Parameters	Size (mm)
Substrate Length	43
Substrate Width	34
Substrate Thickness	1.68
Patch Thickness	0.7
Ground Thickness	0.52
Feed Length	17.48
Feed Width	4.76

III. Bending of Octagonal UWB Textile Antenna

In case of textile antenna system, bending of the antenna occurs at different angles. It is mandatory for the textile antennas to keep their performances with respect to different angles of bending. In this paper the bending effect at four different angles –namely 20, 40, 60 and 80 degrees for designed octagonal UWB antenna is analysed. From the equation (2), the value of the radius (r) for the intended angle of the cylinder was calculated.

$$S = r\theta \quad \text{, in mm} \qquad (2)$$

Where, S is the arc length, r is the radius of the circle and θ is the measurement of the central angle in radians. Width of the antenna was used as the arc length. All the antenna dimensions were maintained the same in all bending angles. CST microwave studio is used to design and simulations purposes. Fig. 2, antenna measurements for bending purposes are given.

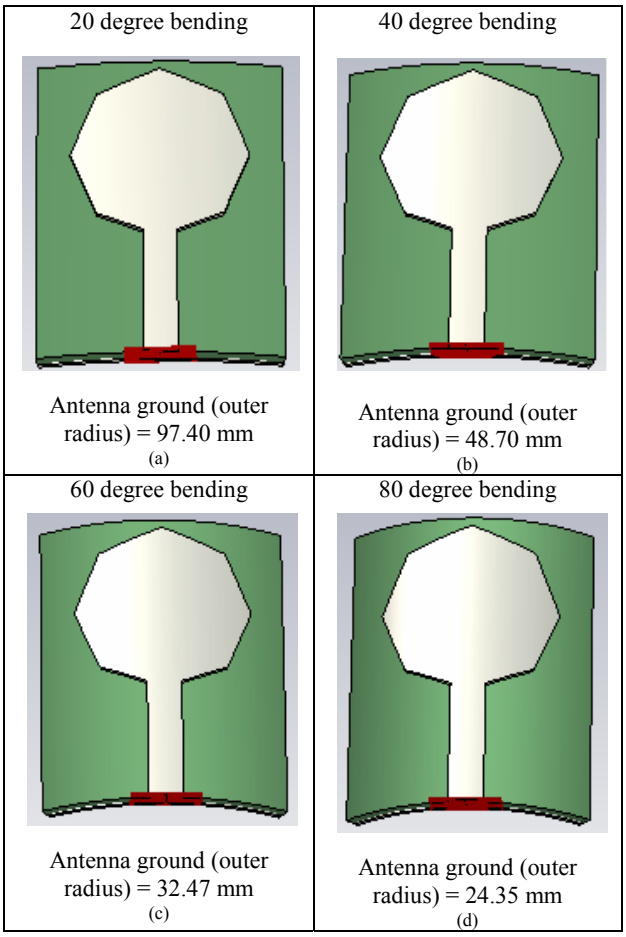

Fig. 2: Octagonal UWB Textile Antenna Measurements for Bending Purpose; 20 degrees bending (a), 40 degrees bending (b), 60 degrees bending (c), 80 degrees bending (d).

IV. Performance of the Proposed UWB Textile Antenna

A. S-parameter Analysis of UWB Textile Antenna

The simulated return loss of the proposed antenna is shown is Fig. 3.

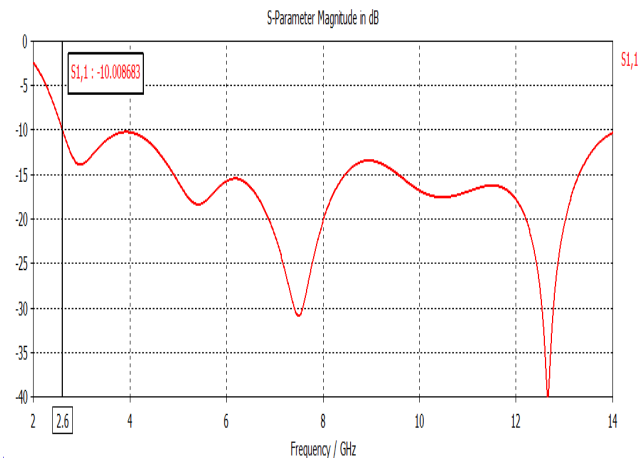

Fig. 3: Simulated return loss (S11) of the proposed antenna.

From the simulated return loss graph, it can be seen that the UWB antenna occupies a bandwidth of 11.4 GHz (2.6 GHz – 14 GHz) for a return loss (S11) less than -10 dB (VSWR < 2).

B. *Gain of The Proposed UWB Textile Antenna*

Fig. 4 shows the gain of the UWB textile antenna.

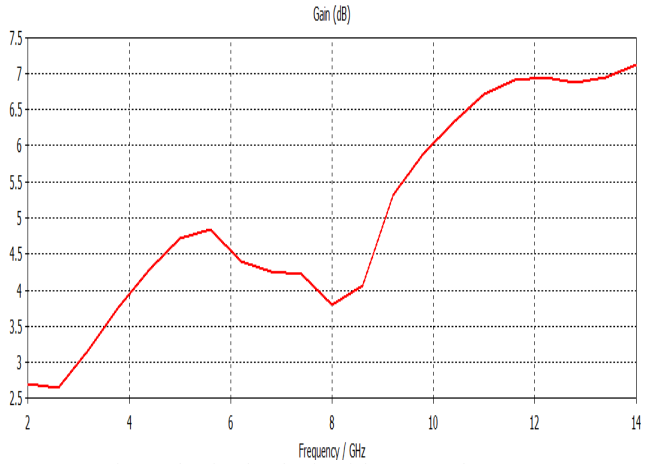

Fig. 4: The simulated gain of the proposed antenna.

In Fig. 4, it can be seen that the peak gain of the proposed antenna in a frequency range of 2 GHz to 14 GHz and gain variations are less than about 7.11 dB.

C. *Radiation Pattern for Different frequencies of UWB Textile Antenna*

The azimuth and elevation radiation pattern of the UWB antenna at 5 and 7 GHz have been shown in fig. 5. For attaining the azimuth pattern, theta (θ) has been set to 90 degree for all values of phi (φ). Similarly for elevation pattern, phi (φ) has been set to 90 for all values of theta (θ).

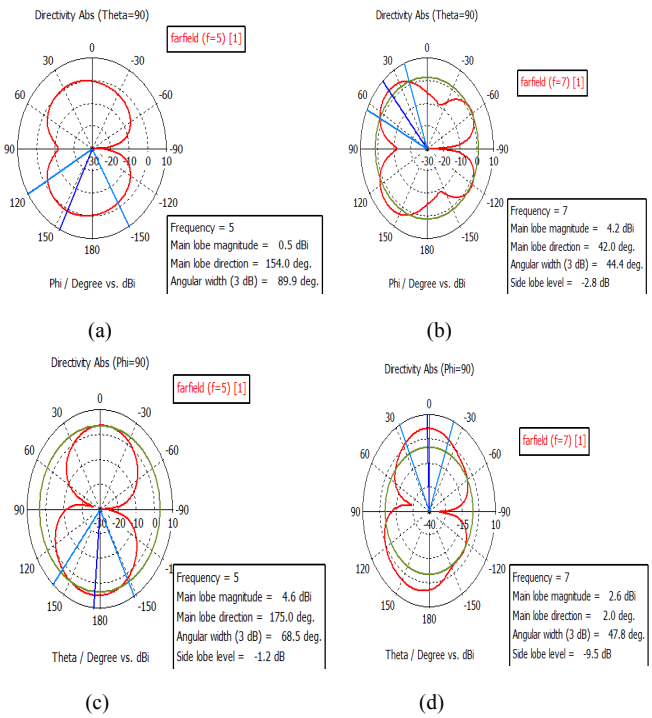

Fig. 5: Azimuth radiation pattern at 5GHz (a) and 7 GHz (b) and Elevation radiation pattern at 5GHz (c) and 7 GHz (c).

In both 5 GHz and 7 GHz the radiation characteristics shows an Omni-directional pattern but at 7 GHz a little deformation from 2 GHz pattern is observed.

V. PERFORMANCE ANALYSIS OF UWB TEXTILE ANTENNA UNDER BENDING CONSEQUENCES

A. *S-parameter Analysis of Bended Proposed UWB Textile Antenna*

In fig. 6, the simulated return loss (S11) under different angle of bending of the proposed UWB antenna is shown.

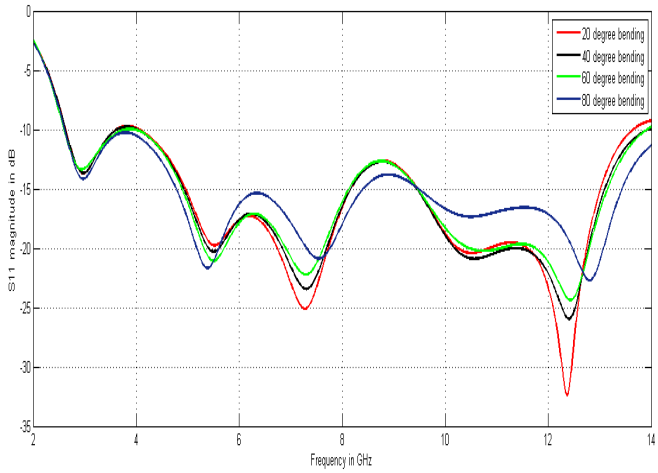

Fig. 6: The comparison of simulated return loss (S11) of the bended UWB antenna under four different angles.

Figure 6 shows the comparison of UWB textile antenna for different angle of bending. The proposed antenna shows better impedance matching with return loss below -10 dB for higher bending angles. At 20 degree bending highest return loss of -32.41 dB at frequency 12.37 GHz is achieved. However, a small portion of bandwidth lies above -10 dB at frequency 3.8 GHz where return loss is -9.7 dB. At higher angle of bending the return loss is below -10 dB and their pattern is quite similar. In 40, 60 and 80 degrees angles of bending maximum return loss of -25.97 dB, -24.39 dB and -22.73 dB are achieved respectively.

B. *Radiation Pattern of UWB Antenna at Four Different Angles of Bending*

Figure 7.1 and 7.2 illustrates the radiation pattern at 5 GHz and 7 GHz for different angles of bending.

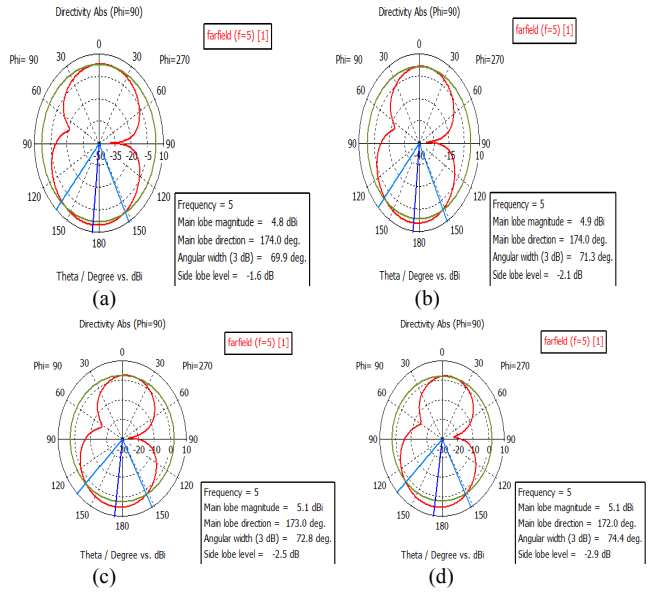

Fig. 7.1: Comparison of elevation pattern at 5 GHz; for 20 degree of bending (a), for 40 degree of bending (b), for 60 degree of bending (c), for 80 degree of bending (d).

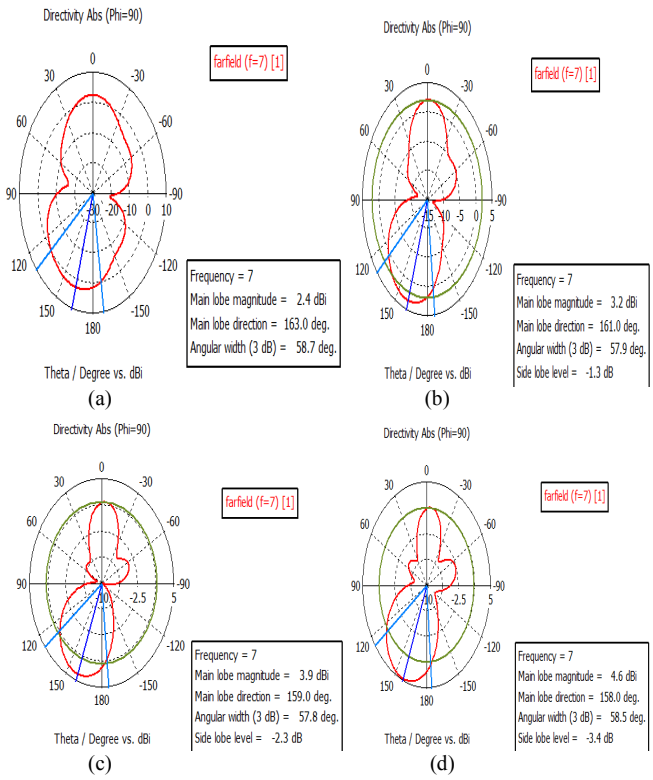

Fig. 7.2: Comparison of elevation pattern at 7 GHz; for 20 degree of bending (a), for 40 degree of bending (b), for 60 degree of bending (c), for 80 degree of bending (d).

In figure 7.1, for different angles of bending Omni-directional radiation pattern is observed at 2 GHz. At 7 GHz, radiation pattern got slightly distorted for different angles of bending. However, the increasing bending angles have very little impact on the radiation pattern of the antenna.

VI. Conclusion

In this paper a design for a compact UWB textile antenna has been proposed. The characteristics of the designed antenna having operating frequency from 2.6 GHz to 14 GHz were analyzed. The bending of the textile antenna at different angles was also focused. At different level of frequencies and bending angles the return loss, radiation characteristics and gain of the proposed textile antenna had very small fluctuations but maintained good efficiency. This performance of the proposed antenna indicates that it is suitable for UWB applications. Increasing the bandwidth as well as decreasing the size could be focus towards the further step of this design.

A Miniaturized Spiral Antenna for Energy Harvesting of Implantable Medical Devices

Qingyun Ma, Laxmi Ray, and Mohammad Rafiqul Haider

Department of Electrical and Computer Engineering, The University of Alabama at Birmingham, Birmingham, AL 35294, USA

E-mail: {maq, laxmiray, mrhaider}@uab.edu

***Abstract*— In this paper, a wireless power transfer system for implantable medical devices using a miniaturized 3 mm diameter single arm circular spiral antenna is presented. The transmission characteristics, S_{21} between the transmitting and receiving antennas with air and tissue as a medium between antennas are analyzed and measured. The receiver antenna receives almost 2 mW average power with power transfer efficiency of 53%. The power transfer efficiency could still reach to 4% with 274 µW average received power, with placement of 1.5 cm tissue and 1 cm air in between two antennas. With one PN diode rectifier, the total DC power from the receiver side is 489 nW.**

***Index terms*— Wireless power transfer, implantable, spiral antenna, biomedical tissue, power transfer efficiency.**

I. Introduction

The implantable medical devices market is expected to exceed $50 billion in 2015 in the US alone due to its immense applications in cardiovascular, neurological, orthopaedic and ophthalmological disorders. For continuous operation, the implanted units could be powered up either from an external source or implantable batteries. The tethered cables for power and data transmission have potential risks of skin infections and irritation. The implantable batteries pose potential battery fluid leakage and biohazard. Wireless power transfer to the implanted medical units has become increasingly important because of the problems seen with less feasible battery power sources. The wireless power transfer shows the great promise by eliminating the risk from the skin irritation and biohazard from battery fluid leakage.

Two most common forms of wireless power transmission are the inductive power link with magnetically coupled resonating coils and the antenna based power transmission through electromagnetic (EM) radiation. Inductive power link consists of two loosely coupled resonating coils separated by a certain distance. The coils in the inductive link must be in perfect alignment, and the distance should be less than one half of the coil diameter. The position of the receiving and transmitting coil could vary due to the body movement of the patients. Furthermore, to satisfy FCC standards the link frequency needs to be in between 5 to 10 MHz which results the inductor diameter over several centimetres [1].

The antenna based power transmission through electromagnetic field has high tolerance on the mismatch of the positions of the transmitting and the receiving antennas. The optimal EM frequency for biomedical tissue of 1.5 cm thickness with high link efficiency could be below 3 GHz [2]. Because of the higher frequency, the antenna diameter can be decreased into millimetre level. To accommodate the antenna for medical applications the antenna must be low profile and small size in order to make the system compact.

Spiral antenna has widespread usage because of its low-profile planar structure, radiation of circular polarization and flexibility of changing resonant and radiation characteristics for desired application by changing circular radius *(r)*, number of turns *(N)*, spacing between turns *(s)* and width of the spiral arm *(w)*. The spiral antenna was investigated previously [3] and feeding of the antenna can be done either from the center or side end of the spiral antenna. The concept of side-fed spiral antenna [4, 5] and center-fed spiral antenna [6, 8] are well known. Several different possible configurations of spiral antenna have been presented lately like flexible double arm side fed circular spiral antenna with microstrip infinite balun for wearable applications [7]. In addition, a single arm circular spiral antenna has advantage on adaptability of changing polarization and beam characteristics using changes in the center and side feed [8].

In this paper we propose a 3 mm diameter compact single arm center-fed circular spiral antenna operating at 524.8 MHz. The communication between transmitting and receiving antenna is studied to analyse the power transfer efficiency. The general characteristics of antenna like return loss, transmission coefficient, and its transient response analysis, power transfer efficiency with air and tissue as a medium between the spiral antennas are shown.

II. Geometry of Spiral Antenna and System of Wireless Power Transfer

A center-fed 3 mm diameter circular spiral antenna operating at 524.8 MHz was designed and simulated. The substrate chosen for realizing the antenna has dielectric constant ε_r=4.6, loss tangent tanδ=0.01 and thickness of 1mm with 0.01 mm thick aluminium metal layer. The Agilent Advanced Design System (ADS) software was used to simulate and analyze the performance and functionality of the proposed spiral antenna. The configuration of the antenna is shown in Fig. 1. The radius*(r),* the spacing *(s),* the number of turns*(N)* and the width of the spiral arm(*w*) are important design parameters of this single arm spiral antenna. For tuning the desired resonant frequency a radius of 1.5 mm with 20 turns and the arm width of 0.015 mm and 0.05 mm spacing between each turn are

maintained. The optimized design parameters of the proposed center-fed spiral antenna are summarized in Table I.

III. Simulation Results

The simulated return loss (S_{11}) plot of the transmitting spiral antenna is shown in Fig. 2. The proposed antenna satisfies -10 dB return loss characteristics from 520 MHz to 529 MHz for 524.8 MHz application. The transmitting antenna when excited at the center gives low return loss of about 30.931 dB at the operating frequency. The simulated gain and directivity of the transmitting spiral antenna at 524.8 MHz is shown in Fig.3. The average gain of the transmitting spiral antenna is about -39dBi and the directivity is 2 dBi at 524.8 GHz operating frequency. The simulated far-field radiation pattern for circular polarization of the transmitting spiral antenna at 524.8 MHz for θ = 0° and θ = 90° are depicted in Figs. 4 (a) and (b), respectively. For the study of wireless power transfer between transmitting and receiving antenna two identical spiral antennas are used. Fig. 5 shows transmission characteristics S_{21} between the transmitting and receiving antennas.

TABLE I: OPTIMIZED PARAMETER OF THE SPIRAL ANTENNA

Parameters	Values
Radius	r = 1.5 mm
Number of turns	N=20
Spacing between turns	s = 0.05 mm
Width of spiral arm	w = 0.015 mm

(b)

Fig. 4. Circular polarization of the spiral antenna at (a) θ = 0° (b) θ = 90°.

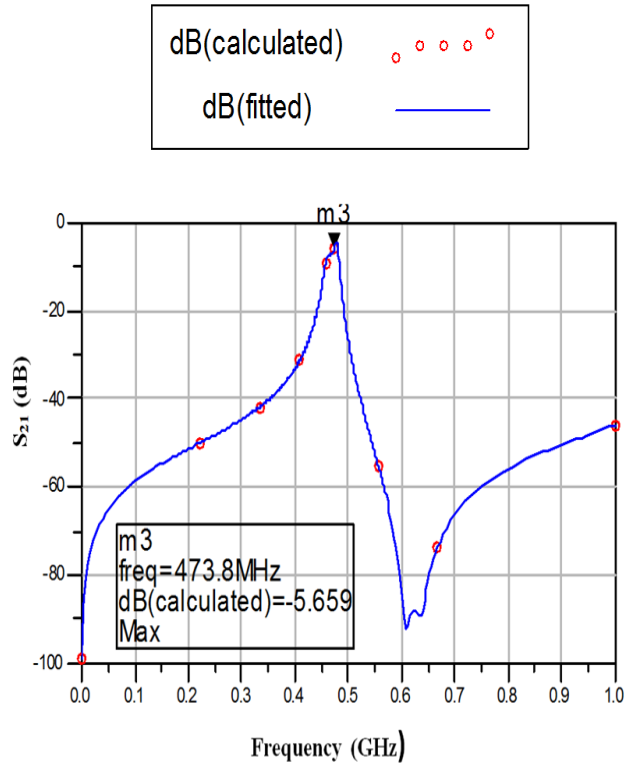

Fig. 5.Transmission characteristics S_{21} between spiral antennas

Due to the coupling of the mutual impedance of two antennas, the frequency is shifted to 473.8 MHz with maximum transmission characteristics of -5.659 dB. This strong coupling shows the influence of nearby placed receiving spiral antenna on radiation characteristics of the antenna.

IV. TRANSIENT SIMULATION RESULTS

The wireless power transfer system structure is converted to a symbol and the performance of this system is analysed in the ADS circuit simulator by using the circuit schematic as shown in Fig. 6. In the transient simulation, a sinusoid source is directly connected to the transmitting antenna through a matching network. The result from this transient simulation is shown in Fig. 7. The received voltage signal is about 1.8 V_{p-p} with 2 V_{p-p} input signal. The transmitting antenna and the receiving antenna are on the two different substrates with 1.5 cm separation distance. With this configuration, the receiver side could receive almost 2 mW average power with power transfer efficiency of 53%. The power transfer efficiency reduces to 4% with 274 µW average received power, when we put 1.5 cm tissue and 1 cm air in between two antennas. The tissue layer acts as a lossy medium which absorbs most of the transmitted power and reduces power transfer efficiency. With one PN diode rectifier, the total DC power from the receiver side is 489 nW.

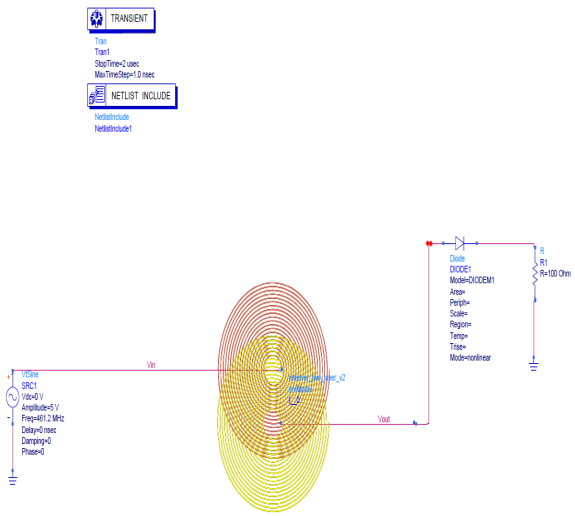

Fig. 6. Circuit simulation setup of the wireless power transfer link system.

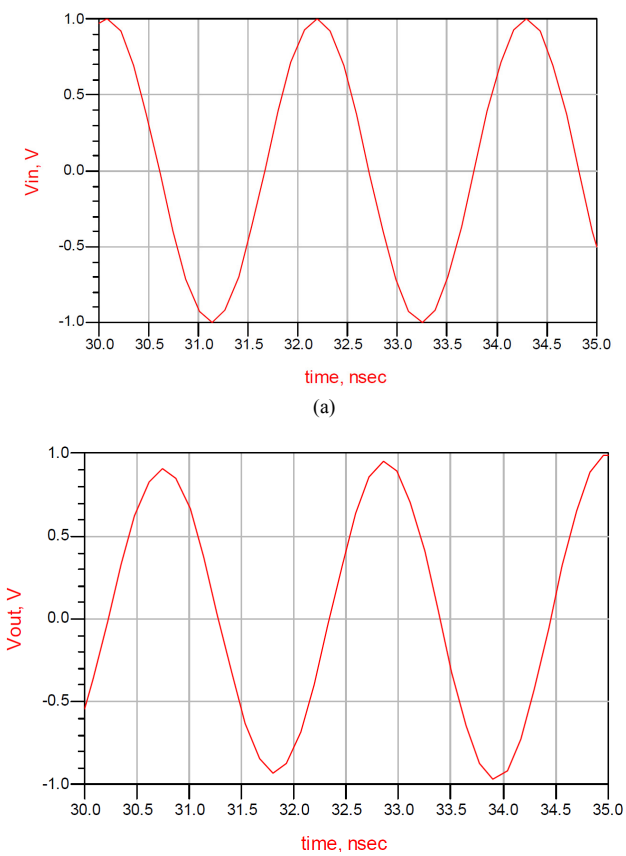

Fig. 7. (a)The input voltage signal (v_{in}) from the transmitting antenna (b) The received voltage signal (v_{out}) from the receiving antenna.

V. Conclusion

This paper presents a wireless power transfer link for medical applications. The proposed single arm center-fed spiral antenna covers 524.8 MHz frequency band. By properly selecting the design parameters of the spiral antenna tunable resonant and radiation characteristics for desired band can be achieved. The transmission characteristic between the transmitting and receiving spiral antennas gives maximum coupling. The transient simulation results shows that the power transfer efficiency is directly proportional to the distance between the center points of two antennas rather than the alignment condition of the two spiral antennas. This is well explained by simulation results with medium as air and tissue between transmitting and receiving antennas. The reduced power transfer efficiency when tissue is used as a medium shows that tissue acts as a lossy medium. From the above discussed result we confirmed that the antenna based wireless power transmission shows the greater promise on tolerance of the position mismatch and size than the inductive power link.

Abstract – **In this paper, the design of a circularly polarized array antenna with 9.56 dBi of gain at 10 GHz frequency is presented. The proposed antenna consists of a 2×2 array antenna with feed network where all microstrip patches are linearly polarized. "Both-Sided MIC Technology" is used to design the proposed array antenna. The simulated return loss of the proposed array antenna is less than -35dB. The 3 dB axial ratio bandwidth of 2.21% is obtained. The unequal feed line is used in order to realize 90° phase difference between the linearly polarized patches. Therefore, the circular polarization is realized by the combination of linearly polarized patches and unequal feed line. The structure and the basic behavior along with the simulation results of the proposed linearly polarized array antenna are demonstrated in this paper.**

Keywords-- circular polarization; patch antenna; array antenna; axial ratio; Both-Sided MIC technology

I. INTRODUCTION

Microstrip array antennas are used in a large number of microwave communication applications due to the attractive features of low profile, light weight, easy fabrication, and conformability to mounting hosts [1-3]. Linear polarization is very simple to generate but circular polarization (CP) is widely used in many microwave application as it exhibits multiple benefits over linear polarization. As circular polarization avoids polarization losses due to misalignment, there is no need to keep the transmitting and receiving antenna in the same alignment. This property is useful for RFID systems [4]. It has the ability to decrease interference between direct and reflected signal due to multipath propagation [5] and this is of huge benefit for navigation systems, especially satellite based. Circular polarization is also immune to Faraday rotation. This is the main reason for using CP in almost all Earth–satellite communication systems [6].

Two orthogonal field components with equal amplitudes and 90° phase difference are needed to radiate circular polarized waves [7]. Many CP antenna design techniques have been developed. The method of producing single-feed CP operation using a square microstrip antenna by truncating a pair of patch corners [8]or a single-fed equilateral-triangular microstrip antenna with a truncated tip [9] have been reported. Circularly polarized antenna with a cross slot of unequal arm lengths using single feed has been demonstrated in [10], [11]. The excited patch surface current path is lengthened due to slot perturbation that splits the dominant resonant mode of the microstrip patch into two orthogonal near degenerated modes. The two near degenerate orthogonal resonant modes can have equal amplitudes and a 90° phase differenceby selecting the proper slot length and the patch at a suitable position; as a result CP radiation can be achieved. Applying same concept, Y-shaped slot in antenna can also be used for CP radiation [12]. By inserting slits or spur lines to the boundary of a microstrip patch, CP radiation can be achieved [13], [14]. A circularly polarized equilateral-triangular-ring microstrip antenna design has been reported with a truncated tip and a Y-shaped conducting strip [15]. Tuning stub or a bent tuning stub can be an effective way to excite circular polarization due to the frequency tuning capability of the tuning stub. This design concept has been successfully applied to a circular patch [16], [17], a square-ring patch [18], and a triangular patch [19].

Use of an external power divider such as the quadrature hybrid, the ring hybrid, the Wilkinson power divider and the T-junction [20] to excite single square or circular patch can be another way to radiate circularly polarized waves. In this configuration the dual-orthogonal feeds excite two orthogonal modes with equal amplitude but in-phase quadrature.

A circularly polarized array can be configured using circularly polarized microstrip patches with appropriate feeding [20]. Arrays of linearly polarized patches can be used for circular polarized radiation [21], [22]. Array of two linearly polarized antennas will radiate circularly if the patches are placed orthogonally with one of the patches being fed 90° out of phase. A method has been presented in [22] for generating circularly polarized radiation from an array composed of linearly polarized elements having unique angular and phase arrangements.

In this paper a circularly polarized array antenna is proposed using Both-Sided MIC technology [23] where circular polarization is achieved having a 2×2 array composed of single feed linearly polarized patches. The patches are arranged in such a way that the resultant array radiation is circularly polarized. The feed network is designed using both

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

mirostrip lines and slot line instead of using only micostrip lines that reduces the problem of step by step impedance matching and provides a simple circuit configuration. The proposed antenna provides a gain of 9.56 dBi at design frequency.

II. ARRAY ANTENNA DEVELOPMENTS

A. Configuration of Array

Fig. 1 shows the complete layout of proposed array antenna. Its configuration consists of radiating square patches with a special feed network on one side of the dielectric substrate which has a ground plane on the reverse side.

The feed network shown in Fig. 2 is composed of microstrip lines on the obverse side and a slot line on the reverse side of the substrate. Two types of branch circuits are used in this feed network and they are the microstrip-slot branch circuit and the slot-microstrip branch circuit. The microstrip-slot branch circuit is connected in parallel and slot line impedance has to be double than microstrip line for proper impedance matching. In this case two output signals at the equal distance point from the branch point on the slot line are of same amplitude and in phase [24], [25].

Moreover, there are two slot-microstrip branches at the two opposite end of slot line. In this case slot-microstrip branch circuit is series coupled and the condition for impedance matching is impedance of microstrip line has to be half than that of slot line. Due to the series coupling, two output signals at the equal distance point from the branch point on the microstrip line are of same amplitude and 180°out of phase. The impedance of the slot line in this design is to be chosen as 100 ohm and the microstrip line impedance is 50 ohm.

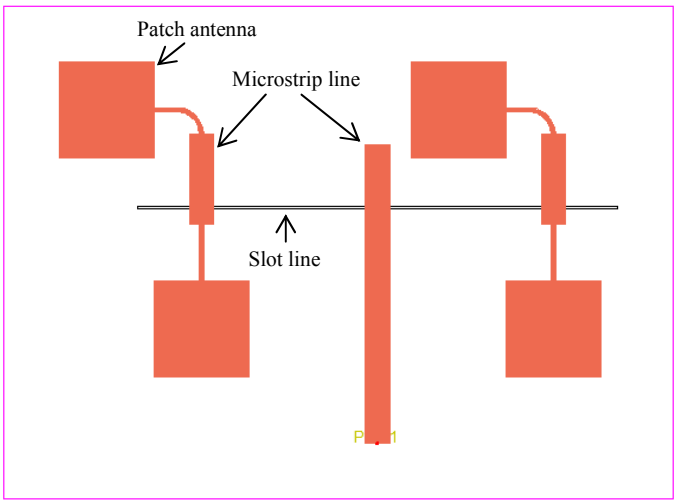

Fig. 1. Layout of proposed array antenna

The design frequency of the each patch antenna used in array is 10 GHz. Each side of square patches is 9.46 mm. Upper two patch elements are placed at 90° angle with respect to other two lower patch elements. Positional distance of upper patch elements from slot line is determined in such a way that the feed line length is quarter wave length (λ\4) greater than that of lower patch elements. This strategy creates 90° phase shift between upper patches and lower patches to excite circular polarized waves. For proper matching between the each patch and slot-microstrip branch circuit, 136 ohm quarter-wavelength transmission lines are used as impedance transformers.

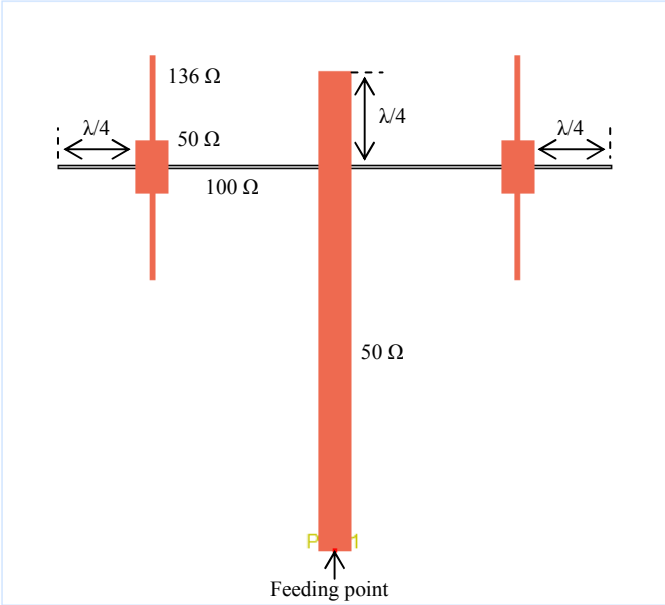

Fig. 2. Basic configuration of feed line network

Teflon glass fiber substrate with a thickness of 0.8 mm and dielectric constant of 2.15 is used to design the proposed array. Copper with a thickness of 0.018 mm is used as radiating plane and ground plane conductor.

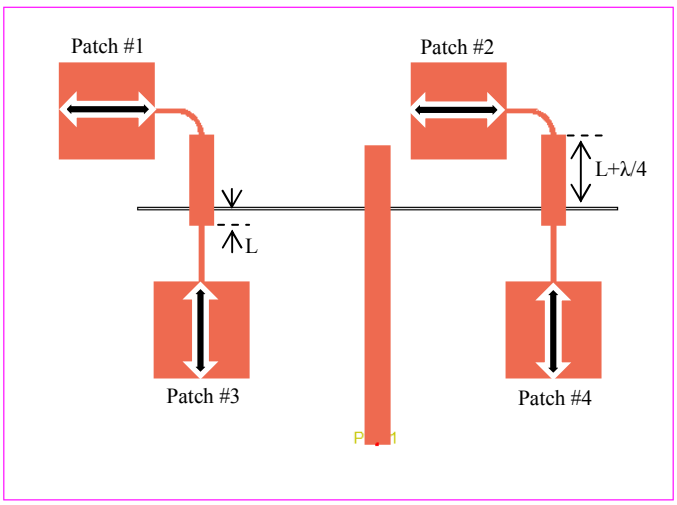

Fig. 3. Basic behavior of the array antenna

B. Basic Behavior of the Array

To generate circular polarized waves, two orthogonal signals of equal amplitude with 90° phase shift between them are needed. The basic behavior of the proposed circularly polarized array antenna can be explained using Fig. 3. When the patch #1 and the patch #2 are 0° linearly polarized, the

patch#3 and the patch #4 are 90° linearly polarized. Combining the signals of patch #1, #3 and patch #2, #4, the modes are orthogonal.

Moreover the length of feed lines is adjusted such a way that there is a 90º phase shift between patch #1 and #3, and patch #2 and #4. Therefore, in the proposed array structure, two orthogonal signals are formed with 90° phase shift and as a result circular polarized signal is excited.

III. SIMULATION RESULTS OF ARRAY ANTENNA

Advanced Design System (ADS) of Agilent Corporation has been used to simulate and optimize the proposed circularly polarized array antenna.

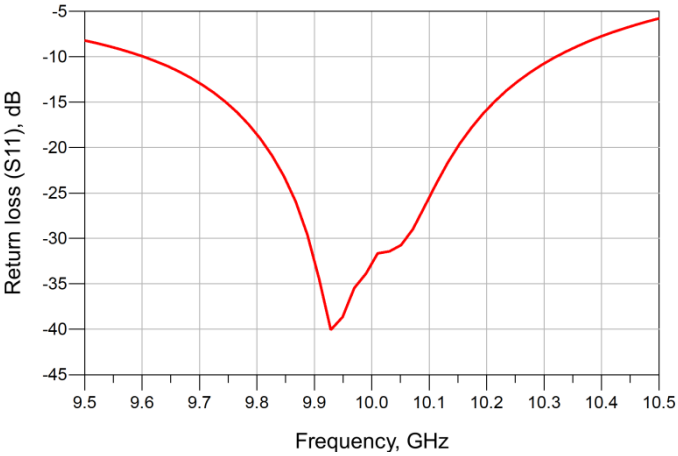

Fig. 4.Input return loss of the array

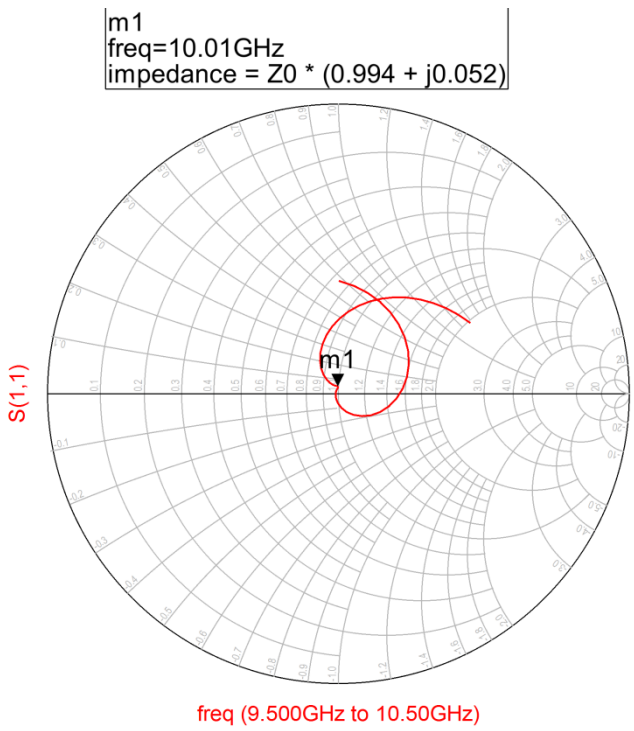

Fig. 5. Input impedance for the array antenna

The simulated return loss of the array antenna is shown in Fig. 4. The result indicates that the return loss is better than -10dB from 9.6 to 10.32 GHz (7.23%). It is the lowest at near of the design frequency of 10 GHz and excellent impedance matching is obtained.

The Input impedance for the array is shown in Fig. 5. The figure shows a dip in the impedance locus near 10 GHz, which indicates that two resonant modes are excited at very close frequencies. This suggests that the fundamental mode in the present design is split into two near-degenerate resonant modes [26]. It can be found that, when upper patch elements are ahead by quarter wave length from lower patches, these two resonant modes can be excited with equal amplitudes and a 90° phase difference, resulting in circular polarized radiation.

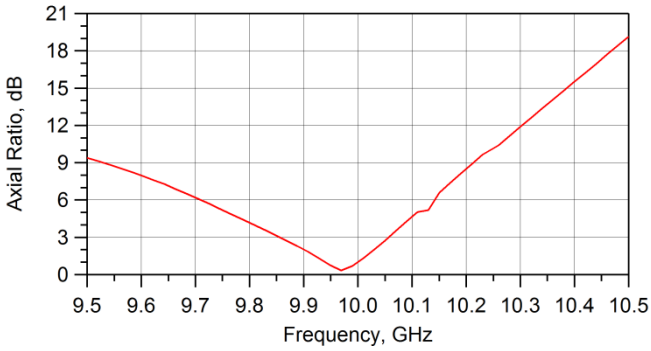

Fig. 6. Axial ratio of the antenna array

Simulated result for the axial ratio is shown in Fig. 6. This result provides a good axial ratio smaller than 3 dB at the design frequency and it indicates that the proper circular polarization is achieved. The 3-dB axial ratio bandwidth of the designed array antenna is 0.22GHz or about 2.21% respect to the center frequency of 9.95 GHz and the minimum value of axial ratio is 0.344 dB at 9.97 GHz.

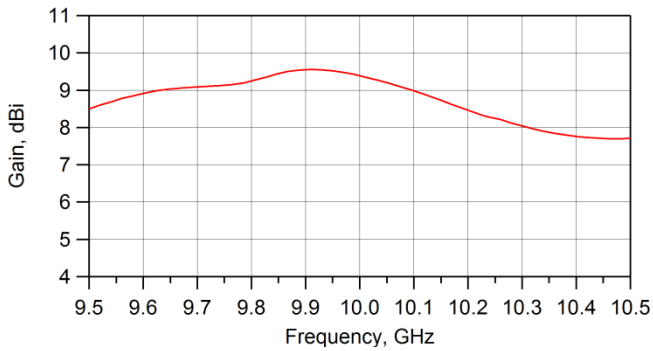

Fig. 7. Array antenna gain

Fig. 7 shows the gain of the array. It is found that from Fig. 7, the peak gain is 9.56 dBi at 9.92 GHz which is much higher than the average 2×2 circularly polarized array antenna where each patch element is linearly polarized. The average gain from 9.6 to 10.3 GHz is above 8 dBi. Fig. 8 shows the radiation pattern of the proposed array antenna. From fig. 8, it is confirmed that the antenna radiation is right hand circularly polarized (RHCP). The cross-polar level is better than -30 dB that indicates good radiation performance of the antenna.

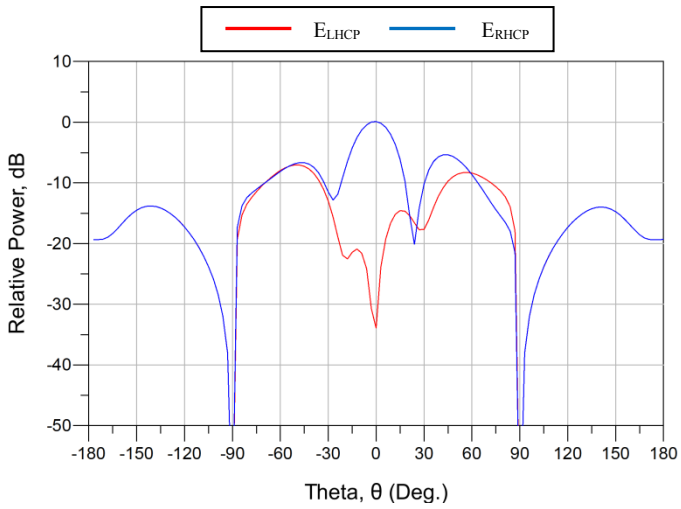

Fig. 8. Radiation pattern of the proposed array antenna at 9.97 GHz

IV. CONCLUSION

In this paper, a circularly polarized array antenna has been presented and the characteristics of the proposed array antenna are discussed.The simulation results show good axial ratio and 9.56 dBi gain at design frequency. All results indicate that the proposed array antenna radiation is circularly polarized with good return loss performance and proper impedance matching. The most remarkable feature of this array antenna is that CP radiation is excited using only linear polarized patches with special feed line network that consists of microstrip lines and slot line. This feed line structure minimizes the impedance matching problem that is faced in conventional microstrip feeding circuits. Moreover, each patch element is excited at a single point. From this study, it is also clear that, the newly designed array antenna has simple structure and besides, the both-sided MIC technology is effectively used at the design process. The experimental investigation of the proposed array antenna will be conducted very soon.

Abstract— **This work deals with the design and simulation of a passive radio frequency identification (RFID) tag antenna operating in ISM band. The antenna has an impedance bandwidth of 60 MHz (2419MHz - 2479 MHz) resonant at 2449.5 MHz. The microstrip antenna has a planar geometry and consists of a ground plane, a substrate, a modified rectangular patch as a radiator. The proposed antenna provides excellent SWR of 1.0435 and a gain of 3.351 dB. The possible adjustment over the entire ISM band is demonstrated by adjusting a single branch. The basic theory and design are analyzed, and the simulation results are obtained using CST Microwave Studio commercial software is employed to optimize the antenna's properties.**

Index Terms—**Passive RFID Antenna, Sensitivity, CST microwave studio, ISM Band**.

I. Introduction

Radio frequency identification (RFID) is an automatic non-contact bidirectional communication identification technology taking advantage of electromagnetic induction and radiation. A generalized RFID system comprises a scanner unit, called a reader, and a set of remote transponders, attached to the objects to be identified denoted as tags [1]. It also includes software (middleware) and a server processor (generally a PC) to communicate with remote tags. RFID is one of the promising technologies employed as an alternative for overcoming some issues associated with current technology used for identifications, such as bar code and optical systems. It employs radio frequency waves to transfer data between a reader and a movable item to identify, categorize and track. Now a days RFID is dominating in sensing technology because of its improved read range, no line of sight stipulation, low cost, capability of handling multiple objects within a single scan and so on.

The RFID tag element consists of an antenna integrated with a microchip. A single antenna both transmits and receives radio waves to or from readers. According to the presences of battery in the transponder and their radiation nature RFID tag may be classified in three major categories, i) Active tag ii) Battery assisted passive or semi active tag and iii) Passive tag [2]. Active tag bears a battery and emits radio wave continuously. But semi active tag has a small on board battery and emits radio wave after receiving reader's command only. Passive tag contains no on board power supply. The reader antenna transmits electromagnetic wave to tag. This signal is received by the tag via antenna. This received energy excites the passive tag and provides the necessary power to the tag that allows the microchip to operate. Reader sends carrier wave to activate the tag as well as commands. When the tag receives the command signal, the microchip enables the tag to scatter a modulated signal back to the reader in response to reader command [3]. This process is referred to as passive backscatter. The reader then demodulates and decodes the signal and delivers the data stored in the tag to host PC.

The two most sensitive factors of RFID tag performance and measurement are i) Tag sensitivity and ii) Read range [4]. Tag sensitivity is defined as the minimum signal strength either field or power at the tag location needed to power up the tag [5]. Tag field sensitivity E_{tag} (V/m) and power sensitivity P_{tag} (W) are directly related. The power collected by a perfectly matched antenna load (chip) can be expressed either via incident power and tag antenna gain or via incident power density and effective tag antenna area [6]:

$$P_{tag}\, G = S\, A_e \tag{1}$$

Here, G is the gain of the tag antenna; S is the power density of an electromagnetic wave with the electric field E incident on the RFID tag, given in free space separation d. by:

$$S = \frac{E^2}{120\pi} = \frac{P_t\, G_t}{4\pi d^2} \tag{2}$$

Here, P_t is the transmitted power and G_t is the gain of the reader antenna. A_e is the effective area of the antenna inversely related to the wavelength.

$$A_e = \frac{\lambda^2}{4\pi}\, G \tag{3}$$

Hence, Tag field sensitivity;

$$E_{tag} = \frac{4\pi}{\lambda}\sqrt{30 P_{tag}} \tag{4}$$

Tag power sensitivity can also be readily expressed as:

$$P_{tag} = G\, p\tau P_{th} \tag{5}$$

Where, p is the polarization efficiency, τ is the impedance matching or the power transmission coefficient between the tag antenna and the microchip and P_{th} is the chip power threshold sensitivity. Equation (5) describes the necessity of a high gain antenna to collect more power from incident wave and to involve maximum reader tag separation to make sure that the sufficient amount of it gets absorbed in the RFID chip and activates it.

The most important tag performance characteristic is read range, the maximum distance at which RFID reader can detect the backscattered signal from the tag. Though the reader receives modulated backscatter from tag due to its high sensitivity in comparison with tag, the read range is defined by the tag response threshold. Read range is also sensitive to the tag orientation, the material on which tag is attached, and to the propagation environment [7]. The read range can be reckoned using Friis free-space formula:

$$r = \frac{\lambda}{4\pi}\sqrt{\frac{P_t G_t G \tau}{P_{th}}} \tag{6}$$

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

In tag antenna designing convenient impedance matching between tag and microchip must be confirmed. So, the antenna should be conjugate matched with the highly capacitive chip impedance i.e. Za = Zc, (where Za = (Ra+jXa) Antenna Impedance and Zc = (Rc+ jXc) Microchip Impedance), which allow the tag to receive the maximum power from the reader's antenna [8]. To achieve highest radiation efficiency at the resonant frequency of the tag is at where Xa = - Xc and Ra close to Rc, which ensures the conjugate matching. Again the power transmission coefficient which indicates the impedance mismatch between the tag antenna and the microchip can be expressed by,

$$\tau = \frac{4R_aR_c}{|Z_a + Z_c|} \quad (7)$$

Based on the above discussion and mathematical expression, it is very convenient to declare that all other factors (P_t, G_t, λ, temperature, environment and so on) remaining constant, the performance and accuracy of RFID depends on tag antenna specifications only such as gain, perfect impedance matching with micro-chip.

In this paper, modified planer microstrip antenna is designed for RFID application in ISM band. RFID transponders operating in ISM have the advantage of being smaller than UHF tags, but generally have shorter ranges [7]. Again passive RFID tags are extensively used due to its several features such as low cost, absence of on board power supply, while its lifetime is theoretically infinite and many more. The antenna is designed by targeting the mid frequency of ISM band, and then possible adjustment over the entire ISM band is investigated.

II. Tag Antenna Design

In this letter, a microstrip patch antenna is designed. The proposed antenna is constructed using several rectangular arms of equal width of 5 mm and oriented irregularly. The proposed antenna shape is shown in Fig. 1. FR4 substrate of thickness 1.6 mm is used on which the total structure is mounted. Dielectric constant (□) is chosen 4.3 while loss tangent is 0.025. The opposite side of the substrate contains the copper plate that acts as a ground plane. This enhanced the directivity of the antenna to a desired level. Copper metal is also used as the radiating element. The thicknesses of both the radiator and ground plane are 0.1 mm.

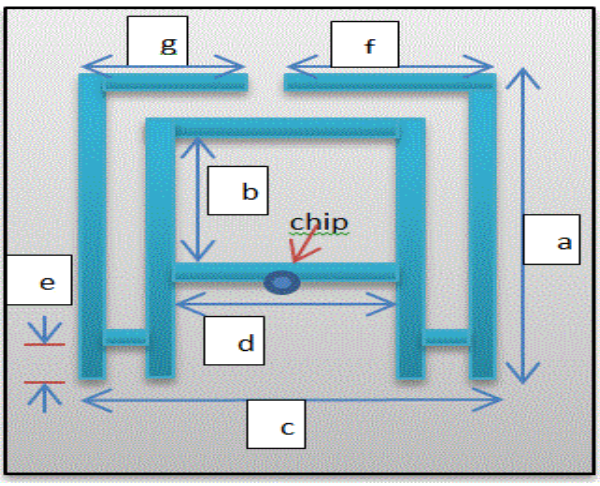

Fig. 1 Structure of proposed tag antenna.

Hence the approximate arm lengths are given in Table 1. The microchip position is allotted in arm "d". All the arms have an equal width of 5 mm and separated from the neighbor arm by 5 mm also.

TALBE I
GEOMETRICAL PARAMETERS OF ANTENNA STRUCTURE

Arm	Length (mm)
A	60
B	25
C	60
D	25
E	5
F	28
G	22

The arms of the proposed antenna along a meandered path, a configuration is produced by distributed capacitive and inductive reactance's which globally affect the antenna input impedance. In this proposed structure, horizontal lines mainly control the radiation resistance; adjacent vertical lines give the storage of electric energy and loss; the overall conductor length affects the inductance.

III. Simulated Results

The proposed antenna is designed and simulated in the CST Microwave Studio in order to extract its electromagnetic parameters. It provides excellent characteristics which demonstrate that proposed antenna can be used in the ISM band RFID applications. The proposed is resonant at 2449.5 MHz with accuracy of 0.02% from the mid of ISM band. Simulated return loss is -33.44 dB with standing wave ratio (SWR) 1.0435. The frequency range having return loss less than -10 dB is found from 2419 MHz to 2479 MHz. So impedance bandwidth is 60 MHz, which is 2.45% of resonant frequency. These are depicted in Fig. 2 and in Fig. 3.

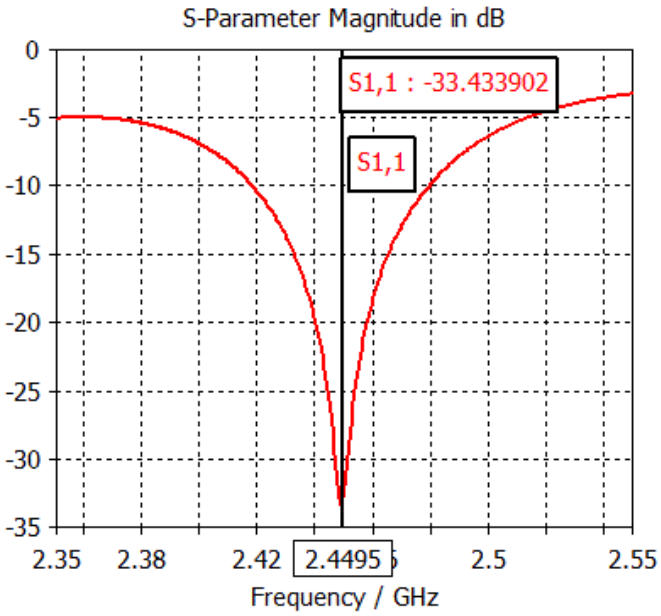

Fig. 2 Simulated return loss of proposed antenna.

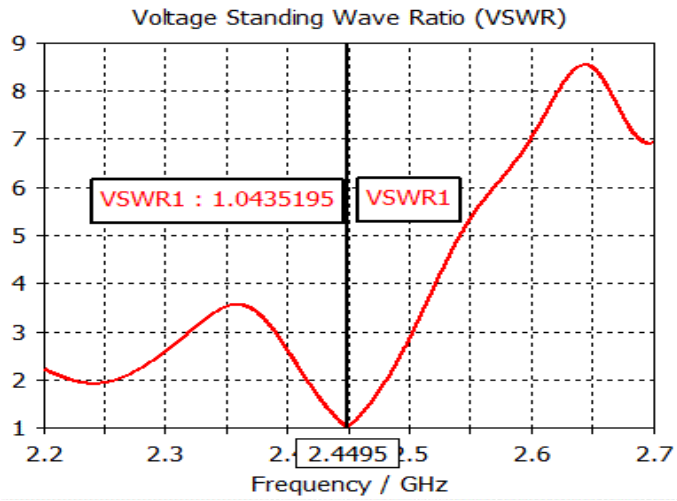

Fig. 3 Computed VSWR plots of the proposed antenna.

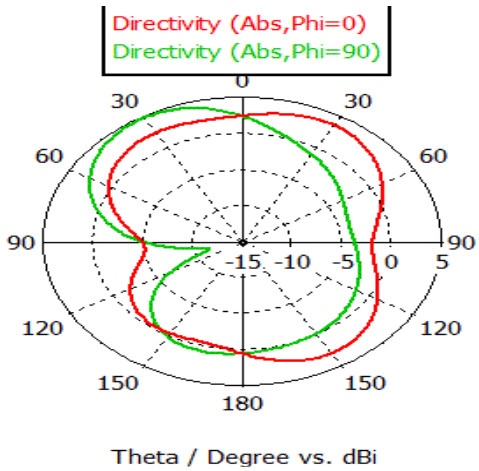

Fig. 4 Computed far field directivity of the proposed antenna.

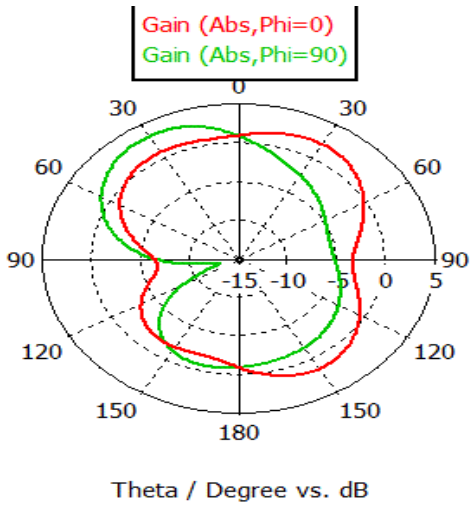

Fig. 5 Computed far field gain of the proposed antenna.

From Fig. 4 and Fig. 5, the pictorial representation of simulated far field radiation pattern, it is very convenient to state that the radiation pattern of the proposed antenna is fairly unidirectional; which is very important criteria of designing tag antenna. So, it could provide necessary power to microchip irrespective to the reader angular position. Proposed antenna bears a directivity of 4.84 dBi and gain 3.351 dB at 2450 MHz.

Passive RFID tag has no on board power supply. The tag antenna should have power collecting capability from the RF signal emitted by reader. Antenna supplies this collected power to the microchip to activate it in order to answer in response to the readers command via backscatter. Amount of collected power would be transferred to microchip depends on the conjugate matching between tag and microchip. The antenna input impedance at the allotted chip location is extracted as 10.43 + j148.5 Ω using inductive coupled feeding instead of direct connection with the excitation source. So it can be perfectly matched with microchip having complex impedance of 10 – j150 Ω. Hence, the power transmission coefficient (τ) would be 0.994.

$P_t G_t$ is termed as effective isotropic radiated power, EIRP. An RFID standard of EIRP is 4 W [6]. The available commercial chip power threshold sensitivity may vary between -20 dBm to -10 dBm. The maximum read range of this proposed antenna would be 3.60 meter while the tag sensitivity is limited to -12 dBm which is close to the worst sensitivity as compared to others.

IV. Adjustment over entire ISM band

Mostly used electromagnetic application in ISM band covers the frequency range of 2400 MHz to 2500 MHz. RFID application in this band is adopted in different frequencies in different country. Designed antenna covers most of the band (60 MHz) with return loss below -10 dB and VSWR less than 2. Possible adjustment of resonant frequency entire the band is investigated with a simple adjustment of length of arm "f" hence satisfactory results are obtained. Comparative simulated results of length adjustment are summarized in Table 2.

TALBE II
Effect of Length Adjustment of Arm " f "

Length of arm " f " (mm)	Resonant frequency (MHz)	Return loss (dB)	VSWR
33	2415	-29.32	1.07
30	2434	-35.63	1.03
28.5	2444	-35.06	1.03
25	2460	-30.79	1.06
22	2477	-32.94	1.04
18	2491	-18.33	1.27

The simulated results obtained with adjustment of length of arm "f" in the CST microwave studio. Corresponding return losses are depicted in Fig. 6 for further clarification. Satisfactory results are obtained for each adjustment. Now it may conclude that by selecting appropriate length of arm "f" any resonant frequency can be achieved within the ISM band. So proposed antenna can be used in other applications such as WiMAX, Wi-Fi, Bluetooth and WLAN at 2.4 GHz to 2.5 GHz band.

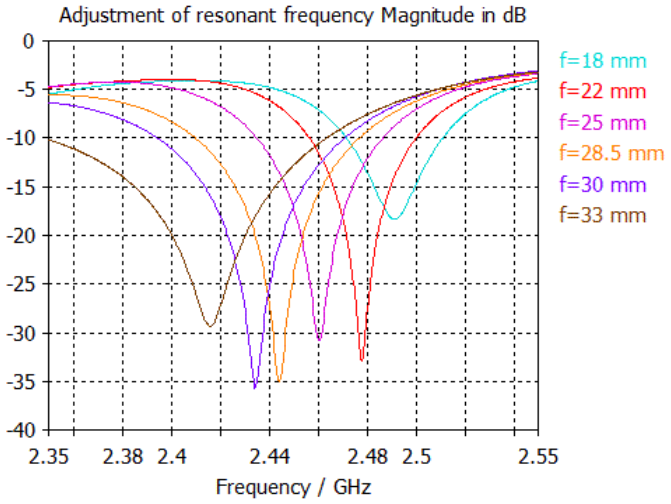

Fig. 6 Adjustment of resonant frequency.

V. Conclusions

Modified rectangular shaped microstrip antenna is designed and its electromagnetic features are investigated. The results are found satisfactory and can be frequently used in RFID application at ISM band. The simulation results show that a high gain, a good impedance matching with the microchip and a fairly unidirectional far field radiation pattern would be obtained. The adjustment of resonant frequency over the entire ISM band is investigated simply by varying length of a single arm; hence satisfactory results are obtained in almost every trial. So, proposed antenna can be used in others commercial communication application. Antenna is designed with 60 mm X 60 mm FR4 substrate with metallic radiators of much less surface area than substrate results in small radiation loss.

Abstract—**This review article presents an overview of the soil moisture measuring technique using microwave radiometry. Remote sensing of soil moisture is a promising field of research if accuracy can be achieved. The optimal frequency to estimate at this state using microwave radiometry is at L-band (~1.4GHz). In this article analysis of basics of soil microwave sensing, parameters responsible for radiation variation, soil dielectric properties and retrieval algorithm is discussed mainly. In the end discussion on synchronization of soil microwave radiation receiving by polarimetric radiometer, conclusions and future perspective has been presented.**

Index Terms—**Soil moisture retrieval, Patch antenna, Polarimetric radiometer.**

I. Introduction

Soil moisture monitoring is important because it reflects land degradation and drought of a land. It is a critical component of climate, hydrology, ecology and agriculture systems too. It is also related to the precipitation variability in an area. The soil can be considered as consisted of water, air and solid particles and with different percentage of those components result different types of soil. An eloquent model formulation would account for the observed effects of various soil components on the complex dielectric behavior of the soil water-air system as a function of frequency [1]. Dry soil and moist soil has different dielectric constants [2], so it can be concluded that it will radiate different patterns for different soils. Using radiation from microwaves makes detection possible in almost all-weather conditions, which is a definite advantage that is not possible using visible or infrared remote sensing.

Earth receives electromagnetic radiation from sun and to maintain thermal equilibrium radiates and absorbs it. Radiometry is the field of study that deals with radiated electromagnetic power. There are two types of microwave remote sensors: Active sensors and Passive sensors. The active type receives the back-scattering which is reflected from the transmitted microwave which is incident on the ground surface. The microwave radiometer is one of the passive microwave sensors [3]. Radiometers measures and detect the radiated energy by radiating body in the microwave frequency range (300 MHz-300 GHz). Passive sensors are sensitive to the emissivity and brightness temperature of the soil. Both are function of dielectric properties, surface roughness, physical temperature, frequency, angle of observation and polarization etc. [4].

The frequency most suitable for this remote sensing is L-band (1 GHz-2 GHz). To design antenna for this frequency range, microstrip patch antennas are natural choice because of their light weight, conformability and low cost [5]. The radiation properties of microstrip structures have been known since the mid 1950's [5]. Rectangular and circular micro strip resonant patches have been used extensively in a variety of array configurations.

Soil moisture measuring technique starting with basics of microwave remote sensing will be discussed next. Microwave radiometer system and future aspects of this research will be discussed in the end.

II. Soil Moisture Measuring Technique Using Microwave Remote Sensing

A. Basics of Remote Microwave Sensing

The power collected by an antenna which is surrounded by a distribution of incident power $B(\theta,\varphi)$ [6] can be calculated using the equation

$$P = \frac{1}{2} A_r \int_{f}^{f+\Delta f} \iint_{4\pi} B_f(\theta,\varphi) |F_n(\theta,\varphi)|^2 \, d\Omega df \qquad (1)$$

Where, A_r is the effective area of the antenna, solid angle of the transmitting antenna Ω_t is $\Omega_t = A_t/R^2$, and R is the distance between the antenna and the radiating target. Δf is the bandwidth and F_n is the normalized antenna pattern. If the brightness is dependent on frequency then $B_f(\theta,\varphi)$ is called spectral brightness density. The equation is illustrated with Fig. 1.

The power absorbed by an antenna with normalized radiation pattern $F_n(\theta,\varphi)$ surrounded by a black body at a constant physical temperature T_0 is given by modifying expression (1) and can be expressed as

$$\begin{aligned} P_{bb} &= k \cdot T_0 \cdot \Delta f \cdot \frac{A_r}{\lambda^2} \cdot \iint_{4\pi} |F_n(\theta,\varphi)|^2 \, d\Omega \\ &= k \cdot T_0 \cdot \Delta f \end{aligned} \qquad (2)$$

Where the antenna solid angle Ω has been expressed as a function of its effective area and T_0 is the absolute temperature.

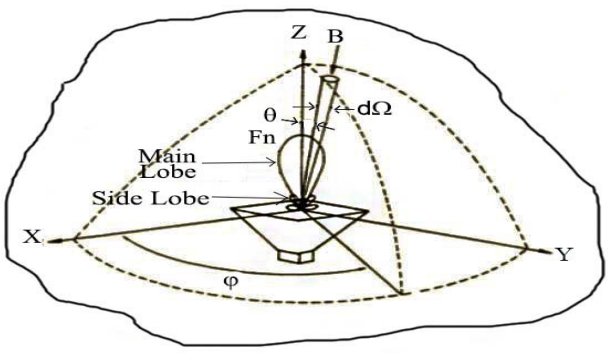

Fig. 1 Geometry of the radiation incident over antenna

Black-bodies are ideal elements that absorb all incident energy and radiate them in omnidirectional way. But in reality, materials do not radiate energy such as black-body and thus called grey-body materials. To express grey-body radiation, two new concepts are introduced, the brightness temperature, $T_B(\theta,\varphi)$ and emissivity, $e(\theta,\varphi)$.

The apparent temperature T_{AP} is an equivalent temperature related to the total brightness incident over the antenna $B_i(\theta,\varphi)$ and the relation of them is

$$B_i(\theta,\varphi)=\frac{2k}{\lambda^2}\cdot T_{AP}(\theta,\varphi)\cdot\Delta f$$

where (3)

$$T_{AP}=T_{UP}+\frac{1}{L_a}(T_B+T_{SC})$$

Where, T_{UP} is the atmospheric upward radiation

T_{SC} is the atmospheric downward radiation scattered reflected by the surface and L_a is the atmospheric radiation.

Brightness temperature can also be calculated by Stokes parameters. The four Stokes parameters describe the polarization and total energy transported by a wave [7], and if the energy acquired at horizontal and vertical polarization are separate issues, then in terms of brightness temperatures expression can be written as-

$$T_B=\begin{pmatrix}T_{Bh}\\T_{Bv}\\U\\V\end{pmatrix}=\frac{\lambda^2}{k\Delta f\eta}\begin{pmatrix}\langle|E_h|^2\rangle\\\langle|E_v|^2\rangle\\2\Re\langle E_vE_h^*\rangle\\2\Im\langle E_vE_h^*\rangle\end{pmatrix} \quad (4)$$

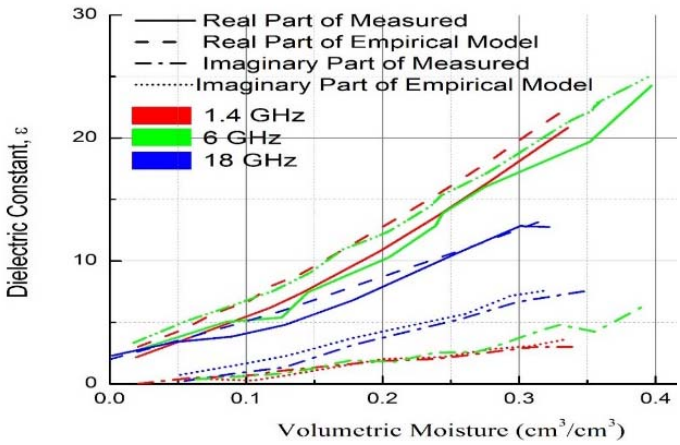

Fig. 2 Comparison of measured ε and that calculated by semi-empirical model for sandy loam in 1.4, 6 and 18 GHz [1]

B. Soil Moisture Measuring

The most important property of soil for measuring moisture using microwave antenna is its dielectric constant. Soil dielectric constant ε, which has no unit and can be expressed as, $\varepsilon=\varepsilon'+j\varepsilon''$ $\varepsilon=\varepsilon'+j\varepsilon''$ $\varepsilon=\varepsilon'+j\varepsilon''$. The real part is responsible for velocity of wave and the imaginary part is for energy losses. The dielectric constant of dry soils is almost independent of temperature [8] and frequency. A series of dielectric constant measurements of five soils with different texture composition at frequencies between 1.4 and 18 GHz was performed [9] and found out that texture has a strong effect on the dielectric behaviour. Models that use a semi-empirical was followed by two widely used models presented in [1, 10]. In [10] a means to estimate a soil's dielectric properties from a knowledge of its texture was proposed. Methods related with theoretical four-component dielectric mixing model to proposed empirical model in [1] were discussed and result is shown in Fig. 2. These relationships can be used for estimating the brightness temperature. Using complex dielectric constant and the volume fraction of each of the soil components as the function the relative gravimetric moisture m in [9] is determined as-

$$\varepsilon^\alpha=1+\frac{\rho_b}{\rho_s}(\varepsilon_s^\alpha-1)+V_a\varepsilon_a^\alpha+V_{fw}\varepsilon_{fw}^\alpha+V_{bw}\varepsilon_{bw}^\alpha-m_v \quad (5)$$

Where, ρ_b , ρ_s s and m_v are bulk density, particle density and volumetric moisture respectively. The relative gravimetric moisture m is determined as, $m=\frac{w_w-w_d}{w_d}$ and the volumetric moisture, $m_v=m\frac{\rho_b}{\rho_w}$. The dielectric constant modelling plays a crucial role because the constant is one of the most also changes and the radiometer output so changes. If the bound water and free water are considered as the same [1] the equation of dielectric constant becomes

$$\epsilon=\left(1+\frac{\rho_b}{\rho_s}(\epsilon_s^\alpha-1)+m_v^\beta\epsilon_{fw}^\alpha-m_v\right)^{1/\alpha} \quad (6)$$

In [4], the variation of Brightness temperature at different angles of incidence with different moisture content for both horizontal vertical polarization was studied and it was observed that the moisture content increases, the value of brightness temperature reduces. The value of brightness temperature increases as the received power increases (see Fig. 3).

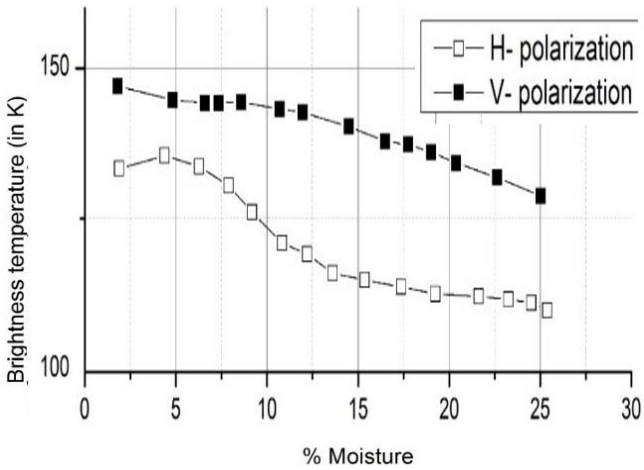

Fig. 3 Variation in brightness temperature with percent of Moisture

Several attempts have been made to explain the effect of surface roughness on the observed brightness temperature. When a radar wave strikes on a smooth surface at a specific incident angle, some energy is scattered in all directions, some of which returns to the sensor as backscatter, and the rest is reflected in the specular direction [11-16]. Physical models [17] are generally driven by surface characteristics derived from measurements of surface height profiles [18]. Using only

the coherent term of the scattered field, [11] proposed a simple model for the reflectivity

$$\Gamma_{sp} = \Gamma_{op} \exp(-4k^2{}_{\lambda}\,\sigma^2{}_s \cos^2(\theta))$$

Where,

$$\Gamma_{oh} = \left| \frac{\cos\theta - \sqrt{\varepsilon_s - \sin^2\theta}}{\cos\theta + \sqrt{\varepsilon_s - \sin^2\theta}} \right|^2, \quad (7)$$

$$\Gamma_{ov} = \left| \frac{\varepsilon_s \cos\theta - \sqrt{\varepsilon_s - \sin^2\theta}}{\varepsilon_s \cos\theta + \sqrt{\varepsilon_s - \sin^2\theta}} \right|^2$$

Where Γ_{sp} is the reflectivity at p-polarisation ($p = v$ or h) of a smooth surface, Where ε_s is the dielectric constant of soils, $k = 2\pi/\lambda$ is the electromagnetic wave number, σ_s is the standard deviation of the height of the surface and θ is the incidence angle.

The soil moisture models are used as forward models, and the geophysical variables are retrieved by minimization of a cost function of the type [19]

$$F = \sum_{\theta} \frac{(T_{Bh} - T_{Bh}^{meas})^2 + (T_{Bv} - T_{Bv}^{meas})^2}{\sigma_{TB}^{\ 2}} + \sum_{n} \frac{(P_n^{ini} - P_n)^2}{\sigma_{Pn}^{\ 2}} \quad (8)$$

Where, the simulated brightness temperature T_{Bp} is computed using a land emission model,T_{Bp}^{meas} is the measured brightness temperature, and P_n is any of the parameters on which T_{Bp} depends. Estimates can be constrained to be close to the initial value by choosing low σ_{Pn} values, or they can be left as a free parameter by selecting $\sigma_{Pn} \ll 1$.

III. Microstrip Patch Antenna and PMR System

Many techniques have been proposed to determine microstrip antenna characteristics. Of them, transmission line model, generalized transmission line model, cavity model, and multiport network model are the popular methods. In details of antenna structure and analysis in not scope of this article, but some basic feeding techniques and polarimetric radiometer (PMR) have been discussed.

1) Microstrip Patch Antenna: Most basic structure of a patch antenna consists of a radiating patch on one side of a dielectric substrate which has a ground plane on the other side as shown. The patch is generally made of conducting material such as copper or gold and can take any possible shape [5]. The radiating patch and the feed lines are usually photo etched on the dielectric substrate [20]. Early microstrip antennas used either a microstrip feed line or a coaxial feed [21-23] offering one degree of freedom by adjusting feed point to adjust input impedance level. But having simplicity it shows some major problems. Increasing substrate thickness can lead to increase in spurious feed radiation, surface wave power and feed inductance [24]. For the feed point is selected on the non-radiating edge of the patch the cross-polarized radiation is high but can be minimized by optimizing the aspect ratio [25]. A number of non-contacting feeds have been developed for microstrip antennas. Of them, proximity feed or electromagnetic coupling uses a two-layer substrate with a microstrip line on the lower substrate, terminating in an open stub below the patch which is printed on the upper substrate [26, 27] thus having two degrees of freedom: the length of the feeding stub and the patch width to line width ratio. This design reduces spurious radiation and coupling in return of complex fabrication process. Aperture coupled microstrip antenna is another type of non-contacting feed method [28, 29]. This configuration uses two parallel substrates separated by a ground plane. A microstrip feed line on the lower substrate is coupled through a small aperture in the ground plane to a microstrip patch on the top substrate. A thin, high dielectric constant substrate for the feed and a thick, low dielectric constant substrate for the antenna decrease spurious radiation and increases bandwidth. In addition, the ground plane eliminates spurious radiation from the feed from interfering with the antenna pattern or polarization purity. This geometry has at least four degrees of freedom: the slot size, its position, the feed substrate parameters, and the feed line width. Also along with different feeding methods, perforating patch, stubs and some innovative features such as dual polarization etc. are used for different requirements.

Polarimetric Radiometer: Polarimetric radiometer receives radiation from soil/ocean, digitize the received data by embedded computer program. The final outcome is the brightness temperature which is calibrated using special set and number of measurements and finally result is verified using stability tests. As discussed in the previous section, radiation fields can be characterized using Stokes parameters. It is convenient to use the modified Stokes parameters [30]. In brightness temperature: the first and second parameter describe the vertically and horizontally polarized brightness temperatures respectively and the third and fourth parameter describe linearly and circularly polarized components respectively. The first successful operation of analogue direct cross-correlation technique for polarimetric radiometry is demonstrated by FPoR (Helsinki University of Technology Fully Polarimetric Radiometer) [31]. The first three Stokes parameters has confirmed the feasibility of these parameters in measuring surface wind vectors in sea areas. The geophysical noise of these parameters was found to be extremely small, showing very homogeneous wave conditions in the test area. The results found in [31] suggest that the relationship between the wind vector and the Stokes parameters may vary locally. Though the centre frequency of [31] was 36.5GHz, these result can be used to form a frequency range of 6-94 GHz. Therefore multiple band operation can be a topic of further research. The available commercial radiometer for L-band is PLMR by Prosensing Inc. [32] which calculates the brightness temperature by a series of calculations. It is an airborne system for remote sensing of environmental parameters such as soil moisture or ocean salinity. This system has two modules which can be divided as receiver module and communication module. This system is capable of measuring 12 measurements in 2 polarization at 6 antenna beam positions. By calibrating initial temperature and setting several gains brightness temperature T_B is measured with accuracy and precision using and its accuracy/stability can be checked. This [32] polarimeter is for only L-band but the principle can be extended for multiband which can be a good future work. If L-band detection is incorporated with some higher frequency bands it is possible to increase the precision and sample number from a certain area under observation. In general the total PMR system for total phased array network for soil moisture measurement can be proposed as Fig. 4 The beamforming network is essential because of the phased array system.

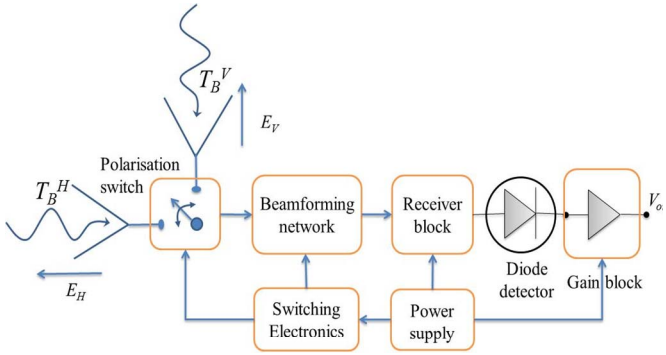

Fig. 4 Block diagram of PMR system

IV. Conclusion and Future Perspective

This article presents a review on the soil moisture measurement using smart antennas. Water, being the most important element of nature, controls the existence and propagation of life in the planet. Soil moisture also plays vital role in agriculture and animal diversity and so water management requires detailed temporal and spatial soil moisture monitoring system. Soil contains several component whose composition determines the dielectric constant of the soil, thus different types of soils have different dielectric constants. The dielectric constant of soil is primarily varied with the soil composition, roughness of soil and temperature of soil. The radiated power from soil also changes with changes in this dielectric constant. The radiation by the soil can be remotely sensed by PMR (Polarimetric Microwave Radiometer). The bands that are used for this PMR are P-, L-, C-, X-, Ku-, Ka- and W-bands. Among them L-band has been proved by research as the optimal band. To provide accurate but high spatial resolution higher frequency band data can be used to downscale the low resolution L-band data. To combine this system with precision and making the system cheap, low profile it is necessary to design multiple band antenna in a compact design. Microstrip antenna becomes the optimum choice for such requirements because of its planar and low profile attributes. Comprehensive studies have been done in this interest and this field has huge possibility for further research. To combine the experimental data regarding soil moisture with brightness temperature calculation and decipher to match the actual will be a big challenge.

Abstract—**In this article, we have applied Maxwell-Schrodinger analogy to introduce the idea of electromagnetic metamaterial based band gap in semiconductor regime. We have found a new type of band gap in semiconductor hetero-structures, which is analogous to the spatial average single negative (SASN) band gap in multi-layer photonic crystal. Interestingly, width of such band-gaps is controllable according to designers' will. Perfect tunneling of the propagating stationary states and strong spatial delocalization of bounded electronic states have also been observed, which is electronic analogue of the enhancement of evanescent waves in Pendry's lens. Finally, a multilayer structure has been proposed, which supports band-gap at some energy bands and perfect tunneling at target energy value. As the on-off ratio (step transition from low transmission to high transmission) is very high even if the applied energy is very low, this kind of multi-layer structures can be very useful as future low power electronic device and logic transistor.**

Index Terms—**electronic metamaterial, semiconductor hetero-structures, perfect tunneling, probability wave, Kane model.**

I. Introduction

Metamaterials are artificially engineered materials which has unusual physical properties. In photonic crystal domain, several metamaterial structures have already been investigated and they have found several interesting applications in cloaking, Optical fibers, perfect lenses, antennas [1-5]. Recently, SNG (Single Negative) type metamaterials has been investigated thoroughly. SNG type metamaterials are such type of material which has only one material parameter negative [3, 5]. It can be epsilon negative ($\varepsilon < 0$) but mu positive ($\mu > 0$) or mu negative ($\mu < 0$) while epsilon is positive ($\varepsilon > 0$). The Epsilon negative SNG materials are usually called ENG (Epsilon Negative) and mu negative materials are called MNG (Mu Negative). Using ENG-MNG multilayer periodic structure [6, 7], we can obtain a photonic band gap which is called Spatially Averaged Single Negative (SASN) band gap [8]. Unlike Bragg band gap [9], SASN band gap originates from the interaction of evanescent waves in the MNG and ENG media [8]. Due to the localization of the field at the interfaces, zero effective phase gap [7] is robust against disorder, independent of scaling and incident angle and has same PBG for both TE and TM polarization [6-11]. SASN band gap [8] is the sub-wavelength version of the zero effective phase band gap [7]. Because SNG PC thickness does not need to be quarter wave thick at operating wavelength, it enables us to reduce the device size whereas for devices with other PBGs this is not possible. Besides, by applying the concept of SASN band gap, it is possible to control the band gap and center frequency according to designers will [8, 11]. Such degrees of freedom are not found in conventional Bragg bang gap based optical devices. At a particular frequency, if the spatially averaged permeability ($\sum_i \mu_i d_i$) or permittivity ($\sum_i \varepsilon_i d_i$) of a layered photonic structure becomes zero, there emerges a band edge of SASN band gap [8, 11]. If both of the conditions are met at two different frequencies then there will be a band gap in between those two frequencies [8, 11]. Using that analogy, we have demonstrated quantum mechanical equivalent of SASN band-gap in semiconductor array structure. Interestingly, width of such equivalent band-gaps is also controllable according to designers' will. In addition, it is possible to get perfect tunneling in semiconductor hetero-structure [12], which has been shown recently. But in multi-layer hetero-structures (array of hetero-structure), such perfect tunneling is counterintuitive. In this article, we have shown such a perfect tunneling is also possible from the analogy of zero width electromagnetic band-gap at target perfect tunneling energy. Finally, the multi-layer structure, which has been proposed in this article, can support band gap (but this band-gap is not equivalent SASN band-gap) and perfect tunneling at different energies. This structure can play a key role in future semiconductor device technology obtaining low power logic transistors with high on-off ratio.

II. Schrödinger - Maxwell analogy and equivalent SASN band-gap in semiconductor

It is somewhat interesting to notice that Schrödinger and Maxwell equations are analogous [12] for some situations. The Schrödinger and Maxwell equations are as follows-

$$\frac{\delta}{\delta z}\begin{bmatrix} E_x \\ H_y \end{bmatrix} = \begin{bmatrix} 0 & i\omega\mu \\ i\omega\varepsilon & 0 \end{bmatrix}\begin{bmatrix} E_x \\ H_y \end{bmatrix}, \tag{1}$$

and

$$\frac{\delta}{\delta z}\begin{bmatrix} \psi \\ \frac{-i\hbar}{m}\frac{\delta\psi}{\delta z} \end{bmatrix} = \begin{bmatrix} 0 & i\frac{m}{\hbar} \\ 2i\frac{(E-V)}{\hbar} & 0 \end{bmatrix}\begin{bmatrix} \psi \\ \frac{-i\hbar}{m}\frac{\delta\psi}{\delta z} \end{bmatrix}. \tag{2}$$

Clearly, we can see an analogy can be drawn from the equations. The analogies are as follows-

$$E_x \to \psi \qquad \mu \to m \qquad \varepsilon \to 2(E-V) \qquad \omega \to 1/\hbar\,. \tag{3}$$

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

From this analogy, we can assume that, may be, we can find an analogous condition of electromagnetic SASN band gap [8,11] in quantum mechanical domain. The conditions for the quantum mechanical equivalent of the SASN band gap would be -

$$\sum_i m_i d_i = 0 \quad \text{and} \quad \sum_i 2(E - V_i)\cdot d_i = 0, \tag{4}$$

at two different target energy values. We have also derived the condition for band edge analytically. For an infinite periodic quantum mechanical structure ($N \to \infty$) consisting of 3 layer unit cells (Fig. 1), and as per [15] the dispersion relation of the quantum modes based on the Bloch condition would be

$$\begin{aligned}\cos(Kd) &= \cos(k_1 d_1)\cos(k_2 d_2)\cos(k_3 d_3)\\ &-\frac{1}{2}\left(\frac{k_2 m_3}{k_3 m_2}+\frac{k_3 m_2}{k_2 m_3}\right)\cos(k_1 d_1)\sin(k_2 d_2)\sin(k_3 d_3)\\ &-\frac{1}{2}\left(\frac{k_1 m_3}{k_3 m_1}+\frac{k_3 m_1}{k_1 m_3}\right)\sin(k_1 d_1)\cos(k_2 d_2)\sin(k_3 d_3)\\ &-\frac{1}{2}\left(\frac{k_1 m_2}{k_2 m_1}+\frac{k_2 m_1}{k_1 m_2}\right)\sin(k_1 d_1)\sin(k_2 d_2)\cos(k_3 d_3),\end{aligned} \tag{5}$$

where $K_i = \sqrt{\frac{2m_i(E - V_i) - K_{||}^2}{\hbar^2}}$, m_i is the effective mass of the electron within a particular media, d_i is the thickness of a particular quantum layer, $d = d_1+d_2+d_3$, and V_i is the potential energy of the electron in a particular quantum layer, E is the total energy of the electron, and $K_{||}$ is the parallel component of the electron wave vector. In the sub-wavelength limit i.e., $k_i d_i \ll 1$, one can expand $\cos(k_i d_i)$ and $\sin(k_i d_i)$ in Taylor series,

$$\begin{aligned}\cos(k_i d_i) &= 1 - \frac{(k_i d_i)^2}{2} + O((k_i d_i)^2),\\ \sin(k_i d_i) &= k_i d_i + O(k_i d_i).\end{aligned} \tag{6}$$

Substituting (6) into (5) and neglecting the higher order terms, the dispersion relationship can be simplified as-

$$\begin{aligned}\cos(Kd) &= 1 - \frac{(k_1 d_1)^2}{2} - \frac{(k_2 d_2)^2}{2} - \frac{(k_3 d_3)^2}{2}\\ &-\frac{1}{2}\left(\frac{k_2 m_3}{k_3 m_2}+\frac{k_3 m_2}{k_2 m_3}\right)k_2 d_2 k_3 d_3 - \frac{1}{2}\left(\frac{k_1 m_3}{k_3 m_1}+\frac{k_3 m_1}{k_1 m_3}\right)k_1 d_1 k_3 d_3\\ &-\frac{1}{2}\left(\frac{k_1 m_2}{k_2 m_1}+\frac{k_2 m_1}{k_1 m_2}\right)k_1 d_1 k_2 d_2.\end{aligned} \tag{7}$$

It is obvious that the band gap occurs at the position where $\cos(Kd) = 1$. The gap edges appear as (also see [16]) :

$$\begin{aligned}&\frac{(k_1 d_1)^2}{2} + \frac{(k_2 d_2)^2}{2} + \frac{(k_3 d_3)^2}{2} + \frac{1}{2}\left(\frac{k_2 m_3}{k_3 m_2}+\frac{k_3 m_2}{k_2 m_3}\right)k_2 d_2 k_3 d_3\\ &+\frac{1}{2}\left(\frac{k_1 m_3}{k_3 m_1}+\frac{k_3 m_1}{k_1 m_3}\right)k_1 d_1 k_3 d_3 + \frac{1}{2}\left(\frac{k_1 m_2}{k_2 m_1}+\frac{k_2 m_1}{k_1 m_2}\right)k_1 d_1 k_2 d_2 = 0.\end{aligned} \tag{8}$$

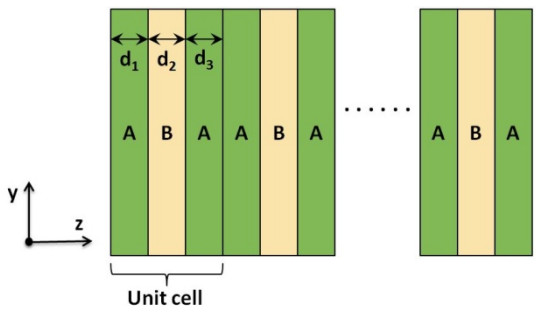

Fig. 1 Schematic drawing of 1D photonic crystal structure Here, $Hg_{0.85}Cd_{0.15}Te$ is the background material (first and last medium).

Solving this equation assuming no parallel component of the electron flux yields exactly the same condition that we drew from the analogy (also see [16] : Type-A structures for analogous electromagnetic conditions of Eq (4) given in this article).

Now we shall use this analogy to predict the band edge energy at which our semiconductor super lattice will show no electron transmission. Of course, just like SASN band gap [8, 11], our semiconductor equivalent band gap only works in sub wavelength regime. This means, the wavelength of the electron wave within the super lattice should be greater than the thickness of our unit cell. In this work, we have used $Hg_{1-x}Cd_xTe$ ternary alloy as our material which has zinc blend structure [13]. At different layers, we have used different mole fractions. The reason of using this II-VI semiconductor hetero-structure is that it is a narrow band gap material. Hence, its mole fractions can be changed to yield inverted band structure which yields negative effective mass within the material [13]. We have calculated the transmission coefficient of the envelop function using Kane model. This material has energy dependent effective mass. The effective mass is related to the energy by the following relation [14,15]-

$$\frac{1}{m} = \frac{2P^2}{3}\left[\frac{2}{E - E_{\Gamma_8}} + \frac{1}{E - E_{\Gamma_7}}\right], \tag{9}$$

Here, E_{Γ_7} and E_{Γ_8} are respectively the band edge energy of the Γ_7 and Γ_8 bands. The quantity,

$$\begin{aligned}P &= \frac{-i}{m_0}\langle S|\frac{\hbar}{i}\frac{\partial}{\partial x}|X\rangle = \frac{-i}{m_0}\langle S|\frac{\hbar}{i}\frac{\partial}{\partial y}|Y\rangle\\ &= \frac{-i}{m_0}\langle S|\frac{\hbar}{i}\frac{\partial}{\partial z}|Z\rangle,\end{aligned} \tag{10}$$

Which is the element of the Kane matrix, where $|S\rangle$, $|X\rangle$, $|Y\rangle$ and $|Z\rangle$ are respectively S-like and P-like Eigen functions for $K = 0$. For semiconductors with a zinc blende structure, the effective potential V can be assumed energy independent, and is equal to $V = E_c$, where $E_c = E_{\Gamma_7}$ is the conduction band (S-type symmetry) edge energy.

For simulation, we have chosen $Hg_{0.73}Cd_{0.27}Te$| $Hg_{0.92}Cd_{0.08}Te$| $Hg_{0.73}Cd_{0.27}Te$ unit cell. The parameters needed for calculating the envelope function can be obtained from reliable measurements or from first principle calculations which suggest $2m_0P^2 \approx 18.5$ eV, $E_{\Gamma_6} = (1.47x + 0.008)$ eV, $E_{\Gamma_7} = (-0.36x + 0.36)$ eV, and $E_{\Gamma_8} = (-0.36x - 0.59)$ eV where x represents the $Hg_{1-x}Cd_xTe$ mole fraction [12].

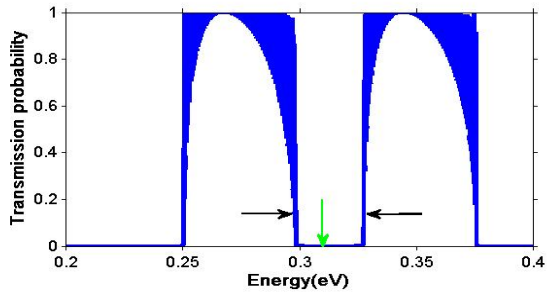

Fig. 2 Transmission Probability vs. energy graph for $Hg_{0.73}Cd_{0.27}Te|$ $Hg_{0.92}Cd_{0.08}Te|$ $Hg_{0.73}Cd_{0.27}Te$ system. The $\sum_i m_i d_i = 0$, condition is met at 0.29eV (left arrow) and the $\sum_i 2(E - V_i)d_i = 0$, condition is met at 0.33eV (right arrow). Here 100 unit cells have been cascaded and dimensions are - $d_1 = 5nm, d_2 = 10nm, d_3 = 5nm$.

We have chosen this material combination to meet the SASN condition and have found band gap at our predicted energy range (Fig. 2). Fig. 2 shows that electronic states cannot exist in between 0.29eV and 0.33eV. So the electrons having the energy in between this energy range cannot propagate through our semiconductor super lattice. From Fig. 3, we can see that the probability wave associated with the energy of 0.31eV (vertical arrow, Fig. 2), which lies in the forbidden region decays exponentially when it penetrates the super lattice.

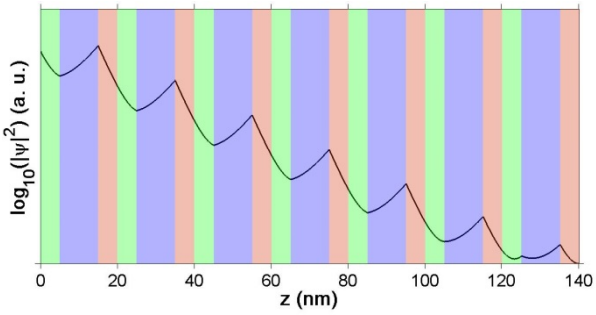

Fig. 3 Amplitude of the envelope function (arbitrary units) within the designed semiconductor heterostructure (seven unit cells has been used).

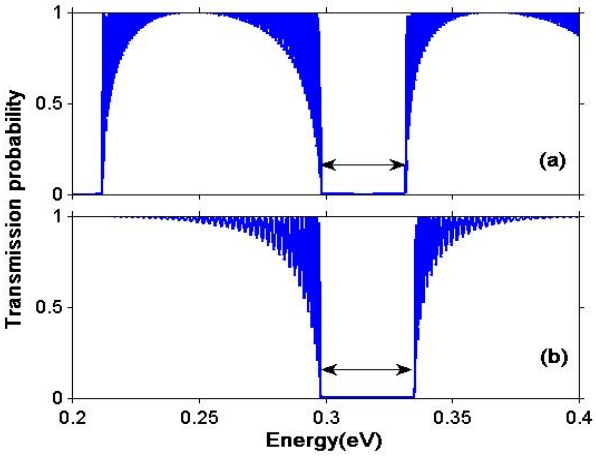

Fig. 4 Lattice constant is scaled by 0.7 (a) and 0.4 (b) for the $Hg_{0.73}Cd_{0.27}Te|$ $Hg_{0.92}Cd_{0.08}Te|$ $Hg_{0.73}Cd_{0.27}Te$ system. The results clearly demonstrate the scaling independent nature of SASN band gap.

Another interesting property of this band gap is- unlike Bragg band gap, it is independent of scaling. Different scaling factors have been employed on our previous design. Still the band gap remained almost same (Fig. 4). Besides it is also possible to vary the zero effective phase gap by varying the ratio of the layer thicknesses in a very controlled and desired way (see Fig. 5)

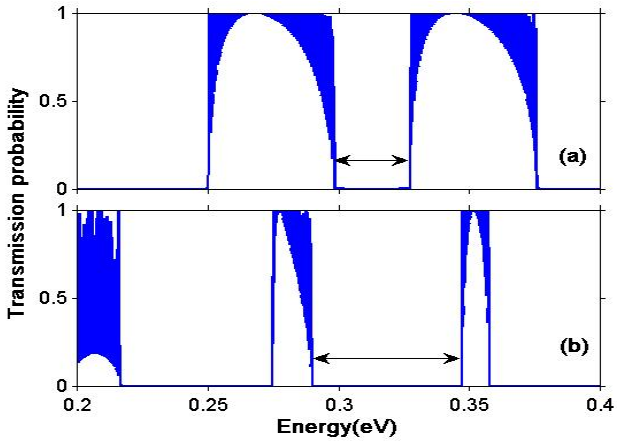

Fig. 5 Layer thickness d_1/d_2 has been changed from 0.5 (a) to 1.0 (b) for the $Hg_{0.73}Cd_{0.27}Te|$ $Hg_{0.92}Cd_{0.08}Te|$ $Hg_{0.73}Cd_{0.27}Te$ system. Variation in the band gap has been obtained by changing the thickness ratio.

III. BANDGAP AND PERFECT TUNNELING IN THE SAME STRUCTURE

It is possible to get perfect tunneling in semiconductor hetero-structure [12], which has been shown recently. But in multi-layer hetero-structures (array of hetero-structures), such perfect tunneling is counterintuitive. Now we shall demonstrate that such a perfect tunneling is also possible at perfect tunneling energy for our array structure, which means transmission probability of electron through the crystal is 100%. Our designed structure has CdTe| HgTe| CdTe sub-wavelength unit cell. When the unit cell is repeated 100 times, we still found perfect tunneling at 0.34eV for which two different conditions in Eq (4) of this article has been applied at single target energy instead of two different energy values (Fig. 6) (also see the condition of perfect tunneling of electromagnetic wave for Type-A unit cells in [16]). Then simply a question arises: how such a perfect tunneling is possible in a multi-layer structure. The answer lies with the idea of Type-A electromagnetic unit cell reported in [16]. Recently, we have shown that such unit cells support perfect tunneling just at the target frequency even if they are used to make an array structure [16] (specially for normal incidence of light) . In addition, it has been observed that electromagnetic wave does not gain any phase shift at the target perfect tunneling frequency for normal incidence in absence of loss [16]. The detail quantum mechanical behavior and physical insights of similar kind of unit cells (not multi-layers) have been rigorously investigated in semiconductor regime in [17]. But the most probable explanation of such perfect tunneling in multi-layer semiconductor hetero-structure (array of unit cells) for ballistic electron is that: at perfect tunneling target energy, the electron wave behaves like photon (canonical or wave nature of photon proposed by Barnett et al. [18]) instead of particle nature and it shows perfect tunneling at normal incidence due to the two matching conditions of Eq (4) satisfied at a single energy. Instead of opening a band gap, at that single target energy, the probability wave will pass through our structure as if the multi-layer super-lattice wasn't even there. According to the band-gap theory of array structures, a more rigorous physical explanation can be drawn [19] in favor of our proposal. The statement reported in [19] : " ….. which

results $K_{BZ} = 0$. The latter quantity assures that the wave is restored after passing through the crystal" is true only for the target frequency for Type-A electromagnetic array structures. K_{BZ} is the Bloch wave vector reported in [19]. That idea of zero width band gap [19] most probably remains valid also for semiconductor hetero-structures at the target energy and hence for ballistic electrons, such perfect tunneling may occur at that energy (see Left side of Eq (7) in this article). We have also plotted the envelope function at the energy of 0.34eV (Fig. 7). The envelope function shows that the input and output wave function has the same amplitude which proves our claim. We can also see from the graph that there is a strong delocalization of electronic states at the interface of equivalent MNG-ENG.

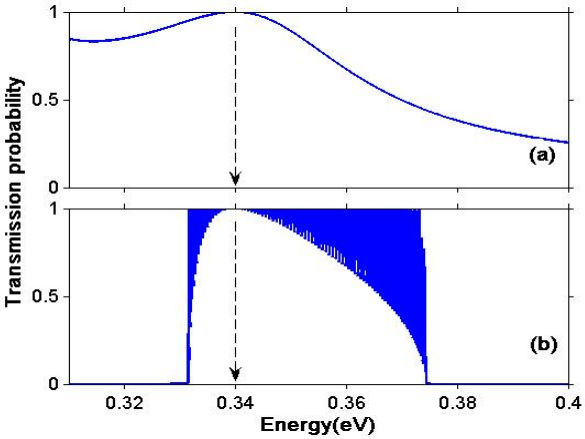

Fig. 6 Transmission probability of electron through CdTe| HgTe| CdTe sub-wavelength unit cell (a) and 100 cascaded unit cells (b). Perfect tunneling is achieved at 0.34eV when two conditions of Eq (4) are applied at that specific energy. Here 100 unit cells have been cascaded and dimensions are - $d_1 = 1.26nm, d_2 = 10nm, d_3 = 1.26nm$. It is important to note that the band gap found in this structure (Fig. 6b) is not the equivalent SASN band-gap that we have proposed in this article. The band-gaps of this multi-layer structure have opened naturally due to repeated array of unit cell hetero-structures.

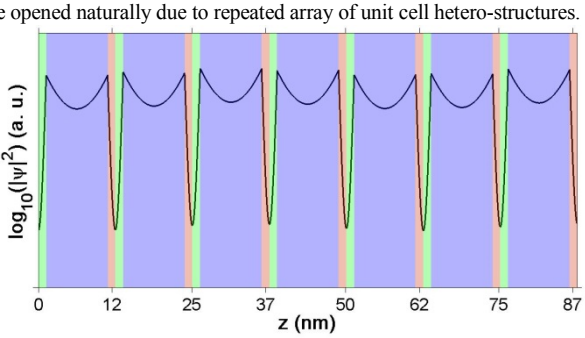

Fig. 7 Envelope function (arbitrary units) for 10 unit cells at perfect tunneling energy (0.34eV)

This perfect tunneling phenomenon (with band-gap) can have significant impact on device technology. High on-off current ratio is always wanted in CMOS technology. Graphene transistors are not considered as logic transistor because of low on-off ratio [20] although having better transport capabilities. Our proposed device shows a steep transition in transmission probability (Fig. 6) which may play a key role in obtaining high on-off ratio even if the applied energy is very low.

IV. Conclusion

We have shown the Maxwell-Schrodinger analogy to import the idea of electromagnetic SASN band gap to quantum mechanical domain as the major contribution of this work. We have successfully demonstrated that the quantum mechanical band gap can be engineered according to designers will and this band gap is independent of scaling given that the sub-wavelength condition remains valid. Moreover, our proposed multi-layer structure is capable of showing perfect tunneling of probability wave (ballistic electron has been considered) through the hundreds of layers even though the wave function is decaying in individual layers. We have also shown strong localization of electrons near interfaces. As the on-off ratio (step transition from low transmission to high transmission) is very high even if the applied energy is very low, this kind of tunneling structures can be very useful as future low power electronic device and logic transistor.

Abstract—**We presented improved density and aspect ratio of ZnO nanowires which were hydrothermally grown on spin coated ZnO seed layer. After UVO treatment on silicon surface, spin coated ZnO seed layer showed a high coverage density due to increased surface wettability without forming island like growth in conventional method. ZnO active nucleation sites showed a positive increasing relation with increase in coverage density. Whereas, increased spin coating time had risen surface roughness with rise in coverage area, UVO treated surface wettability change had showed lower surface roughness. Moreover, seed layer thickness remained unaffected for surface wettability changing effect. This let ZnO nanowires grow on the increased ZnO active nucleation sites without hindrance of other nanowires. Hence, higher density and aspect ratio ZnO nanowires were achieved by controlling surface wettability via UVO treatment.**

Index Terms—**ZnO seed layer, ZnO growth, UVO treatment, Surface treatment, Surface wettability.**

I. Introduction

Zinc oxide (ZnO) has attracted much attention during the past decade owing to its applicability as building blocks in numerous electronic, optic and photonic devices [1]-[3]. Being an ample, nontoxic and II-VI semiconductor material, it provides high electron mobility, wide band gap energy (3.3 eV), high exciton binding energy (60 meV) and large piezoelectric coefficient [4], [5]. Especially, in nanoscale extent, ZnO nanowires or nanostructures provide several important chemical and physical properties due to its high aspect ratio and growth density [1]. Therefore, it has showed significant performance in advanced applications like gas sensors, chemical sensors, light emitting diodes, photodiodes, solar cells, piezoelectric devices and so on [6]-[12]. Several growth methods for ZnO nanowires have been developed like pulsed-laser deposition (PLD), chemical vapour deposition (CVD), vapour-phase transport (VPT), thermal evaporation, electrode deposition and so on [6]-[17]. However, costly apparatus and complex processes with high working temperature have made these techniques tough to implement for industrial production. Instead, hydrothermal method offers facile operating technique in low temperature with low cost simplest apparatus, thus it is regarded as much compatible method for large scale production [18].

However, ZnO seed layer plays a vital role for ZnO nanowires growth in hydrothermal method. ZnO nanowires grow on ZnO active nucleation sites presented in seed layer in accordance with their crystallinity [19]. Uniformity, coverage area and thickness of seed layers need to be optimized for better growth of ZnO nanowires. In conventional method, with increased time spin coating to increase seed layer coverage area and ZnO active nucleation sites, surface roughness and thickness is also increased which ultimately results in lower density and aspect ratio ZnO nanowires growth [20]. In this study, we introduced controlled surface wettability via UVO treatment to enhance coverage area and density of ZnO active nucleation sites without affecting seed layer surface roughness and thickness.

Although, surface wettability change has been applied to enhance various applications of ZnO, but it has not been implemented to control ZnO seed layer growth in hydrothermal method. Furthermore, ultraviolet ozone (UVO) treatment has already verified itself as a well-established surface treatment method to change surface wettability in low cost approach besides cleaning the surface via vacuum cleaning process [21]. Previously, works like ECR plasma treatment effect on ZnO nucleation by atomic layer epitaxy method, effect of UVO treated seed layer on ZnO nanowire growth, UVO and self-assembled monolayers for patterned growth of ZnO nanowires had been conducted, but no work had investigated surface wettability changing effect on ZnO seed layer and nanowires growth using UVO treatment in hydrothermal method [22]-[24].

In this work, UVO treated surface wettability changing effect on spin coated ZnO seed layer growth was explored. Furthermore, its consequence on hydrothermally grown ZnO nanowires was examined as well.

II. Experimental Procedure

ZnO nanowires were grown on silicon substrate in hydrothermal method. Silicon substrate was first cleaned with acetone, isopropyl alcohol (IPA) and deionized (DI) water successively in sonic cleaner. Then it was etched in buffered

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

oxide etch (BOE) to remove native oxide layer, afterwards it was UVO treated to change surface wettability and surface energy. For seed growth, the seed solution was prepared using zinc acetate dehydrate ($Zn(CH_3COO)_2.2H_2O$, 30 mM) dissolved in ethanol (50 mL, 99.9%). The seed solution was dropped onto the silicon substrate surface and spin-coated at 850 rpm for 30 sec. It was followed by a soft baking at 80°C. To observe UVO treatment effect on various times spin coating, this spin coating and baking process was done for 1, 3 and 5 times. Afterwards, the spin coated substrates were annealed at 80˚C for 1 hour. After annealing process, ZnO nanowires were formed over the seed layer using aqueous solution consisting of zinc nitrate hexahydrate ($Zn(NO_3)_2.6H_2O$, 25 mM), hexamethylenetetramine (25 mM) and DI water. The ZnO nanowires were grown using sample dipping method. The spin coated samples were suspended vertically in the solution for 3 hours at 92˚C for the final growth of the ZnO nanowires.

Contact angle measurement equipment (KRUSS DSA100) was used to check the contact angle as well as surface wettability for different UVO treatment time. Energy dispersive x-ray spectroscopy (EDX) was used to characterize ZnO active nucleation sites in the seed layer depending on spin coating time and UVO treatment. Field emission scanning electron microscope (FE-SEM) (Hitachi S4800) was used to characterize the growth density and aspect ratio of ZnO nanowires.

III. Result and Discussion

A. *Effect of UVO Treatment and Spin Coating Conditions on Seed Layer*

The silicon substrate surface was UVO treated to control surface wettability. Before UVO treatment, silicon substrates were etched with BOE which removed the native oxide layer over silicon substrate surface and grew SiH or SiH_2 groups over it. The ozone presented in UVO treatment had reacted with hydrogen sited over the silicon substrate surface and converted it into hydroxyl group [21], [25]. This hydroxyl group attracted water molecules and increased surface wettability as well as surface energy [21], [25], [26].

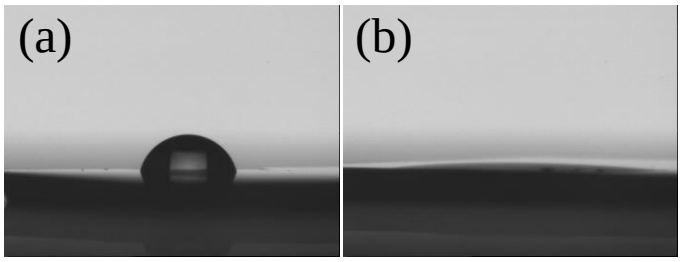

Figure 1. Effect of UVO treatment on silicon substrate surface wettability: (a) etched sample with no UVO treatment (water contact angle: 78˚), (b) etched sample with 540 second UVO treatment (water contact angle: <1˚).

Initially, Surface wettability changed rapidly with UVO treatment, but slowed down gradually with increased surface wettability by more UVO treatment time as shown in Fig. 1.

ZnO seed layer growth was enormously enhanced with surface wettability change via UVO treatment. The presence of extra hydroxyl group over the silicon substrate surface attracted zinc ions of the seed solution and bind them on the surface. Thus more ZnO nucleation sites were created. This would be comprehended with EDX images of Fig. 2, as dense active nucleation sites were observed in the seed layer of UVO treated substrate surface in each case of different time spin coating. The inside of this phenomena could be explained with the following seed solution reaction mechanism [28]:

$$Zn(CH_3COO)_2 \,.\, 2H_2O + 2CH_3\text{-}CH_2\text{-}OH \longrightarrow ZnO + 2CH_3\text{-}CH_3\text{-}CH_2\text{-}CO + 3H_2O \quad (1)$$

In this substitution reaction, hydroxyl group from ethanol replaced acetate group of zinc acetate and formed zinc oxide. In our case, extra hydroxyl group sited over the silicon substrate via UVO treatment reacted with the seed solution. This correspondingly forwarded the reaction and produced more ZnO active nucleation sites in the seed layer for each case of spin coating time. Additionally, with increased surface wettability, seed solution was moderately spread over the surface during spin coating, that ultimately increased interaction with hydroxyl group presented in the surface and produced moderate seed layer all over the surface. That resulted in continuous thin film growth for each case of spin coating time.

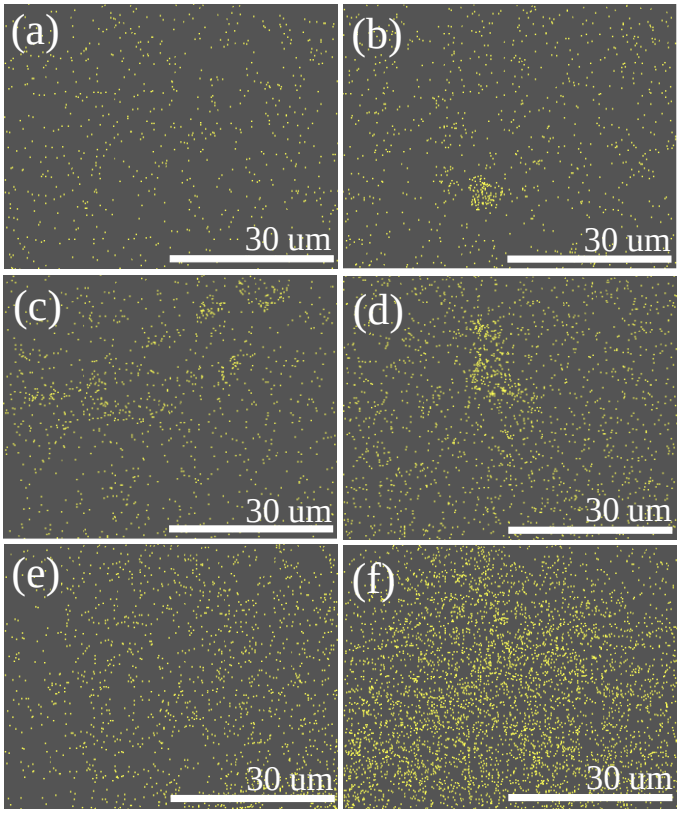

Figure 2. EDX images showing relative position of ZnO seed layer active nucleation sites with different UVO treatment and different times spin coating: (a), (c), (e) are 1, 3 and 5 time spin coated samples with no UVO treatment respectively and (b), (d), (f) are 1, 3 and 5 times spin coated samples with 540 second UVO treatment.

However, in seed growth without UVO treatment, seed layer was not uniformly distributed throughout the surface, rather island like growth was observed. With increased time spin coating, this island area and thickness were increased. However, ZnO active nucleation sites were also increased as shown in Fig.2. Therefore, with increased time spin coating, seed layer growth covering whole surface area would be achieved but would be accompanied by higher seed layer surface roughness and thickness [20].

In accordance with this phenomenon, it was confirmed by the AFM images that, with increased time spin coating,

surface roughness was increased, but UVO treated surface wettability change had lowered surface roughness. Furthermore, thickness of the seed layer was unchanged with change in surface wettability. This would remove the influence of other nanowires in growth process of each nanowires in its neighborhood, which would ultimately result in higher density and aspect ratio ZnO nanowires growth [20].

B. ZnO Nanowires Growth Dependence on Seed Layer

Change in the properties of ZnO seed layer actively affected ZnO nanowires growth in hydrothermal method. As shown in Fig. 3, uniformly distributed high density growth of ZnO nanowires all over the substrate surface were achieved for each case of spin coating by changing surface energy using UVO treatment. This was due to uniformly distributed growth of ZnO seed layer and active nucleation sites for change in surface wettability. In contrast, without UVO treatment, island like growth of ZnO nanowires were observed according to seed layer growth for various time spin coating.

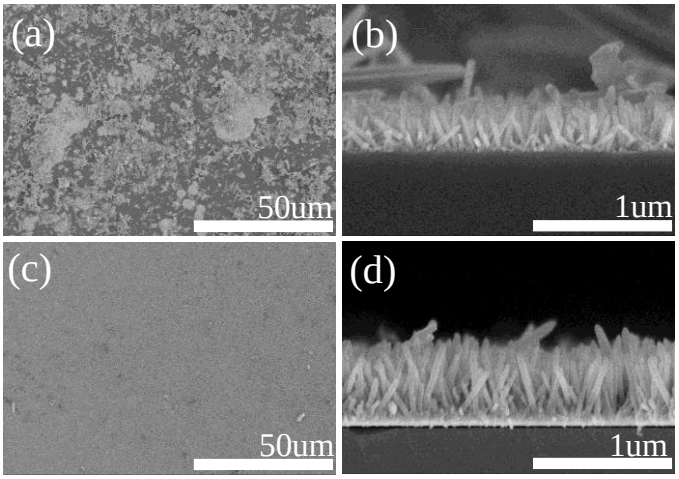

Figure 3. SEM images of ZnO nanowires growth showing effect of UVO treatment, (a),(b) surface and cross section of ZnO nanowires growth at 3 time spin coating with no UVO treatment and (c),(d) surface and cross section of ZnO nanowires growth at 3 time spin coating with 540 second UVO treatment.

However, Fig. 4(a) and Fig. 4(b) respectively shows change in density and aspect ratio of as grown ZnO nanowires at different conditions. Density was uniformly increased with change in surface wettability for 1 time and 3 times spin coating, but drastic negative change was observed in case of 5 times spin coating. This was because, increased surface roughness had produced more thick ZnO nanowires which was directly affected by enriched ZnO active nucleation sites of increased time spin coated thick seed layer. Each nanowire growth was affected by nearby nanowires that resulted comparatively bad crystalline, high diameter nanowires. Additionally, 5 times spin coating with and without UVO treatment results were almost same, because higher time spin coating had produced seed layer covering almost whole surface area of the silicon substrate as achieved in surface wettability controlled growth. But in case 1 time or 3 times spin coating, the uniformly distributed seed layer with moderate roughness and distributed ZnO active nucleation sites with surface wettability change, enabled nanowires to grow without hindrance from other nanowires in the vicinity. Thus higher density nanowires growth was achieved with precise surface wettability.

Moreover, aspect ratio of ZnO nanowires was always increased with surface wettability change via UVO treatment. As shown in Fig. 4(b), a highest 30% increase of aspect ratio was observed for surface wettability change in case of 3 times spin coating. Well crystalline uniform growth of seed layer over the surface resulted this phenomenon. Additionally, 5 times spin coated with and without UVO treated substrates showed almost same density, but aspect ratio was greatly enhanced. It was because, with increased time spin coating, although seed layer covered whole surface area, but its surface roughness was drastically increased, on the other hand, UVO treated sample had lower surface roughness that resulted in higher aspect ratio growth. Moreover, the uniformly distributed seed layer active nucleation sites by lower surface roughness removed interference of other nanowires during growth process. This enhanced the ZnO nanowires growth process and higher aspect ratio nanowires were formed.

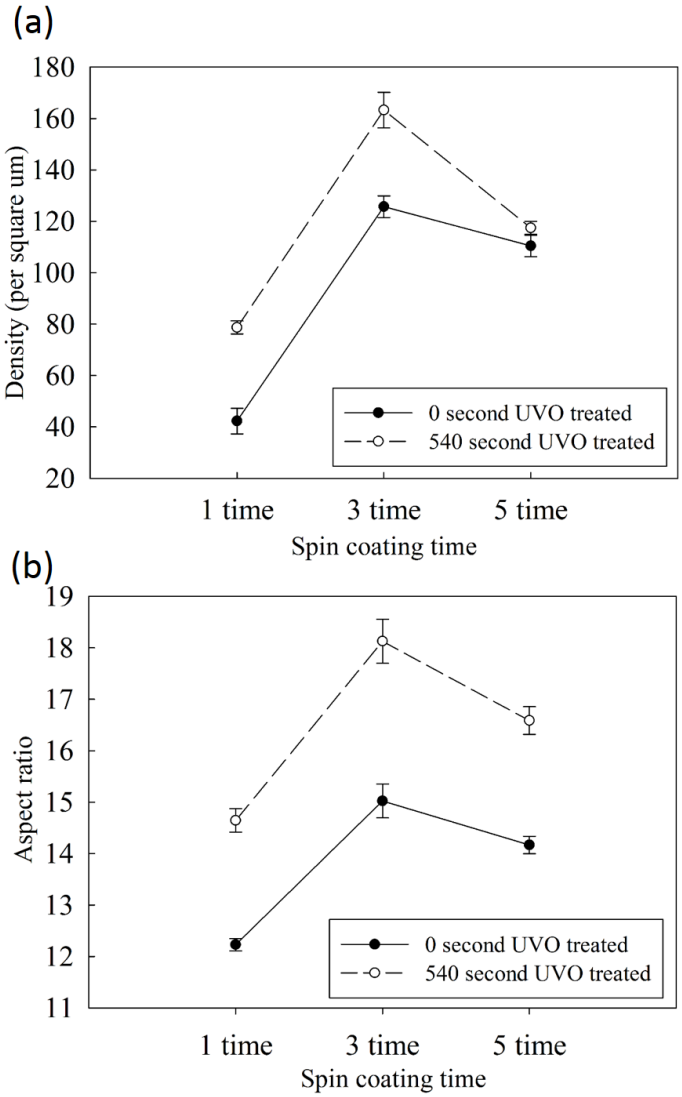

Figure 4. UVO treatment surface wettability changing effect on ZnO nanowire growth at different spin coating time; (a) effect on growth density, (b) effect on growth aspect ratio.

IV. CONCLUSIONS

UVO treated controlled change in surface wettability positively and significantly affected ZnO nanowires growth. Interaction between the extra hydroxyl group formed over the silicon substrate during UVO treatment and ZnO seed solution had produced uniformly distributed seed layer all over the

surface in each case of spin coating time. It had produced moderately distributed extra ZnO active nucleation sites in seed layer. Most importantly, seed layer surface roughness was enhanced that ultimately resulted in uniformly distributed higher density and aspect ratio ZnO nanowires growth covering the whole surface of the silicon substrate. Furthermore, we have been investigating its applicability for patterned growth in low cost hydrothermal method. Therefore, optimized spin coating time with UVO treatment would be very useful for large scale practical implementation in elementary and industrial applications.

***Abstract*—Electronic solders are widely used for making interconnections between the electronic chips with the circuit board. The substitution of traditional Lead bearing solders is one of the key challenges to the electronic industries in the current drive for eco-friendly manufacturing. In the present study, Ni powder is added with Zn to investigate the effect of Ni on the microstructural, mechanical and electrical properties of the newly developed solder composites. The microstructures of the Ni/Zn solder composites were composed of pure Zn and Ni-Zn δ phase. Addition of Ni causes to increase the hardness of Zn and keeps the electrical resistivity unchanged.**

***Index Terms*—Pb-free solder, Ni/Zn composite, microstructure, micro-hardness, electrical resistivity etc.**

I. Introduction

In these days, the development of Pb-free solders has become an important issue for electronic interconnection materials because of the health and environmental safety concerning lead usage [1-3]. Pb-free solder systems that have been disclosed in the literature include Sn-based [4-5], Au-based [6-7], Bi-based [8-9] and Zn-based [10-17] alloys. Moreover, the tendency for miniaturization of the electronic devices causes to higher heat flux dissipation and thus requires the solder materials which have a melting temperature higher than 300^0C [3].

Among the several systems Zn-based solders have a lot of prospects due to its competitive price and mechanical properties. The effect of the addition of Al, Cu, Sn, Ca, Mg, Cr and Ti is reported so far [10-17]. Zn-Sn alloys show a much improved ductility compared to other Zn-based alloys, excellent electrical properties and oxidation resistance at high temperature and humidity [13]. Though it has an eutectic composition of 85wt.% Sn at 199˚C, but it can withstand multiple reflows of up to 260 ˚C. In these days, Zn-Al alloys are used to join Al structures [10]. Zn-Al phase diagram shows only one eutectic point with a composition of 6wt.% Al at 381˚C. The high oxygen affinity of these alloys with low wettability is the only drawback [11]. Addition of Cu, Mg, Ga and In as third element in Zn-Al binary system has been investigated [15-17]. Zn–Al–Cu solder alloys showed a reasonable electrical resistivity and spreadability making them suitable for electronic applications [15]. Zn–4Al–3Mg–3Ga shows solidus and liquidus at 309˚C and 347˚C respectively [16]. Good die-attaching with a small amount of voids was achieved at 320˚C or higher in the die-attaching test.

The lifetime of electronic devices depends on the reliability of a solder. It is important for a solder to match the coefficient of thermal expansion, have a high elastic modulus, hardness, yield strength and shear strength together with resistance to corrosion, fatigue and creep [2]. Studies have shown that forming a composite by adding an appropriate second phase particles, of ceramic, metallic or intermetallic is a potentially viable and economically affordable approach to improve the mechanical properties of a solder matrix. In previous research, the control of solderability by the formation, presence and growth of the second phase has been proposed by Guo et al. [18].

So far, the composites of Sn-based [29-32] and Bi-based [33] Pb-free solders are reported. Gain et al. found that the shear strengths and hardness of solder joints containing higher percentage of Ni nano-particles added Sn–9Zn and Sn-8Zn-3Bi exhibited consistently higher value than those of plain solder joint due to control of the fine microstructure as well as homogeneous distribution of Ni nano-particles [19]. Tama et al. [20] and Ahmed et al. [21] found the similar result for $Al_2O_3$and Ag nano-particles added eutectic Sn–9Zn composite solders. Shen et al. [22] successfully prepared a ZrO_2 reinforced composite solder by mechanically dispersing ZrO_2 particles into a eutectic Sn–3.5Ag solder paste, and the composite solders had a refined microstructure with an improved microhardness.

In the present study, different weight percentages of Ni particles were mixed into Zn to prepare Zn/Ni composite solders. The influence of a small amount of reinforcing Ni particles on the microstructural evolution, especially, the morphology and distribution of intermetallic compounds (IMCs) were investigated using metallographic analysis. In addition, the thermal, mechanical and electrical properties of these Zn/Ni composites were measured depending on the content of the reinforcing Ag micro-particles.

II. Experimental

This project aimed to develop high temperature lead-free solder composite. Key materials were commercially available pure Zn (99.99%) and Ni Powder (size < 10 μm, M = 58.71

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

g/mol, Purity > 99.5%, E Merck, Germany). Three different amounts of Ni powders were added to Zn, i.e. 0.20, 0.30 and 0.40 wt.% Ni. In this paper pure Zn, 0.20Ni/Zn, 0.30Ni/Zn and 0.40Ni/Zn (wt.%) composites are referred as 2NZ, 3NZ and 4NZ respectively.

A batch weighing 1.5 kg was cast in each time. Depending upon the composition the amount of raw materials for mixing varied as that of Table I. The constituent elements were melted in a gas fired pit furnace and homogenized at ~530°C. The melts were then poured in a steel mold to prepare the chill cast ingot. The schematic diagram of the cast product is shown in Fig. 1. Our aim was to keep the mould preheat temperature to 210 ± 10°C and the superheat temperature of the molten metal at 120 ± 10°C. The heating parameters that were controlled for casting is listed in Table IIIII.

TABLE IV

AMOUNT OF RAW MATERIALS USED (IN GRAMS)

Sample	Zn	Ni
Z	1496	-
2NZ	1490	2.98
3NZ	1560	4.76
4NZ	1590	6.42

The as-cast solders were sectioned and polished according to non-ferrous metallography with 0.5 µm Al_2O_3 particles in order to obtain the microstructure. After cleaning with acetone, the samples were investigated by an optical microscope with digital camera (LEICA-MZFLIII, Italy).

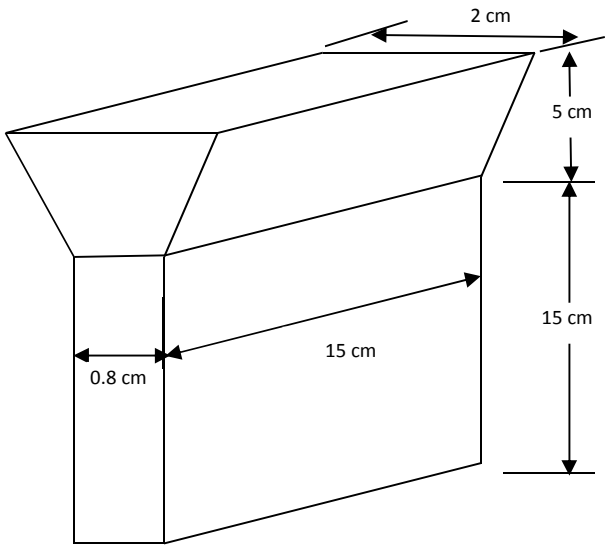

Figure 1: Showing the schematic diagram of the casting with dimensions.

Grinding and polishing were necessary to obtain polished, smooth and flat parallel surface before indentation testing. Thus, the polished samples were placed in a Vickers micro-hardness tester (FV-800, FUTURE-TECH, Japan) to measure the micro-hardness. The applied load was 10 kg for 10 s and at least 10 readings of different indentation were taken at room temperature to obtain the mean value.

TABLE VVI

HEATING PARAMETERS USED FOR CASTING

Samples	Z	2NZ	3NZ	4NZ
Mould Preheat Temperature (°C)	220	219	213	211
Pouring Temperature (°C)	536	534	530	540
Solidus Temperature (°C)	419	419	418	419
Superheat Temperature (°C)	117	115	112	121

In order to reveal the electric resistivity of the composites, solid blocks of 30 mm x 30 mm x 6 mm was prepared. The surfaces of the blocks were then grinded and polished. The electrical resistivity of the samples was measured by electric conductivity meter (with digital display), type 979, Technofour, India.

III. RESULTS AND DISCUSSIONS

A. *Microstructural Analysis*

Fig.2 shows the optical micrographs of NZ samples at magnification of 500X. Fig. 2 (a) shows the presence of pure Zn grains with some pores. Fig. 2 (b) proeutectic Zn phase in a matrix of eutectic (pure Zn + Ni-Zn δ) in 2NZ sample. Fig. 2 (c) shows the evidence of incomplete dissolution of Ni particles in Zn and positioned preferentially at the grain boundaries in the form of a second phase of Ni-Zn δ. There is a certain possibility that the grain boundary particles are affected by compositional variation along the diameter, the indication of coring. Fig. 2 (d) shows the existence of a second phase which is also the evidence of incomplete dissolution of Ni in Zn. It is observable that the complete dissolution of Ni causes to reduce the melting temperature and therefore increases the grain size of Zn. This is due to the longer time of solidification of the proeutectic Zn grains, seen in Fig. 2 (b). Whereas the incomplete dissolution of the Ni particles is responsible for the pinning of the Zn grains at the boundaries and therefore results to the smaller grain sizes in 3NZ sample in Fig. 2 (c). A mixed effect is observed in the case of 4NZ sample in Fig. 2 (d).

B. *Vicker Microhardness Testing*

In Fig. 3 the hardness plot of Vicker's microhardness of the representative samples of Z, 2NZ, 3NZ and 4NZ is shown for general comparison. The evolution of δ-phase is the reason for the higher hardness in the NZ samples as compared to the Z sample. The pinning of the particles at the grain boundaries of Zn is seen in the microstructure 3NZ sample. Whereas lamellar structure of Zn and δ-phase is seen in 2NZ sample and spheroidal δ-phase is seen in the 4NZ sample. As the order of increase of hardness of the samples are Z<3NZ<2NZ<4NZ, we can say that the order of effects are uniphase hardening < grain boundary pinning < eutectic hardening < second phase hardening.

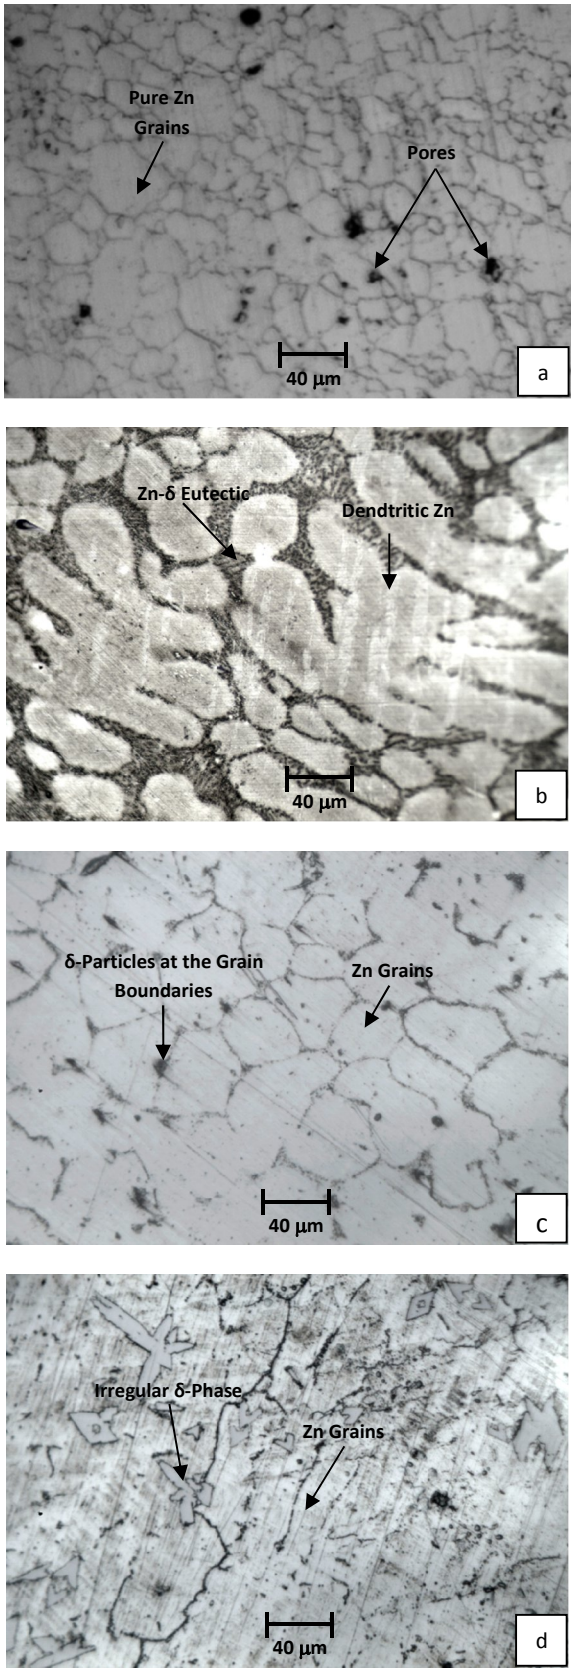

Figure 2: Showing optical micrographs of (a) Z, (b) 2NZ, (c) 3NZ and (d) 4NZ at 500X magnification.

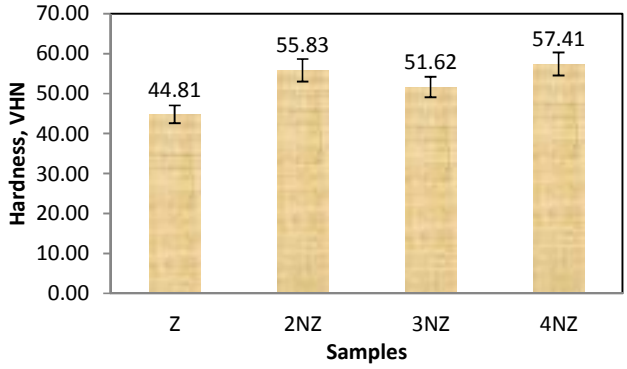

Figure 3: Showing Vicker's microhardness of the NZ samples.

C. *Electrical Resistivity Analysis*

Electrical resistivity of the Z and NZ samples are measured and listed in below (Fig. 4). It is observed that the electrical resistivity of NZ samples is slightly higher compared to the Z sample. Between the NZ samples, 4NZ has the maximum resistivity value of 6.53 µΩ.cm. 2NZ and 3NZ samples has almost equal resistivity value. The higher resistivity of the NZ samples is due the presence of Ni in Zn as δ-phase. As the amount of δ-phase is increased in the order of 3NZ < 2NZ < 4NZ, the order of increasing the electrical resistivity is also 3NZ < 2NZ < 4NZ.

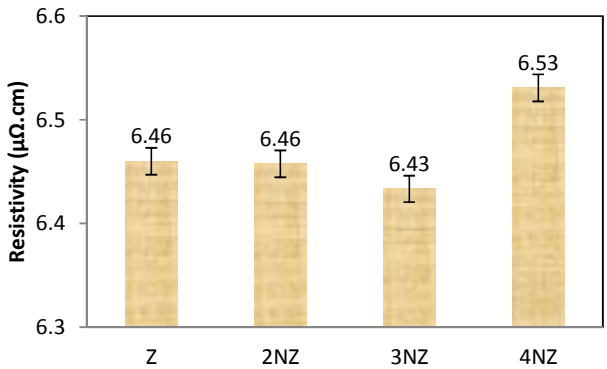

Figure 4: Showing the electrical resistivity of NZ samples.

IV. Conclusions

The results found in this research are concluded as follows:

- Presence of proeutectic Zn phase in a matrix of eutectic (pure Zn + Ni-Zn δ) is identified in the microstructure of 2NZ sample. 3NZ sample shows the evidence of incomplete dissolution of Ni particles in Zn and positioned preferentially at the grain boundaries in the form of second phase particles. Microstructure of 4NZ sample shows the existence of a second phase. As the addition of Ni on Zn causes to reduce the melting temperature, it was expected that the NZ-composites will show the larger grains compared to pure Zn. Pinning of the δ particles at the grain boundaries of Zn causes to the smaller grain size in the 3NZ sample.

- Vicker's Hardness of the NZ samples is higher than the Z sample. Among the NZ samples 3NZ sample has the lowest hardness of 51.62 VHN and 4NZ sample has the highest of 57.41 VHN.
- Between the NZ samples, 4NZ has the maximum resistivity value of 6.53 μΩ.cm. 2NZ and 3NZ samples has almost equal resistivity value 6.4 μΩ.cm. It can be concluded that the effect of addition of Ni on NZ composites are completely dependent on the microstructure.

ACKNOWLEDGMENT

The authors would like to thank the Bangladesh University of Engineering and Technology (BUET) in funding the present research. The authors are highly grateful to the Pilot Plant and Process Development Centre (PP and PDC) of Bangladesh Council for Scientific and Industrial Research (BCSIR) for providing the necessary facilities to carry out the research successfully.

Sensitivity in Polycrystalline HgI_2 X-ray Imagers for Mammography

Farzana Kabir,[1,*] Dewan Fahim Noor,[2] Zubayer Ibne Ferdous[3] and Shaikh Asif Mahmood[4]
[1]Department of Electrical and Electronic Engineering , Bangladesh University of Engineering and Technology
Dhaka-1205, Bangladesh
*orpia.1337@gmail.com

***Abstract*—The sensitivity of polycrystalline HgI_2 (poly-HgI_2) X-ray detector is determined. A generalized expression for charge carrier transport and absorption-limited sensitivity of X-ray photoconductors is derived by analytically solving the continuity equation for both holes and electrons considering the drift of electrons and holes in the presence of deep traps. Sensitivity is studied as a function of varying applied electric field across the photoconductor for both positive and negative bias under mammographic condition. The theoretical model is fitted to the published results for physical vapor deposited (PVD) poly-HgI_2 mammographic detector. The fitted values of the electron and hole ranges are $1.6896 \times 10^{(-5)}cm^2V^{-1}$ and $5.916 \times 10^{(-6)}cm^2V^{-1}$ respectively. Concentration of deep trap for electrons and holes were found out to be $2.6082 \times 10^{13}/cm^3$ and $3.3806 \times 10^{12}/cm^3$ respectively . Effect of decreasing electron and hole lifetime on sensitivity is studied for varying detector thickness for positive bias under mammmographic condition. Under these conditions, deteriorating hole lifetime has much more impact on sensitivity than deteriorating electron lifetime. Presence of an optimum detector thickness has been found at low hole lifetime**

***Index Terms*—X-Ray Sensitivity, Photoconductors, Monoenergetic Beam,Polycrystalline Mercuric Iodide .**

I. Introduction

Polycrystalline mercuric iodide (poly-HgI_2) is a promising photoconductor to be used in direct conversion flat-panel X-ray detectors. One of the main advantages of polycrystalline mercuric iodide is that, it has very low effective work function (W±∼5 eV) compared to other available photoconductors [1][2]. Low effective work function is a desirable property for a photoconductor since it results in higher sensitivity. Another big advantage is that, the effective work function does not depend on applied electric field. Low effective work function, high atomic number and the possibility of large area deposition makes poly-HgI_2 an attractive candidate for use in direct conversion flat-panel X-ray image detectors[3].The HgI_2 layer is deposited onto conductive glass plates by either physical vapor deposition (PVD) or screen printing methods to fabricate a poly-HgI_2 detector.

In this paper, we have investigated sensitivity of poly-HgI_2 X-ray imagers under mammographic condition. The carrier ranges of poly-HgI_2 deposited by screen printing method have been determined for chest radiology conditions in a previous work [4]. In this paper, carrier ranges of poly-HgI_2 deposited by PVD method have been determined for mammographic condition.

The X-ray sensitivity of a photoconductor is defined as the collected charge per unit area per unit exposure of radiation. The continuity equation for both holes and electrons is analytically solved by considering the drift of electrons and holes in the presence of deep traps under the situation of exponentially decaying distribution of electron hole pair generation across the thickness of the photoconductor. An expression is derived for determining sensitivity in terms of electron hole pair creation energy, W± , monoenergetic X-ray photon energy E, linear attenuation coefficient α, energy absorption coefficient α_{en} of the photoconductor, transport properties of the photoconductor i.e. carrier mobility μ and carrier lifetime τ, the operating conditions(electric field applied across the detector, F and detector thickness L).

II. Theoretical Model

Consider a photoconductor sandwiched between two large area parallel plate electrodes and biased with a voltage V to establish an electric field F. A monoenergetic beam of X-ray is applied. The X-ray photons are absorbed exponentially as exp $(-\alpha x)$ along the photoconductor thickness and generate an electron hole pair concentration that follows the X-ray photon absorption profile. The electrons and holes are drifted in opposite directions by the applied field and give rise to a transient X-ray photocurrent. The radiation receiving electrode can be biased positively or negatively.

To deduce the mathematical equation of the total collected charge some necessary assumptions are made- (1) The thermal equilibrium concentration of charge carriers is negligibly small (2) The diffusion of carriers is negligible compared to their drift because of high applied field across the photoconductor (3) A constant drift mobility μ and a single deep trapping time (lifetime) τ are assigned to each type of carriers (holes and electrons) since the interrupted field time-of-flight measurements indicate a single deep trapping time for both types of carriers [2][5]. (4)The field remains relatively uniform. (5) The loss of carriers by deep trapping is more significant than bulk recombination. (6) The trapped charge concentrations are very small compared to the trap center concentrations and thus trap saturation effect is negligible. (7) The photoconductor is exposed to a monoenergetic pulse of X-ray radiation that has a very short duration compared to the charge carrier transit times across the sample thickness.

The continuity equation for holes for these assumptions with positive bias applied on the radiation receiving electrode is-

$$\frac{\partial \rho(x,t)}{\partial t} + \mu_h F \frac{\partial \rho(x,t)}{\partial x} = -\frac{\rho(x,t)}{\tau_h} \text{.....(1)}$$

where $\rho(x,t)$ is the concentration of holes at location x at time t, and F is the applied electric field. According to the features of X-ray absorption and electron hole pair generation, the initial hole or electron distribution at time t=0 across the photoconductor is

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

$$\rho(x,0) = n(x,0) = \frac{\alpha_{en}\varphi_0 E}{W_{\pm}e^{(\alpha x)}} = Be^{(-\alpha x)} .....(2)$$

Where E is X-ray photon energy assuming a monoenergetic beam has been applied and

$$B = \frac{\alpha_{en}\varphi_0 E}{W_{\pm}}$$

The incident X-ray photons per cm^2 is related to X-ray exposure X by [6]

$$\varphi_0 = \frac{5.45 \times 10^{13}}{\frac{\alpha_{air}}{\rho_{air}}E} X .....(3)$$

The solution of Equation (1) is a drifting hole distribution that is given by-

$$\rho(x,t) = Be^{(\alpha\mu_h F - \frac{1}{\tau_h})t} e^{(-\alpha x)}; \mu_h F t < x < L$$

$$\rho\,(x,t) = 0; (x < \mu_h F t) or (x > L) .....(4)$$

The collected positive charge per unit area per unit exposure of radiation would be

$$Q_h = \frac{\mu_h F e}{L} \int_0^{t_h} \int_{\mu_h F t}^{L} \rho\,(x,t)\, dx dt .....(5)$$

This gives

$$Q_h = \frac{B\tau_h \mu_h F e}{\alpha L} \left\{ \left(1 - e^{-\alpha L}\right) + \frac{\left(e^{-\alpha L} - e^{-\frac{t_h}{\tau_h}}\right)}{1 - \frac{1}{\tau_h \alpha \mu_h F}} \right\} ..(6)$$

where $t_h = L/(\mu_h F)$=transit time of hole across the semiconductor and e is the charge of an electron or hole. Similarly, we can calculate the collected charge per unit area per unit exposure of radiation,Q_e due to electron drift.

Sensitivity is determined by S=Q_h+Q_e. Sensitivity can be written as-

Sensitivity,S=

$$\frac{e\varphi_0 E}{W_{\pm}} \frac{\alpha_{en}}{\alpha} \frac{\mu_h \tau_h F}{L} \left[\left(1 - e^{-\alpha L}\right) + \frac{\left(e^{-\alpha L} - e^{-\frac{t_h}{\tau_h}}\right)}{1 - \frac{1}{\tau_h \alpha \mu_h F}} \right]$$

$$+ \frac{e\varphi_0 E}{W_{\pm}} \frac{\alpha_{en}}{\alpha} \frac{\mu_e \tau_e F}{L} \left[\left(1 - e^{-\alpha L}\right) - \frac{\left(1 - e^{-\alpha L - \frac{t_e}{\tau_e}}\right)}{1 + \frac{1}{\alpha \mu_e F \tau_e}} \right] ...(7)$$

When negative bias is applied on the radiation receiving electrode, sensitivity can be written as-

Sensitivity,S=

$$\frac{e\varphi_0 E}{W_{\pm}} \frac{\alpha_{en}}{\alpha} \frac{\mu_h \tau_h F}{L} \left[\left(1 - e^{-\alpha L}\right) - \frac{\left(1 - e^{-\alpha L - \frac{t_h}{\tau_h}}\right)}{1 + \frac{1}{\alpha \mu_h F \tau_h}} \right]$$

$$+ \frac{e\varphi_0 E}{W_{\pm}} \frac{\alpha_{en}}{\alpha} \frac{\mu_e \tau_e F}{L} \left[\left(1 - e^{-\alpha L}\right) + \frac{\left(e^{-\alpha L} - e^{-\frac{t_e}{\tau_e}}\right)}{1 - \frac{1}{\tau_e \alpha \mu_e F}} \right] ...(8)$$

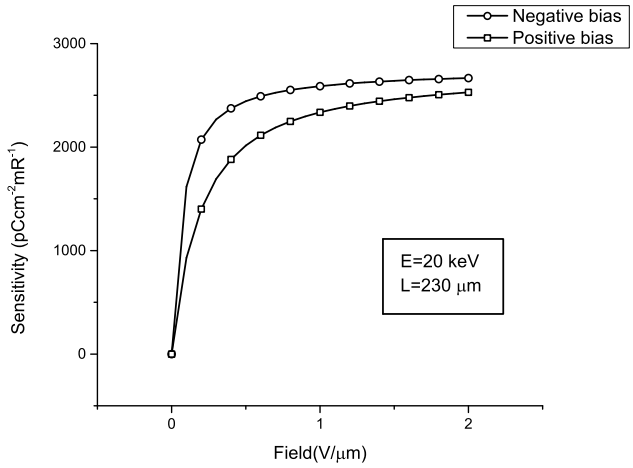

Fig. 1. Sensitivity versus applied electric field with both positive and negative bias applied on the radiation receiving electrode for a detector of thickness 230 μm

III. Result and Discussion

The sensitivity model is applied to PVD type polycrystalline HgI_2 to evaluate its performance as X-ray photoconductor. The sensitivity calculations were carried out using equation (7)and equation (8) for a monoenergetic beam of X-rays at 20 keV to very approximately represent mammographic condition.

In Fig.1, Sensitivity is examined as a function of varying applied electric field F for a monoenergetic beam of X-rays having photon energy, E=20 keV for a typical detector thickness L of 230 μm.This thickness corresponds to about 7δ (δ = 1/α =absorption depth) to absorb nearly all the incident radiation to minimize the patient exposure. It is observed that, the sensitivity increases with increasing electric field before reaching an asymptotic level of maximum collection efficiency. After reaching the maximum value, sensitivity becomes constant as the electron hole pair creation energy of polycrystalline HgI_2 is a constant and thus does not depend of the applied field. It is also observed that the sensitivity is higher when negative bias is applied. This can be explained by the following facts. Sensitivity is mainly controlled by charges having the same polarity as the bias applied at the radiation receiving electrode as they get collected at the bottom electrode. When negative bias is applied on the radiation receiving electrode, electrons control sensitivity and electron range is much higher in polycrystalline HgI_2 than hole range.

In Fig.2, The sensitivity model is fitted with experimental data for sensitivity of PVD polycrystalline HgI_2 when a monoenergetic beam of 20 KeV is applied with negative bias applied on the radiation receiving electrode. This is approximately the mammographic condition. The data have been extracted from Fig.7 of [1]. As apparent from Fig.2, there is a very good fit of the experimental data to Equation 8. From the curve fitting in Fig.2, in case of the PVD sample, the electron lifetime was found to be, $\tau_e = 1.917 \times 10^{(-7)} s$ and hole lifetime was found to be $\tau_h = 1.479 \times 10^{(-6)} s$. From the lifetime data, electron range and hole ranges for PVD poly HgI_2 are determined. Electron range has been found to be $\mu_e \tau_e = 1.6896 \times 10^{(-5)} cm^2 V^{-1}$ and hole range has been found to be $\mu_h \tau_h = 5.916 \times 10^{(-6)} cm^2 V^{-1}$.The electron and hole range of PVD poly HgI_2 have been reported to

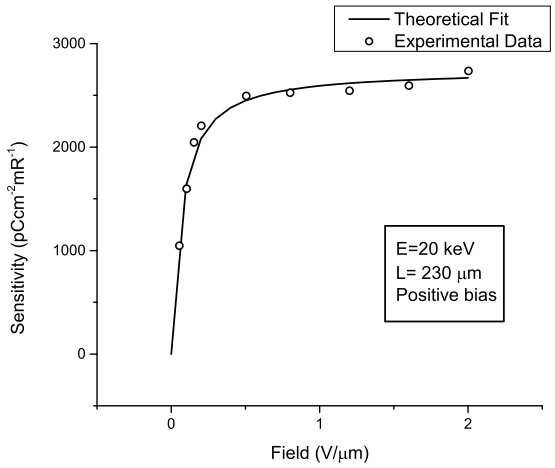

Fig. 2. Sensitivity versus applied electric field with negative bias applied on the radiation receiving electrode for a detector of thickness 230 μm. The sensitivity model is fitted with the experimental data

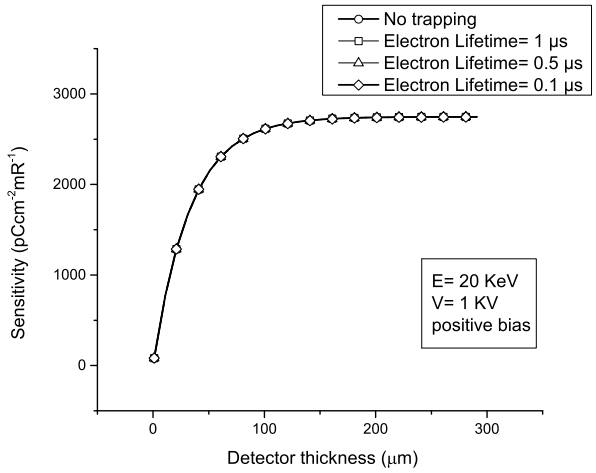

Fig. 3. Sensitivity versus detector thickness operating at an applied voltage V = 1 kV for various levels of electron trapping. Hole trapping neglected

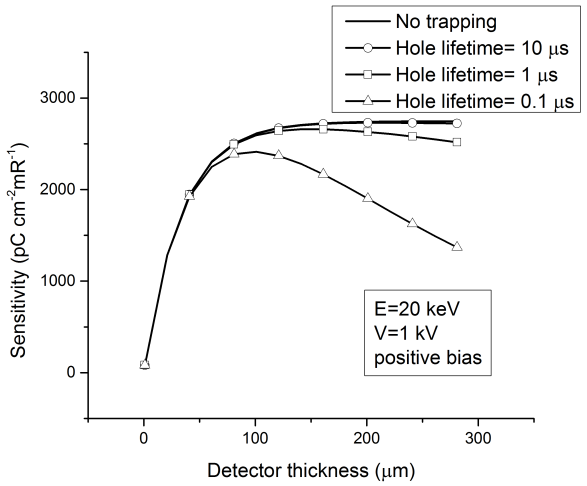

Fig. 4. Sensitivity versus detector thickness operating at an applied voltage V = 1 kV for various levels of hole trapping. Electron trapping neglected

be $\mu_e\tau_e \approx 1 \times 10^{(-5)} - 1 \times 10^{(-4)} cm^2V^{-1}$ and $\mu_h\tau_h \approx 1\times10^{(-6)} cm^2V^{-1}$ respectively [7][8]. Therefore, the electron and hole ranges are found to be within acceptable range. It is further observed that, electron range is far greater than hole range in polycrystalline HgI_2.

Carrier lifetime depends on concentration of deep trap centers. In the sensitivity model, neutral deep trap centers are assumed so that there is no bulk recombination. Deep trapping levels at room temperature is related to carrier lifetime, τ by the following equation [9] -

Carrier lifetime,

$$\tau = \frac{1}{vC_tN_t} .....(9)$$

Here v is the carrier velocity(1×10^7 cm/s). C_t is the Charge capture cross section of the trapping centers of HgI_2 ($2 \times 10^{(-14)} cm^2$) and and N_t is the concentration of deep trap centers for carriers. Concentration of deep trap centers for both electrons and holes are determined from equation (9).

Concentration of deep trap centers for electrons,

$$(N_t)_{electron} = 2.5963 \times 10^{13}/cm^3$$

Concentration of deep trap centers for holes,

$$(N_t)_{hole} = 3.3652 \times 10^{12}/cm^3$$

It is instructive to observe detector thickness dependence of sensitivity for an incident monoenergetic X-ray beam of 20 keV (mammographic condition) operating at an applied voltage of 1kV with positive bias applied on the radiation receiving electrode. Fig.3 and Fig.4 illustrate the effects of deteriorating electron and hole trapping times respectively while varying detector thickness.

It is observed that, in case of deteriorating electron lifetime, sensitivity increases with increasing detector thickness as more charge carriers are generated and collected as detector thickness increases. It is also noticed that, deteriorating electron lifetime does not have much impact on sensitivity. On the other hand, it is observed that, as discussed above, effect of deteriorating hole lifetime is more pronounced. This is also explained by the fact that holes control sensitivity when positive bias is applied on the radiation receiving electrode. The interesting case is when the hole lifetime is so poor that the sensitivity can only be optimized by reducing the detector thickness L (thereby reducing the amount of absorbed radiation) just to enable the generated holes to be collected. It is also noticed that, S versus L behaviour has a maximum that moves to smaller thicknesses as the hole lifetime gets shorter.

If negative bias is applied on the top electrodes, the shape of the Fig.3 and Fig.4 are swapped as sensitivity is controlled by electrons when negative bias is applied.

IV. Conclusions

A model for determining sensitivity of photoconductors has been developed. The model has been applied to polycrystalline mercuric iodide detectors. Sensitivity has been observed under varying applied electric field. The proposed physics based theoretical model shows a very good agreement with the experimental results. The carrier ranges of PVD polycrystalline mercuric iodide have been determined by curve fitting under mammographic condition. Electron range has been found to be $\mu_e\tau_e = 1.6896 \times 10^{-5} cm^2V^{-1}$ and hole range has been found to be $\mu_h\tau_h = 5.916 \times 10^{-6} cm^2V^{-1}$. The electron

and hole range of PVD poly HgI_2 have been reported to be $\mu_e\tau_e \approx 1 \times 10^{(-5)} - 10^{(-4)} cm^2V^{-1}$ and $\mu_h\tau_h \approx 1 \times 10^{(-6)} cm^2V^{-1}$ respectively previously [7][8]. So, the carrier ranges determined from the sensitivity model are in very good agreement with the reported carrier ranges for poly HgI_2. The trap center concentrations for both electron and holes have been determined. Concentration of deep trap centers for electrons and holes were found out to be $2.5963 \times 10^{13}/cm^3$ and $3.3652 \times 10^{12}/cm^3$ respectively. Effect of deteriorating electron and hole lifetime on sensitivity is observed while varying detector thickness. Deteriorating hole lifetime had much more impact on sensitivity than deteriorating electron lifetime for positive bias. Presence of an optimum detector thickness for maximizing sensitivity has been observed at low hole lifetime.

ACKNOWLEDGMENT

We are grateful to the Robert Noise Simulation Lab of Department of Electrical and Electronic Engineering , Bangladesh University of Engineering and Technology for the contribution to our effort.

Abstract—**In this paper the barrier height control of n-type InGaN has been demonstrated by a simple physics based unified model. Metal induced gap states (MIGS) model for metal-semiconductor contact has been extended to metal-insulator-semiconductor (MIS) contact for unpinning of Fermi level and low contact resistivity formation. Metal/n-$In_{0.2}Ga_{0.8}N$ contact is strongly pinned with a pinning factor value of 0.28. This work has improved the pinning factor from 0.28 to almost closer to 1 by inserting an ultrathin GeO_2 (2 nm) insulator layer and by varying this layer thickness, density of interface electronic states has been controlled which modulated the barrier height. Finally an excellent ohmic contact has been formed by using Cu as the metallic contact with contact resistivity as low as 1.4×10^{-8} Ω-cm^2 at 600K.**

Index Terms—**Pinning factor, MIGS Model, MIS contact, Barrier Height Control, Ohmic contact.**

I. Introduction

InGaN has got a great attention by the researcher for its structural properties. It has already involved in some applications such as high temperature and high power electronics [1], [2] light emitting diodes and detectors operating in the blue and ultra-violet wavelength range [3], [4]. It has a band gap ranging from 0.7 eV to 3.4 eV which covers the entire visible spectrum. That's why they are of concern for the future optoelectronics applications. To make a device stable and efficient, some outlines such as contact issues, surface preparation are needed to be considered carefully. Schottky Barrier-FET (SB-FET) implementation using III-V semiconductors including both binary and turnery materials such as GaAs, InAs, GaN, AlGaN, InGaAs can be challenging because Fermi level at metal/III-V interfaces are pinned [5]-[9]. Wave-function of electron in the metal penetrates the semiconductor band gap. This penetration forms electron states. This states in the band gap results in Fermi level (FL) pinning [7]. So, for implementing III-V materials in SB-FET, barrier height modulation is needed. S. Hara *et al.* first proposed a systematical method for controlling Barrier Height (BH) at metal/semiconductor interface by controlling surface electronic states [10]. Controlling of interface electronic state means to control of FL pinning factor. For the modulation of barrier height at the metal-semiconductor interfaces, two methods have been proposed [5]. One is dopant segregation which is the introduction of appropriate dopants at the semiconductor surface and it has been investigated both theoretically and experimentally [11]. Another is the insertion of an ultrathin insulator between metal and semiconductor [5], [7]-[9].

Monch through his Metal-Induced-Gap-States (MIGS) model described the FL pinning factor for Metal-Semiconductor (M-S) contact [12]. In our work this model has been extended to Metal-Insulator-Semiconductor (MIS) contact by a simple physics based approach. By insertion of a thin insulator layer between metal and semiconductor and varying its thickness, pinning factor can be varied. A thin insulator is capable of diminishing FL pinning caused by MIGS by subduing wave function of metal that penetrates into semiconductor band gap [5]. MIS technology to mitigate FL pinning by inserting interfacial layer (IL) has been demonstrated with Si [6], Ge [6], [13], GaAs [7], [9] and InGaAs [5], [6]. Also for some III-N materials such as GaN and AlGaN, theoretical band offsets using the MIGS Schottky pinning factor has been determined [9], [14] and there are a very few experimental works too [15], [16]. In this paper we first demonstrated the Barrier Height (BH) control mathematically for the InGaN using MIGS model. GeO_2 has been introduced as the insulator layer for the MIS contact. Simulations have been performed using MATLAB software. The pinning factor of the InGaN is 0.28. We have improved this value to closer to 1 and by varying this pinning factor the variation of the barrier height for the same metallic contact has been demonstrated. This work has been concluded with formation of an excellent ohmic contact. An ultralow barrier height of 0.07 eV has been found for Cu as the metallic contact. The contact resistivity in the 10^{-8} ohm-cm^2 range at various temperature (300-600K) has been investigated which is the evidence of an outstanding ohmic contact. The total working procedure of BH control and ohmic contact formation demonstrated in this paper has brought out in a flow diagram as shown in Fig. 1.

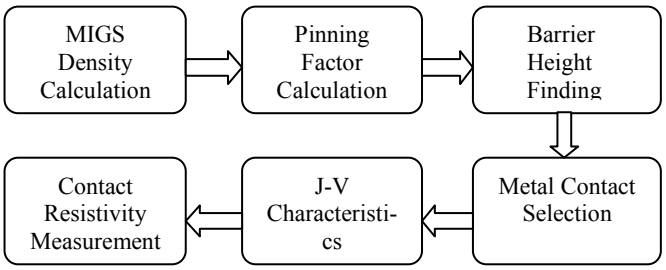

Fig. 1 Block Diagram of Barrier Height Control and ohmic contact formation

II. MIGS Model For Barrier Height Control

A. MIGS Density Calculation

Physical explanation of the FL pinning factor has been nicely described by Monch through his MIGS model for M-S contact [12]. In this paper this model has been improved in case of MIS contact. We have proposed that metal-interfacial layer (M-IL) has MIGS and its density is expressed as

$$D_{M0} = \frac{2}{\pi a^2 E_g} \quad (1)$$

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

Here E_g and a are bandgap and lattice constant of the insulator respectively. The reduction of this MIGS density into the insulator is exponential in nature and is expressed by the equation [13]

$$D_M = D_{M0} e^{-\frac{t}{\delta_i}} \quad (2)$$

In that equation t is the width of the insulator and δ_i is the decay length of the MIGS density through the IL. This decay length is given by [13]

$$\delta_i = \frac{h^2}{2\pi m_0 a E_g} \quad (3)$$

Its decay in the semiconductor(δ_S) can be found from equation (3) by replacing the value of lattice constant (a) and band gap (E_g) for semiconductor.

B. Pinning Factor Calculation

When metal is deposited on the semiconductor, there will be a change of Fermi level. But in some semiconductors the surface states pin the FL. Surface states compel the FL to be there. Surface states are due to electron wave function of metal penetrating the semiconductor bandgap and causes FL pinning [5], [7]. The BH alteration is very little although by varying the metal work function to a wide range. The value of the FL pinning factor, S lies between 0 and 1. S=0 means FL is completely pinned and S=1 means FL is completely unpinned.

Monch found an empirical formula to the experimentally observed value of pinning factor for the M-S contact for MIGS model [9]:

$$S = \left[1 + 0.1(\varepsilon_\infty - 1)\right]^{-1} \quad (4)$$

But the pinning factor equation for a MIS contact considering intrinsic pinning factor of insulator layer is [13]

$$S = \left[1 + \frac{\varepsilon_i (1 - S_i) e^{-\frac{t}{\delta_i}} \left(\delta_s \varepsilon_i + t\varepsilon_s\right)}{S_i \delta_i (\varepsilon_i + \varepsilon_s)}\right]^{-1} \quad (5)$$

In this equation S_i is the intrinsic pinning factor of the insulator GeO_2 itself. It is given by [13]

$$S_i = \left(1 + q^2 \frac{D_{M0}\delta_i}{\varepsilon_0 \varepsilon_i}\right)^{-1} \quad (6)$$

C. Barrier Height Measurement

Due to difference in charge neutrality level (CNL) value of insulator and semiconductor, a dipole is risen which must not be ignored in case of calculating barrier height. If ϕ_S, χ_S and ψ_S are the work-function, electron affinity and total equilibrium band bending of the semiconductor respectively then the BH of an n type semiconductor can be written as [6]

$$\phi_{Bn} = \phi_S - \chi_S - \psi_S \quad (7)$$

The equilibrium band bending of semiconductor ψ_S depends upon insulator-semiconductor (I-S) dipole as [13]

$$\psi_S = -\frac{C_I}{C_I + C_S}\phi_{MS} - \frac{C_{il}}{C_{il} + C_{is}}\Delta_{IS} \quad (8)$$

Again, I-S dipole voltage Δ_{IS} which depends upon the CNL difference between semiconductor and insulator and pinning factor of I-S interfaces is expressed as [6].

$$\Delta_{IS} = (1 - S_{IS})(\phi_{CNLS} - \phi_{CNLI}) \quad (9)$$

Here S_{IS} is the pinning factor of I-S interface. ϕ_{MS} is the work function difference between metal and semiconductor. C_I and C_S are the insulator and semiconductor surface capacitance densities respectively. C_{il} and C_{iS} are the IL-semiconductor dipole capacitance densities for the IL and the semiconductor, respectively [6].

$$C_I = \frac{\varepsilon_I}{t}, \quad C_{il} = \frac{\varepsilon_{\infty l}}{d_{il}}, \quad C_{is} = \frac{\varepsilon_{\infty s}}{d_{is}} \quad (10)$$

Here d_{il} (d_{is})is the dipole layer thickness and $\varepsilon_{\infty l}(\varepsilon_{\infty s})$ is the high frequency dielectric constant. Now for an n-type semiconductor surface capacitance depends on band bending as [6]

$$C_s(\psi_s) = q\sqrt{\frac{\varepsilon_s N_D}{2K_B T}} \left| \frac{e^{\frac{q\psi_S}{K_B T}} - 1 - \left(\frac{n_i}{N_D}\right)^2 e^{\left(-\frac{q\psi_S}{K_B T}\right)}}{\sqrt{e^{\frac{q\psi_S}{K_B T}} - \frac{q\psi_S}{K_B T} - 1 + \left(\frac{n_i}{N_D}\right)^2 \left[e^{\frac{-q\psi_S}{K_B T}} - 1\right]}} \right| \quad (11)$$

Now combining equation (7) & (8) and then differentiating ϕ_{Bn} with respect to ϕ_M, the mathematical relation of pinning factor and semiconductor surface capacitance densities can be obtained.

$$S = \frac{d\phi_{Bn}}{d\phi_M} = \frac{C_I}{C_I + C_S(\psi_S)} \quad (12)$$

III. Ohmic Contact Formation

A contact is whether ohmic or rectifying determined by the contact resistivity value. An ohmic contact has a very low contact resistivity. The contact resistivity is determined from the current density equation. It has linear current-voltage characteristics. This type of contact formation is achievable by keeping the barrier height as low as possible and doping the semiconductor heavily. Current density equation for a MIS contact is [17]

$$J = A^* T^2 \exp(-\sqrt{\zeta}t) \exp\left(-\frac{q\phi_{Bn}}{\eta KT}\right)\left[\exp\left(\frac{qV}{\eta KT}\right) - 1\right] \quad (13)$$

The term $\exp(-\sqrt{\zeta}t)$ is known as the tunneling probability where ζ(in eV) is the effective barrier height and t (in A) is the thickness of the insulator layer. A^* in this equation is the Richardson constant and η is the ideality factor. Contact resistivity is related to the current density as

$$\rho_C = \left(\partial J / \partial V\right)^{-1} \quad (14)$$

IV. Result and Discussions

Unpinning of FL is a complex effect. It combines not only the effect of fixed surface charge but also interface dipoles

TABLE 1
PARAMETERS FOR $In_{0.2}Ga_{0.8}N$ AND GeO_2

Sl. No	Parameters	Values	
		$In_{0.2}Ga_{0.8}N$	GeO_2
01	Bandgap (eV)	2.63 [18]	4.3[13]
02	Work function (eV)	5 [19]	--
03	Electron affinity (eV)	4.56[20]	--
04	Lattice constant (A)	3.26 [18]	4.402[13]
05	Dielectric constant	11.146[18]	5.9[13]
06	High frequency dielectric constant	6.056[21]	1.8[13]
07	Charge neutrality level (eV)	2.48[22]	3.2[13]

[5], [7]. Pinning factor of $In_{0.2}Ga_{0.8}N$ calculated from equation (4) without the presence of GeO_2 is 0.28. So, FL is strongly pinned between metal and semiconductor. In this work the pinning factor of $In_{0.2}Ga_{0.8}N$ has been investigated by insertion of GeO_2 as the IL between metal and semiconductor.

Parameters used for $In_{0.2}Ga_{0.8}N$ and GeO_2 have been listed in Table. 1. Most of the parameters of $In_{0.2}Ga_{0.8}N$ have been calculated by using Vagard law. Strong FL pinning is due to the interface state density. This surface state forms by the penetration of electron wave function of metal into the semiconductor bandgap. This pins the Fermi level. Surface state density has reduced by inserting GeO_2 insulator layer between metal and semiconductor with suitable thickness. Presence of GeO_2 has mitigated electron wave-function, thus avoiding FL pinning.

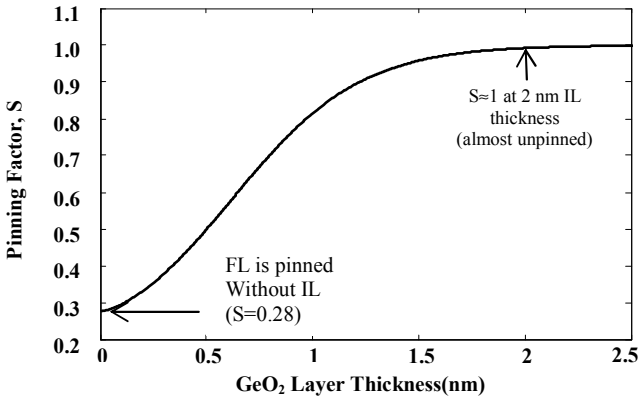

Fig. 2 FL pinning factor of $In_{0.2}Ga_{0.8}N$ as a function of GeO_2 thickness

Fermi level pinning factor variation of $In_{0.2}Ga_{0.8}N$ with the variation of GeO_2 layer has been plotted in Fig. 2. With the presence of IL, electron wave function of metal becomes attenuated. So, pinning factor is rising. For complete unpinning of the FL(S=1), the thickness required is almost 3 nm. But the noticing thing is that the more the thickness of the IL, the more the tunneling resistance. So, here a tradeoff is needed between pinning factor and thickness of insulator. Fig. 2 indicates that a 2 nm thickness of GeO_2 can make the value of S almost closer to 1. So, FL is almost unpinned (S≈1) with 2 nm GeO_2 layer.

Pinning factor shift also shifts the BH for the same metallic contact. Pinning factor varies with the variation of the insulator layer thickness. It results a barrier height variation for the same metal contact. We have investigated this variation with some metals having work functions ranging from 4.5 eV to 6 eV. Fig. 3 shows the barrier height modulation for the same metallic contact with various S values.

Cu (4.65) [23], Ag (4.73) [24], Au (5.1) [23], Ni (5.15) [8] and Pt (5.65) [23] have been used to test the BH variation. From Table.2 we can see that $In_{0.2}Ga_{0.8}N$ has a barrier height of 0.33 for Cu without having any IL between them. But with the presence of an ultrathin GeO_2 of 2 nm, barrier height shifts from 0.33 to 0.07 eV. Similarly, barrier height shifting happens for rest of the metals. Barrier height with Cu and Ag decreases with the increase of pinning factor because their work-function is less than that of $In_{0.2}Ga_{0.8}N$. On the other hand Ni, Au and Pt contacts show larger BH because of having work-function more than $In_{0.2}Ga_{0.8}N$. So, with the increase of pinning factor barrier height shows more dependence on metal work-function.

Insulator (C_I) and semiconductor (C_S) surface capacitance densities vary with the IL thickness.C_I is inversely proportional

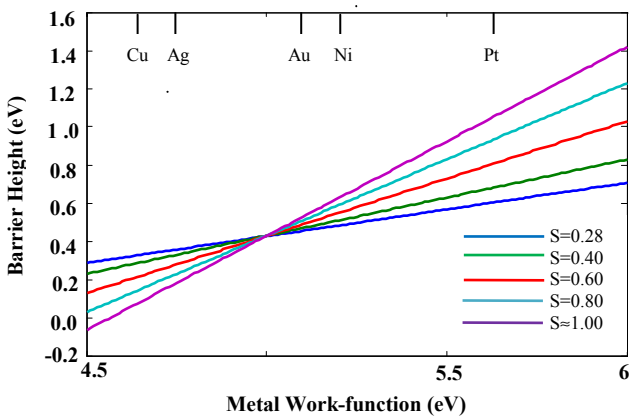

Fig. 3 Barrier Height variation with metal work-function for different pinning factor

to GeO_2 thickness. On the other hand, the initial FL position of the InGaN was near the conduction band and it is shifted from near the conduction band to near the mid-gap. BH shift is due to dipole formation between GeO_2 and InGaN (Δ_{IS}) and the insulator (C_I) and semiconductor (C_S) surface capacitance densities. Because of this dipole, the atomic structure of the InGaN changes. GeO_2 creates a polar I-S interface, thus inducing a dipole which leads to a barrier shift. This magnitude of the dipole is independent of the metal. It depends on the charge neutrality level (CNL) misalignment between insulator and semiconductor.

TABLE 2
CALCULATED BARRIER HEIGHT FOR DIFFERENT METALS

Pinnig factor	ϕ_{Bn} for Cu(4.65 ev)	ϕ_{Bn} for Ag(4.73 ev)	ϕ_{Bn} for Au(5.1 ev)	ϕ_{Bn} for Ni(5.15 ev)	ϕ_{Bn} for Pt(5.65 ev)
S=0.28	0.33	0.36	0.44	0.47	0.60
S=0.40	0.28	0.32	0.47	0.50	0.69
S=0.60	0.21	0.26	0.49	0.53	0.82
S=0.80	0.15	0.21	0.51	0.56	0.95
S≈1.00	0.07	0.16	0.54	0.60	1.08

Semiconductor surface capacitance changes with the variation of the pinning factor as shown by equation (12). The pinning factor is closely related to IL thickness and it increases with the increase of the thickness. So that's why the surface capacitance densities also vary with the variation of the GeO_2 layer thickness.

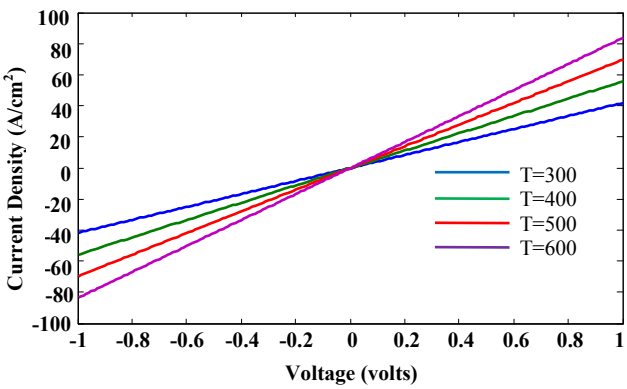

Fig. 4 Temperature dependent J-V characteristics for Cu/GeO_2 /$In_{0.2}Ga_{0.8}N$

In our investigation Cu formed an ultralow barrier height of 0.07 eV with 2 nm GeO_2 between Cu and InGaN. So, an excellent ohmic contact can be formed using Cu. Fig. 4 represents the Current density-voltage characteristics of

Cu/GeO_2 (2nm)/$In_{0.2}Ga_{0.8}N$ for different temperature. Doping concentration (N_d) has been taken as 10^{19} cm^{-3}.

Current density-Voltage characteristics formed straight lines which is a clear indication of ohmic contact. So, tunnelling resistance offered by IL didn't create strong impact on contact resistivity which has been plotted as a function of temperature for Cu/GeO_2 (2nm)/$In_{0.2}Ga_{0.8}N$ at Fig. 5. So, considering the effect of tunneling resistance, the contact resistivity has been found as low as 1.4×10^{-8} Ω-cm^2 at 600K which is an excellent ohmic contact.

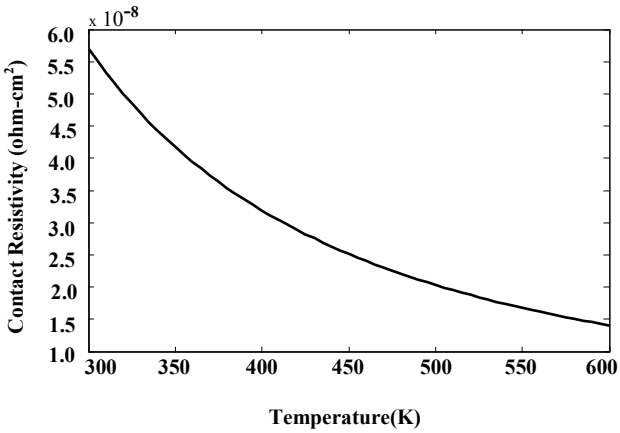

Fig. 5 Contact resistivity of Cu/GeO_2(2nm)/$In_{0.2}Ga_{0.8}N$ at various temperatures

V. CONCLUSION

In summary, MIGS model to change the FL pinning position and BH modulation at metal/InGaN interfaces has examined by insertion of ultrathin GeO_2(2 nm) interlayer. This work has set out an excellent framework for MIGS-based FL pinning in MIS contacts in case of InGaN. FL depinning is a complex effect which combines both the effect of fixed surface charge and interface dipole. Insertion of IL attenuates the electron wave-function of metal which prevents FL pinning and improves the pinning factor. BH modulation also activates due to the creation of an electric dipole at the GeO_2/ $In_{0.2}Ga_{0.8}N$ interface which introduces the barrier shift. Its alteration is due to the variation of insulator and semiconductor surface capacitance densities with IL thickness. This works concluded with forming a suitable ohmic contact for n-InGaN. Cu formed an ultralow barrier height of 0.07 eV with pinning factor closer to 1. With a moderate doping concentration and considering the tunnelling resistance offered by IL, Cu/GeO_2 (2nm)/$In_{0.2}Ga_{0.8}N$ establishes an excellent ohmic contact with contact resistivity 1.4×10^{-8} ohm-cm^2. However, this ultralow contact resistivity value put the MIS contact in compatibility with incorporation with conventional CMOS for source/drain applications.

Abstract— **p-InGaN epitaxial layer is crucially important for advanced electronic and optoelectronic devices. The activation energy (E_A) of Mg-acceptor, universally accepted p-type dopant, and hole concentration (p) of Mg-doped $In_xGa_{1-x}N$ alloys (x~0.4) have been investigated herein. The E_A has been calculated using an equation almost fitted with experimental data available in literatures in which E_A decreases with the increase in In content (x) in $In_xGa_{1-x}N$. The observed E_A in Mg doped $In_{0.4}Ga_{0.6}N$ alloys is about 41 meV which is few times smaller than Mg doped GaN, widely used active p-layer from III-nitride. The increased carrier concentration (p) due to increasing In content is near about 9.7×10^{18} cm^{-3} for x~0.4. The hole concentration starts to decrease at around the Mg concentration of 4.5×10^{19} cm^{-3}. These results indicate that self-compensation occurs in Mg-doped InGaN at higher-doping levels.**

Index Terms—**Mg-doped $In_xGa_{1-x}N$, Activation energy, Hole concentration, Self-compensation model.**

I. Introduction

III-nitride semiconductors and their alloys are extensively being explored for the assessment of advanced practical devices. Amongst them, InGaN is a direct bandgap semiconductor alloy having bandgap tunability from NIR (E_g^{InN}=0.65 eV) to UV region (E_g^{GaN}=3.45 eV) [1]. This attributes make this alloy apposite for advanced single junction and multi-junction solar cells, LEDs and LASER [2]. It is a highly potential alloy for High electron mobility transistor (HEMTs), Heterojunction Bipolar Transistors (HBTs) and some other advanced electronic devices [3], [4]. Inspite of this, still now InGaN is not available in device level due to the complexity of fabricating p-InGaN [5]. Among III-V semiconductors, generally Mg-doped GaN epilayers are used as p-type active layers for device purposes. The factors limiting p-GaN is the higher activation energy, E_A of Mg. Due to higher E_A of Mg in p-GaN, the self-compensation (SC) of Mg atoms increases which results in low conductivity in p-GaN [6]. Recently, it has been reported that p-InGaN can replace the p-GaN layer [7]. The high hole concentration (p) in Mg-doped InGaN/GaN super-lattice with optical and electrical properties of p-InGaN layer has been reported by hall measurement [8].

With decrease in bandgap, E_A decreases [9]. Hence Mg-doped $In_xGa_{1-x}N$ (x~0.4) is expected to have higher hole concentration than Mg-doped GaN. Besides low etching damage and low temperature requirement to synthesis p-InGaN than p-GaN [10] are other superior characteristics for device application. After the synthesis of p-InGaN in 1995 [11], a number of literatures have been available on the properties of p-InGaN [12-16]. This paper addresses the investigation of hole concentration (p) as function of In content (x), in Mg doped $In_xGa_{1-x}N$ alloys, for x up to 0.4. The E_A of Mg has been reported mathematically with a fitting equation and compared with practical aspects. It also includes the limited conductivity in Mg-doped $In_xGa_{1-x}N$ is due to donor impurity background compensation, namely self-compensation by intrinsic lattice defects such as vacancies or interstitial host atoms.

II. Investigation Of Low Activation Energy

A. Activation Energy of Mg in p-InGaN

E_A of the dopants in an epitaxial layer is a key parameter to get a doped layer. Fig. 1 shows the E_A of Mg-acceptor in Mg doped p-$In_xGa_{1-x}N$ alloys as a function of In content (x). It has been found that E_A decreases with the increase in In content (x). Lower value of E_A is the main reason for higher value of p of Mg doped $In_xGa_{1-x}N$ alloys with higher In content. For $In_xGa_{1-x}N$ epitaxial layer B.N Pantha et al. [17] reported experimentally that E_A is 43 meV when x is up to 0.35 which is roughly four times smaller than that in Mg doped GaN. The minimum E_A, (~41 meV) for x=0.4, is calculated by following fitting equation which coincides with the experimental results [10], [17], [15], [12]. The fitted parameters for E_A are chosen arbitrarily considering physical phenomena. This equation provides such a close agreement with the experimental findings and able to calculate E_A of Mg acceptor with different In composition, x in p- $In_xGa_{1-x}N$ epitaxial layer.

$$E_A = \frac{117}{1+(5x^{4/5})^3} + 33 \quad (1)$$

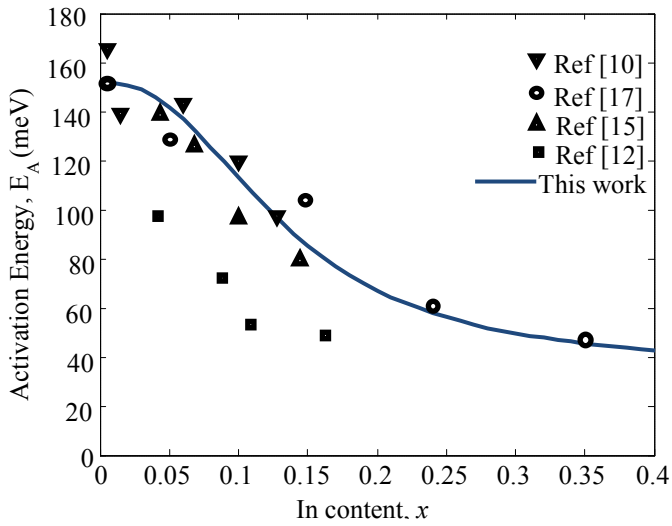

Fig. 1 Decrease of Activation Energy, (E_A) of Mg acceptors in Mg doped p-$In_xGa_{1-x}N$ alloys with increase in In content, x.

B. Hole Concentration in p-InGaN

The hole concentration (p) in Mg doped $In_xGa_{1-x}N$ which depends on the activation energy, has been shown in Fig. 2 as a function of In content, x at room temperature. The increase in hole concentration is caused by the decrease in Mg acceptor activation energy [10], [12]. By using equation (2) [18] and from Fig. 2, it is found that the hole concentration continuously increases from 4.9×10^{17} cm^{-3} for x=0 (GaN) to 9.7×10^{18} cm^{-3} for x=0.4. Such values suggest that it can be able to achieve good ohmic contacts between metal-contact and p-InGaN which is very congenial to reduce the contact resistance. Due to the presence of high background electron concentration in p-$In_xGa_{1-x}N$, the value of p reduces for x>0.40, has been discussed latter.

$$p = -\frac{N_D + K}{2} + \sqrt{\left(\frac{N_D + K}{2}\right)^2 + K(N_A - N_D)} \qquad (2)$$

When

$$K = \frac{1}{\beta} N_{val} \exp(-\frac{E_A}{k_B T}) \qquad (3)$$

Where N_D is the donor impurity density, N_A the Mg doping concentration, β is the valance band (vb) degeneracy factor taken as 3.6, N_{val} is the tem perature dependent vb density of states (DOS), E_A is the thermal Mg-acceptor ionization energy obtained from equation (1), k_B is the Boltzmann constant and T is the room temperature. N_{val} is obtained 3.2×10^{19} cm^{-3} for 40% In composition in the InGaN epitaxial layer [19].

$$N_{val}\,(In_xGa_{1-x}N) = N_{val}(InN)\times(x) + N_{val}(GaN)\times(1-x)$$
$$= \{5.3\times x + 1.8\times(1-x)\}\times10^{19} \qquad (4)$$

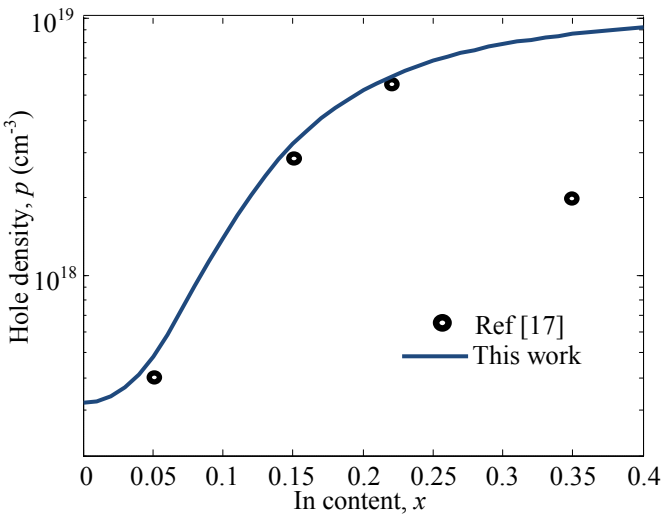

Fig-2: Room temperature hole concentration (p) as a function of In content x in Mg doped $In_xGa_{1-x}N$

III. Modelling of Self-Compensation

Fig. 3 shows the hole density (p) with the variation of Mg-concentration (N_A). The three curves corresponds to three residual donor concentrations, N_D in an impurity compensation model which indicates that, in moderate doping range , 5×10^{18} cm^{-3} ≤ N_A ≤ 3.0×10^{19} cm^{-3} , hydrogen de-passivation is very effective and impurity compensation as well as self-compensation (SC) having less effect. They are calculated at room temperature with the expression of p

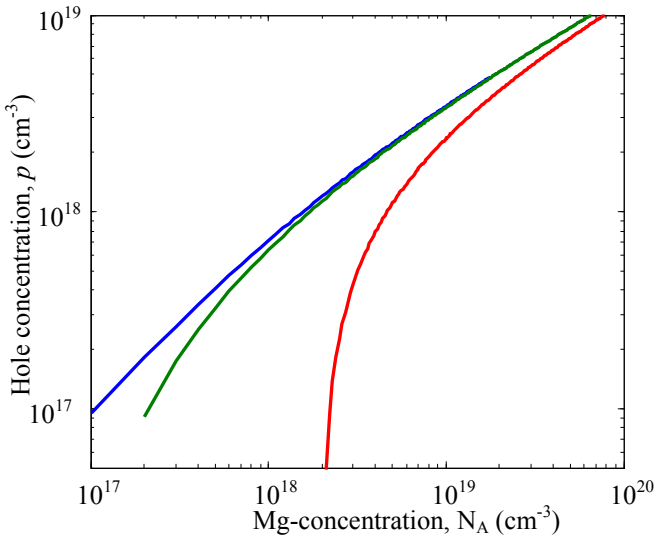

Fig. 3 Hole concentration (p) with respect to Mg-concentration (N_A) in p-$In_xGa_{1-x}N$ for three residual donor densities as shown in the legend

shown in equation (2). The values of donor concentration N_D are chosen 0, 1×10^{17} cm^{-3} and 2×10^{18} cm^{-3} and K at room temperature is obtained as K=1.8×10^{18} cm^{-3}. For this situation, E_A=41 meV has been kept fixed. Actually, this figure indicates that when N_A becomes larger than 3.0×10^{19} cm^{-3}, the measured hole concentration falls progressively due to the increase of the degree of compensation whatever the donor concentration N_D is.

Considering two idealized case of SC, one due to isolated nitrogen vacancy V_N which has a triple donor (multiplicity, m=3) and other due to the nearest neighbor complex MgV_N which has double donor (multiplicity, m=2) [20]. The former case is considered to be less realistic. But it has been included for the comparison purposes with the latter case. The latter case is considered important since the large amounts of dopants and vacancies are ionized and became mobile. Thus they tend to form near neighbor pair (MgV_N) when the doping concentration is high (upper 10^{19} cm^{-3}) and the mean separations are in the order of a few nanometers only. Self-compensation coefficient (c) can be defined by c=N_D/N_A where N_D and N_A are the donor and the Mg doping concentration, l indicates corresponds to case 1 (l=1) and case 2 (l=2) and N_{CC} introduces a fit parameter. Equation (1) can be rewritten for impurity compensation where all symbols have been defined above [21].

$$p = -\frac{mcN_A + K}{2} + \sqrt{\frac{(mcN_A + K)^2}{4} + KN_A(1-3c)} \qquad (5)$$

$$c = \frac{1}{3}\left(\frac{N_A}{N_{cc}}\right)^{l+1}\left(\frac{1+\sqrt{1+\alpha N_{cc}/N_{val}}}{1+\sqrt{1+\alpha N_A/N_{val}}}\right)^3 \qquad (6)$$

It should be noted that the parameter α and N_{val} in equation (6) are not independent, rather, α/ N_{val} ≡ 4/K where K has already been given. In Fig. 4, p vs N_A are plotted for case 1 and case 2. The fitting parameter N_{CC} for two curves were obtained N_{CC} ~1×10^{21} cm^{-3} and 1.5×10^{20} cm^{-3} for case 1 and case 2 respectively. Now, the desired $p(N_A)$ at room temperature can

be calculated from equation (5) by using the described input parameters of Mg acceptor E_A, the vb (β, N_{val}), as well as the fit parameter N_{CC}. If N_A is small compared to N_{CC}, the SC co-efficient c obtained from equation (6) are very small. This requirement is satisfied when $N_A<2\times10^{19}$ cm^{-3}.This indicates that SC in Mg doped InGaN is negligible for $N_A<2\times10^{19}$ cm^{-3}, but the SC becomes more significant when N_A approaches N_{CC}. The hole concentration (p) reaches at maximum near $N_A=4.5\times10^{19}$ cm^{-3} and decreases at higher Mg concentrations. Thus provides strong evidence that SC is the cause for the reduction in p at very high doping levels. If a better control of back-ground electron concentration could be achieved, it would be possible to improve p-type conductivity in Mg doped InGaN.

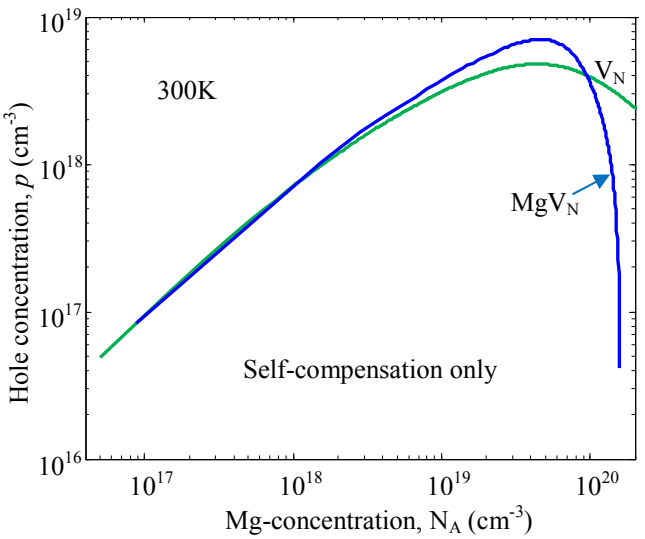

Fig. 4 Hole concentration (p) vs Mg concentration (N_A) based on self-Compensation

IV. Results & Discussion

Investigation of low activation energy (E_A) of Mg as well as higher hole concentration (p) in Mg doped p-$In_xGa_{1-x}N$ alloys is the promising issues for device application. The lower the E_A, the higher the p, will be possible if the better control of high background electron concentration in p-$In_xGa_{1-x}N$ is achieved. A comparison table of different E_A has been demonstrated below where calculated E_A from equation (1) has been compared with the practically obtained E_A. The calculated value of E_A is near about 41 meV and p was approximately 9.7×10^{18} cm^{-3} when In composition, x is 40% in Mg doped $In_xGa_{1-x}N$. At higher doping level when $N_A=4.5\times10^{19}$ cm^{-3}, the hole concentration has been investigated as maximum and then decreased for further increase of N_A due to the effect of self-compensation.

TABLE 1
COMPARISON OF E_A (CALCULATED AND PRACTICAL) AT DIFFERENT N_D AND N_A

Sample $In_xGa_{1-x}N$:Mg	$N_D\times10^{18}$ cm^{-3}	$N_A\times10^{19}$ cm^{-3}	E_A (meV)	E_A (meV) (This work)
x=0.04	1.0	0.53	141 [15]	144
x=0.10	2.0	3.0	120 [10]	111
x=0.35	2.0	3.0	43 [17]	43
x=0.40	2.0	3.0	….	41

V. Conclusion

In summary, the activation energies of Mg-acceptor in p-$In_xGa_{1-x}N$ alloys have been demonstrated mathematically by fitting equation for In composition, x up to 0.40. It has been found that the activation energy of Mg in p-$In_xGa_{1-x}N$ ($0<x<0.4$) decreased with increasing In content, x. The value, calculated using this equation is about 41 meV which is in close agreement with the experimental findings. The maximum hole concentration (p) of $In_{0.4}Ga_{0.6}N$ was 9.7×10^{18} cm^{-3}. Two semi quantitative Self-Compensation models with either isolated V_N or MgV_N pair predicts that p reaches maximum near $N_A=4.5\times10^{19}$ cm^{-3} and fall progressively beyond this N_A, that is why obtaining high hole concentration in p-$In_xGa_{1-x}N$ is difficult.

***Abstract*— An analytical model has been developed to determine the accumulation layer thickness of an inverted back interface silicon-on-insulator (SOI) four-gate transistor (G^4 - FET) by solving two dimensional Poisson's equation. To do so a geometric factor is introduced that combines the neglected inversion effects along with the existing device physics. Moreover, this factor considers the charge redistribution due to change in bias condition in different electrodes of the device. Physically, it indicates the non-availability of space for both depleted and inverted charges. The proposed model, named as modulated model for accumulation thickness considering inversion effects is verified numerically. The model commenced here successfully correlates the effect of all four gate bias.**

***Index Terms*— G^4-FET, Accumulation layer thickness, Inversion operation, Geometric Factor.**

I. Introduction

The four gate transistors (G^4-FET), formerly known as MOS-JFET, first introduced in 2002, features the maximum number of gates that can be accommodated in a single transistor and is a genuine four-gate transistor whose four gates can be biased independently [1]. Preliminary investigation confirms the potential of the G^4-FET for innovative analog circuits that can be conceived within a standard partially depleted SOI technology. Due to its multiple independent gates, the use of the G^4-FET enhances circuit design flexibility while reducing transistor count as compared to standard CMOS implementation [2]. This device can be manufactured using conventional SOI processes [3], without necessitating additional fabrication steps, being adaptable to more aggressive technology nodes [4].

Charge sheet model is vastly applicable to long channel devices. It leads to a very simple algebraic formula for the current of long-channel devices [5]. The same formula applies in all regimes from sub-threshold to saturation, neither splicing nor parameter changes are needed, no discontinuities occur in either the current or the small-signal parameters, or in the derivatives of the small-signal parameters. Also it can be easily extended to two to three dimensional modeling.

When the device is scaled to nano-range, this accumulation layer or channel can no longer be approximated as a sheet of charge of zero thickness, since the thickness becomes comparable to the silicon film thickness [6]. So mathematical modeling of accumulation layer thickness is necessary for different bias condition to determine the range of operation where charge sheet model can be applied. The analysis to determine the dependence of accumulation layer on the structural parameters of the device is also needed.

II. Device Structure

G^4-FET is a majority carrier, buried channel, accumulation mode device where the source, drain, and body / channel regions are all same type. It has two vertical MOS gates: a conventional polysilicon top gate, as well as the substrate, which can act as a bottom gate. In addition, it has two lateral JFET gates that form PN junctions with the channel region [7]. Figure 1 shows basic structure of G^4-FET illustrating different region.

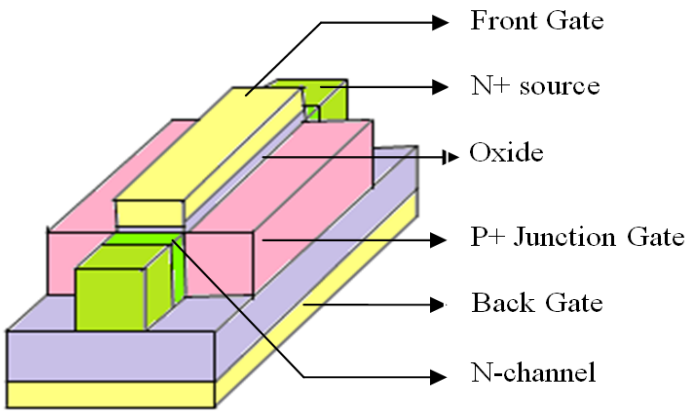

Figure 1 : G^4-FET Basic Structure (n-channel G^4-FET)

Application of a negative voltage to the top gate of an n-channel G^4-FET depletes the channel region. Negative voltages at JFET gates cause the PN-junction depletion region to broaden, further narrowing the channel. So both MOSFET and JFET like control is present in G^4-FET.

In partially depleted G^4-FETs, two distinct mode of operation are identifiable. In MOSFET mode, operation of G^4-FET is based on the front surface accumulation current controlled by V_{G1} . In this case V_{G2} and V_{JG} are parameters of the device [8]. Meanwhile in JFET mode, operation of the G^4-FET is based on the variation of the cross section of the channel (volume neutral current) controlled by V_{JG} while V_{G1} and V_{G2} are parameters inducing depletion or inversion at the front and back interfaces [9].

III. Modeling Accumulation Layer Thickness

The accumulation surface potential is given by the drops across the accumulation layer formed under the front oxide-silicon interface. Under fully depleted approximation, total charge can be approximated as

$$\rho(x,y) = qN_D.$$

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

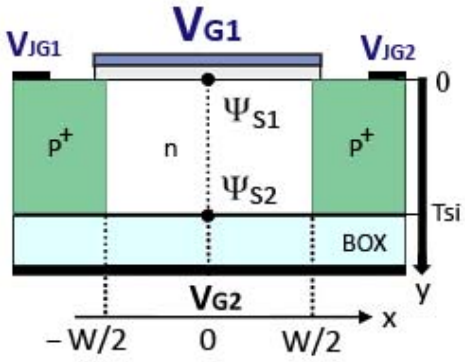

Figure 2 : n-channel G^4-FET cross section

Then the 2D Poisson equation is given by,

$$\frac{d^2\Psi}{dx^2} + \frac{d^2\Psi}{dy^2} = -\frac{qN_D}{\epsilon_{si}}$$

Assuming,

$$\Psi(x,y) = ax^2 + bx + c \text{ ... (1)}$$

Potential at the centre of bulk Silicon in G^4FET,

$$\Psi(-W/2,y) = \Psi(W/2,y) = V_{JG} - \varphi_B \text{ ... (2)}$$

So from (1) and (2),

$$\frac{d^2\Psi}{dx^2} = -\frac{8}{W^2}\Psi + \frac{8}{W^2}\left(V_{JG} - \varphi_B\right) \text{ ...(3)}$$

After some mathematical calculation,

$$dy = \frac{d\Psi}{\sqrt{\left\{\frac{8}{W^2}[\Psi^2 - 2(V_{JG} - V_P)] + C\right\}}} \text{ ... (4)}$$

Where, $V_P = \varphi_B - \frac{W^2 qN_D}{8\epsilon_{si}}$

Integrating from surface of bulk Silicon to accumulation layer thickness (0 to y_{acc}) at the front gate centre,

$$y_{acc} = \frac{W}{2\sqrt{2}}\left[\sinh^{-1}\left\{\frac{\Psi_{s1} - V_{JG} + V_P}{\zeta}\right\} - \sinh^{-1}\left\{\frac{V_P - V_{JG}}{\zeta}\right\}\right] \text{ ... (5)}$$

Here, $\zeta^2 = \frac{W^2}{8}C - \left(V_{JG} - V_P\right)^2$

IV. Introducing Geometric Factor (G)

A charge sheet model was proposed [10] to analyze the behavior of fully depleted SOI four gate field effect transistors (G4-FET) above the threshold condition. That model was derived assuming parabolic potential variation between junction gates and by solving 2-D Poisson's equation. Using the charge sheet model current-voltage characteristics were analyzed. Different back surface conditions were considered for each analysis. The models were compared with 3-D Silvaco/Atlas simulation results. They showed pretty good agreement most often. But observing each characteristic for different back gate conditions, it was found that models barely follows the simulated results for back gate inversion condition even in depletion. This section is going to investigate the reason behind this matter and search for a remedy to overcome the discrepancy. Here the device physics is been rethought from different angles as well as reconsider some neglected phenomena which are no longer negotiable for an inverted back gate bias.

A. *Problem with Usual Assumption on Charge Distribution in Bulk of Device*

The accumulation layer thickness is a function of front gate biases and junction gate biases for different back surface charge conditions. While full depletion approximation is used model, that is derived and stated in previous section (Equation 5) shows good agreement with simulation results, from onset of accumulation to the point where strong accumulation is achieved. The layer thickness becomes constant at strong accumulation.

With classical physics the foremost wrong was to assume the Silicon body is still depleted fully when back gate is in moderate or strong inversion mode. Obviously this assumption makes the analysis comparatively simpler as analytical model is derived through 2D Poisson equation, that has charge quantity on the right hand side. When fully depleted body is considered the charge density associated is simply given by $\rho(x,y) = qN_D$. But with a moderate inversion condition, this quantity is no longer valid. Moreover in case of a strong inversion at back surface, the sum of charge, encircled by the body may be the opposite (from +ve to –ve in n-channel / from –ve to +ve in p-channel) to that of in depleted back gate case. Thus fully depleted body assumption is no longer valid for inverted back surface potential.

The uniformly distributed charge assumption lessens the complexity of device electrostatics as well as electromagnetic. That assumption is pretty much valid with small front and junction gate bias (near zero) and sub-threshold condition (very small drain bias, nearly zero) while back gate is depleted. But an inverted back surface ends the validity of this assumption. Uniform charge distribution is hampered by each and every electrodes of the device on prior of bias voltage value.

B. *Geometric Factor (G)*

With an inverted back gate potential neither the fully depleted idea nor the uniform charge distribution is appropriate or acceptable. So the charge distribution phenomena need to be modified for using 2D Poisson equation. But it is very difficult to consider all the electrostatic and electromagnetic phenomena, involving in a device structure and then transform them into mathematical representation. Thus different assumptions have been made usually while analysis (as was the fully depleted body assumption), until the assumption results significant scale of error.

So it is required to rethink and reconsider the charge distribution fact. One thing is to keep in mind that there is not enough scope to consider one electrode and find its effect on non-uniformity as it is a nano range device and all electrodes' effects are interconnected.

One way to reconsider the charge density is to modify the doping density (N_D). When back gate inverted, no longer uniform charge distribution, charge density $\rho(x,y) = qN_D$ is violated. As charge is quantized, it can be called as "effective doping density" (N_D^{eff}) for inversion operation. The modified doping density modifies the charge density that will ultimately compensate the non-uniform charge and the error of fully depleted body assumption as well.

Now, consider a cross section of G4FET. Cross section of this plane has four electrodes - two junction gates, front gate and back gate .This is an n-channel device. The back gate has a high negative bias thus back surface is in strong

inversion. Junction gates have small negative bias. The charge profile is shown in figure 3 approximately. Clearly charge is non-uniformly distributed across the plane. Let the doping density of the body is N_D.

For a given V_{JG}, the charge condition at the back interface is governed by V_{G2}. Back gate bias can be represented by the following equation.

$$V_{G2} = V_{FB2} + \left(1 + \alpha\frac{C_{jg}}{C_{ox2}}\right)\Psi_{s2} - \gamma\frac{C_{jg}}{C_{ox2}}\Psi_{s1} + (\gamma - \alpha)\left(\frac{C_{jg}}{C_{ox2}}\right)(V_{JG} - V_P)$$

The back surface point, which is at mid-width between the junction gates, reaches accumulation for $V_{G2} \geq V_{G2}^{acc2}$ and is in inversion for $V_{G2} \leq V_{G2}^{inv2}$ [12].

$$V_{G2}^{acc2} = V_{FB2} + (\gamma - \alpha)\left(\frac{C_{jg}}{C_{ox2}}\right)(V_{JG} - V_P)$$

$$V_{G2}^{inv2} = V_{FB2} + \left(1 + \alpha\frac{C_{jg}}{C_{ox2}}\right)2\phi_F - (\gamma - \alpha)\left(\frac{C_{jg}}{C_{ox2}}\right)V_P + (1 + \gamma\frac{C_{jg}}{C_{ox2}})V_{JG}$$

That is the minimum back gate voltage that, make the back surface onset of inversion. Now with the increase in back gate voltage more charges gradually pile up at the back gate surface.

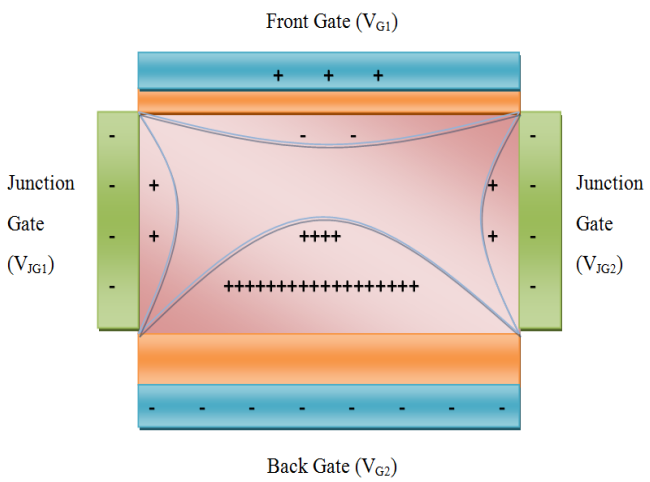

Figure 3 : Charge Profile in n-channel G4FET Cross Section.

Near the back surface in inversion, average charge per unit area can be given as

$$Q_{Bulk} = -(V_{G2} - V_{G2}^{inv}) \cdot C_{OX2}$$

where ,

$$C_{OX2} = \square_{OX2}/t_{OX2}$$

So, average charge density throughout the bulk Silicon can be given as

$$Q_n = Q_{Bulk} / t_{Si}$$

It is important to note that while finding the charge density the charge per unit area has been divided by t_{Si}. This implies that Q_{Bulk} is considered to be the charge per unit area along the whole Si thickness i.e. throughout the bulk. But it is not true, as earlier the non-uniformity of charge has been emphasized. To compensate for this assumption, geometric factor (G) has been introduced. Geometric factor (G) can be given by the following equation.

$$G = \frac{(1 + aV_{G1})(1 + c|V_{G2}|^r)}{1 + \frac{1}{(1 + |V_{JG}|)^b}}$$

Without considering this geometric factor, effective doping density

$$N_D^{eff} = Q_n / q$$

Where, q = charge of an electron =1.6 x 10^{-19} C

Taking the geometric factor into consideration,

$$N_{inv} = Q_n / qG$$

The name "geometric factor" represents that G is a mathematical way to indicate geometric area for both depleted and inverted charges. An increase in the value of G, due to the increase in bias voltage, results in more non-availability of space for both depleted and inverted charges.

Empirical constants (a,b,c,d) are dependent on the device design parameters and geometric structure as well. With proper modification of these constants or finding the dependency of these constants on the design parameters, proposed geometric factor can be used in wide range of device operations.

V. Numerical Verification

Fully depleted body approximation is applicable when the device is operating in depletion mode, so model obtained from this assumption considering classical physics cannot be applied for all bias conditions and modes of operation. Though until the onset of inversion this model is in good agreement with simulation result, when back gate is in inversion mode, the device shows significant deviation from assumed fully depleted Model [11].

In this section, the proposed model (with geometric factor) to include inversion effects, will be numerically verified. For all the simulations used device parameters are: Channel width, W=120nm; front oxide thickness, t_{ox1} = 5nm; back oxide thickness, t_{ox2} = 50nm; silicon body thickness, t_{si} =40nm; channel doping concentration, $N_D=10^{17}cm^{-3}$; silicon body doping concentration, $N_A=10^{20}$ cm^{-3}.

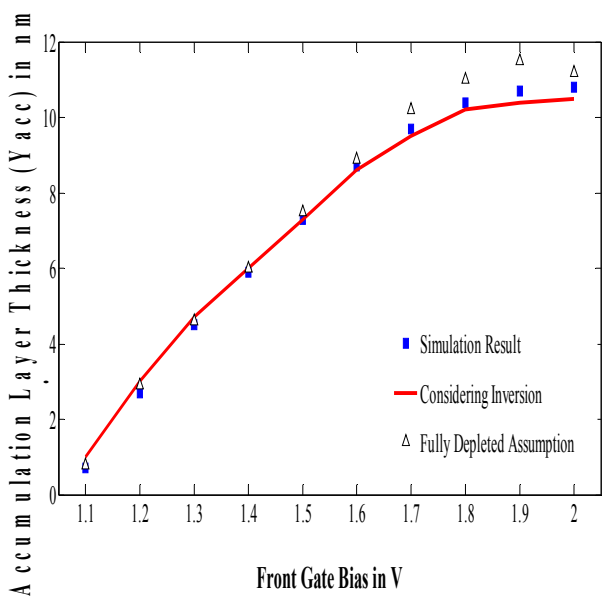

Figure 4 : Comparison between Inversion Model, Depletion Model and Simulation Result (Back gate bias -10V)

Figure 4 illustrates the simulation result along with the model results (both depletion assumption and considering inversion effects) for accumulation thickness for varying front gate bias while a back gate bias of -10V is applied. It is apparent that with lower front gate bias, depletion Model is fairly accurate. It can be deduced that, at -10 V device is not even at the onset of inversion and with a low voltage at front gate, not significant level of inversion occurs. So, fully depleted approximation is valid enough. But at higher front gate bias full depletion assumption wear out.

With a back gate bias much high (V_{G2} =-20V), device is in moderately strong inversion region. So, uniform charge distribution and fully depleted condition are no longer valid. In Figure 5 depicts the compatibility of Model considering inversion with simulation result much better than Model considering full depletion.

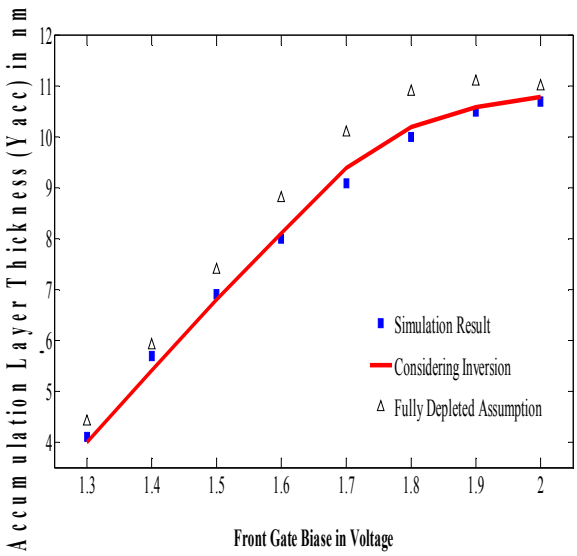

Figure 5 : Comparison between Depletion Model, Inversion Model and Simulation Result (Back Gate Bias -20V)

Figure 6 plots Inversion Model at -20 V back gate bias varying junction gate bias. It is apparent that simulation result is fairly in accord with the deduced model. Percentage of error is significantly less for model considering inversion.

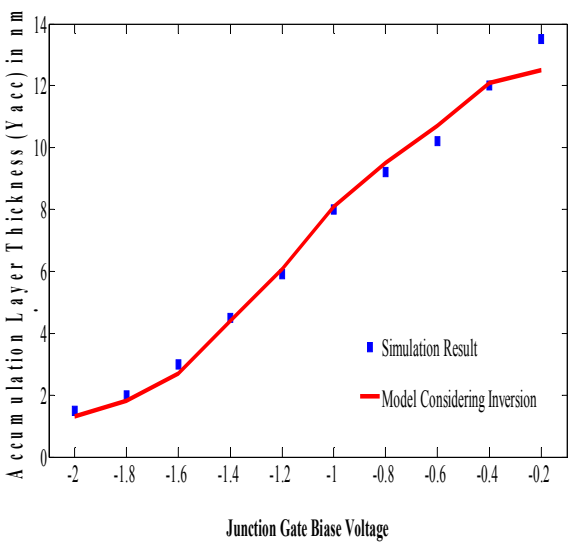

Figure 6 : Accumulation Layer Thickness Vs Junction Gate Bias (comparison between different models and simulation result)

VI. Conclusions

The proposed model that includes geometric factor provides enough satisfactory results in case of inverted back surface and depleted back surface as well. The Stronger the inverted back surface, the more compatible the analytical model with the numerically simulated ones. Most importantly the bias voltage dependent geometric factor gives us the scope for considering dynamic charge profile with the change of bias voltage in different electrodes of the device. With proper modification and improvisation of this factor, it is possible that, analysis of any device with any structural parameter will be much error free in any operating conditions.

***Abstract*— Traditional imaging has been limited to the visible spectrum that humans can see. Imaging technologies are transcending into the invisible spectrums in the infrared (IR) region to enable imaging beyond human vision. We highlight the capabilities and advantages and therefore the value of IR imaging focused primarily on shortwave IR (SWIR) with some elements of long wave IR (LWIR) over the visible spectrum (VIS). We present an overview of SWIR and LWIR device structures based on InP and HgCdTe devices for the respective bands. We also highlight our development of a high-performance multispectral camera system for VIS-SWIR imaging for the most demanding high-sensitivity and high-speed commercial and industrial applications. The 640x512 pixel VIS-SWIR camera system is designed to provide a compact, small-form factor to within a cubic inch, high sensitivity needing less than 100 electrons, high dynamic range exceeding 190 dB, and high-frame rates (>1000 FPS) at full resolution.**

***Index Terms*—** Infrared, camera, multispectral, VIS-SWIR, InP, InGaAs, HgCdTe, MCT, FPA, high-performance

I. INTRODUCTION

Traditional imaging has been closely tied to human vision so that whatever our eyes could see, process and interpret naturally were our limits. Science and technology has over the decades developed other forms of non-visual imaging including radio frequency and thermal signatures, but the most prominent unnatural mode of imaging to emerge has been infrared (IR) imaging. IR has blossomed on a slow trajectory in technical fields and especially in military applications, and in recent years due to various strides in materials, devices and technologies, IR imaging is steadily finding applications and adoption in commercial and industrial applications.

The extension of imaging system sensitivity from the visible (VIS) spectrum into the IR region has the potential to bring tremendous improvements and new capabilities to dual-use commercial and industrial imaging systems that are already standard in defense imaging applications. However, even as IR imaging systems are becoming commercially available from a number of companies with applications as diverse as security, biological imaging, and agricultural processing, the benefits, advantages and ultimate value over visible imaging is not well understood by target users. Furthermore, existing infrared imaging technologies are still very expensive. At costs in the tens of thousands of dollars per camera [1], it is difficult to make a strong case for its necessity and value as a precursor for penetrating high-volume commercial markets. Last, but no least, to make imaging beyond human vision practical, IR imaging needs to achieve high-performance, small form-factor or reduced size, weight, power and cost effective imaging units suitable for broader adoption.

This paper provides an overview of IR imaging sensors that will extend human vision beyond the limited capabilities provided by solid-state silicon-based image sensors (CCD/CMOS) already in wide use for the visible spectrum. Specifically, we discuss short wave IR (SWIR) sensors using InP devices and long wave IR (LWIR) sensors implemented with mercury cadmium telluride (HgCdTe or MCT) devices. We provide an assessment of the value that IR imaging in the SWIR and LWIR bands provides over the visible (VIS) spectrum by taking a close comparative look at capabilities and performance in a variety of environments including, haze, fog, smoke, and clouds. In addition to presenting device structures for IR sensors extending imaging to broadband or multispectral coverage, we also discuss high performance requirements for IR imaging, emerging applications and trends, strategies for their mass adoption as well as the challenge and opportunities with bearing to our activities in developing a high-performance multispectral camera system for dual-use applications.

II. TRADITIONAL HUMAN VISION – STANDARD VISIBLE IMAGING

Solid-state image sensors have become commonplace in everyday commercial applications including digital cameras, smartphones, automotive sensors, security and surveillance systems, and novel medical applications such as a pill-sized camera that could replace colonoscopy for cancer detection, to name a few. Such imaging sensors typically comprise of CCD (charge coupled device) or CMOS (complementary metal oxide semiconductor) image sensors with associated switching elements, and address (scan) and read out (data) lines [2]. Both CCD and CMOS image sensors are fabricated from silicon (Si) technology, which is so matured today that several millions of pixels and surrounding circuitry can be fabricated in small devices quite cheaply. The number of sensors and the variety of functions they perform is also increasing largely due to the proliferation of the CMOS sensor, which has become the de facto image sensor displacing the CCD sensor, primarily due to its low cost.

CMOS has also been great in increasing imaging resolution into multiple megapixels while also becoming more compact into smaller form factor and achieving pixel sizes as small as few micron, the smallest to date. The advantage has been the ability to achieve high definition imaging at the consumer level with devices that are as small as the tip of your finger and at nearly disposable cost structures.

The CMOS sensor has closely emulated human vision with its ability to image in the visible spectrum generally with good performance between 0.4 to 0.9 μm with the availability of good lighting. However, as CCD and CMOS image sensors technology are based on Si-technology, the detectable spectral ranges are limited to wavelengths below 1 μm where Si exhibits absorption. Besides that, CCD and CMOS image sensors also have other shortcomings such as lower responsivity combined with lower quantum efficiency over broad spectral range. Therefore when the light level begins to deteriorate in low visibility situations such as fog, haze, smog, and especially night time, CMOS performance drops

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

drastically. This is because silicon's absorption only extends to 0.9 μm, its cutoff wavelength and thereafter becomes blind.

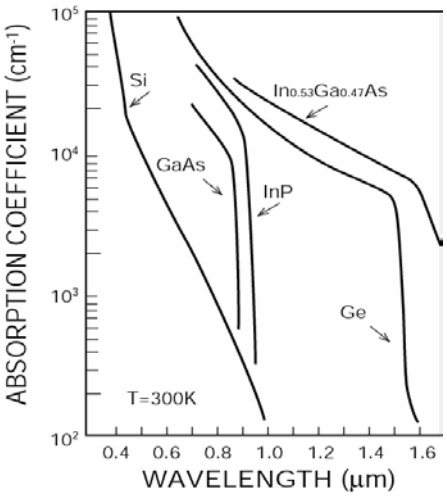

Figure 1: Dependence of the absorption coefficient on the wavelength for different semiconductors used in image sensors.

It is at this point where alternative imaging technologies come into play using other materials with capabilities beyond silicon's absorption wavelength and therefore beyond human vision.

Figure 1 shows the dependence of the absorption coefficient on the wavelength for different semiconductors used in photodetectors. Absorption has asymptotic behaviour near bandgap wavelength λ_g where the material is transparent, and there is a strong dependence of the absorption on the wavelength shorter than λ_g.

III. EXTENDED HUMAN VISION – FROM VISIBLE TO SWIR IMAGING

As we shift from the visible spectrum into increasing wavelengths, we get into the IR spectrum, which is itself made up of several bands from near IR (NIR) into SWIR, mid wave IR (MWIR) and LWIR. Through a selection of materials with absorption at appropriate wavelengths, we are able to fabricate image sensors with capabilities within the various bands. VIS is the 0.4 to 0.7 μm band, NIR is the 0.7 to 1.0 μm band, and SWIR is 1.0 to 1.7 μm band.

Below we discuss imaging capabilities across various environmental conditions which primarily compares and contrasts the visible spectrum with the SWIR spectrum and therefore highlighting the benefits and advantages offered by the ability to see beyond normal human vision.

III.1 Atmospheric Transmission: Atmospheric transmission, which includes light absorption and scattering through various types of atmospheric conditions, provides a good reason to move imaging towards longer wavelengths in the reflective bands. Atmospheric transmission ranges from the less challenging types such as the U.S. and Arctic, weighted more heavily on light scattering, to the more challenging atmospheres that are more visually degraded such as tropical, desert, and desert dust storms, which have more absorption. At the longest ranges, where range measures the distance between sensor and target, the SWIR band can have 10 times (or 10x) the atmospheric transmission of the VIS band. This is even more pronounced in better atmospheres as scattering is more important and less absorption occurs. Long range and low visibility makes for SWIR transmission that can be 100x and even as high as 1000x the transmission of VIS [3]. Atmospheric transmission or penetration clearly favors SWIR and then NIR over VIS imaging.

In studies [4] comparing the performance of VIS-NIR systems against SWIR, performance has been shown to be similar under good atmospheric conditions meaning with visibility up to 23 km. However, as atmospheric conditions are degraded for example with visibility at 6 km, VIS-NIR system exhibit severely poor performance compared to SWIR systems, which is consistent with the conclusions that SWIR imaging is the best band for long range and therefore also for degraded atmospheric spectral discrimination.

III.2 Imaging Through Haze: Haze is a commonly occurring visually degraded environment due to a variety of small particles that cannot be seen or felt individually, but on aggregate diminishes horizontal visibility. Haze is differentiated from fog by its optical density. It has an optical density of less than 2 per km at a wavelength of 0.55 μm while fog has a higher optical density. Haze is made up of water and dust particles that are small (diameter ~0.1 μm) that in effect reduces scattering at longer wavelengths. The optical density of Haze reduces at longer wavelength. As such there is a marked advantage to imaging through haze with SWIR sensors, which have longer wavelengths over VIS sensors whose shorter wavelengths result in much higher optical density and therefore difficulty penetrating though haze as illustrated in Figure 2.

Figure 2: Imaging through Haze with VIS sensor (left) and SWIR sensor (right).

III.3 Imaging Through Fog: Fog is comprised of water particles that are larger than those of haze. In addition, these particles are constantly larger than VIS, NIR and SWIR wavelengths. As such there is little difference by wavelength and therefore not much advantage between VIS and SWIR sensors in penetrating fog since the larger particles scatter light in a manner that results in the same optical density for both bands. However, moving to longer wavelengths, which exceed the large particle diameter, i.e. LWIR sensors are capable of penetrating fog and overcoming the VIS/SWIR limitations.

III.4 Imaging through Clouds: Understanding sensor performance through cloud cover is important especially for sensors operating in high altitude. Cloud has essentially larger water particles, behaves in much the same way as fog except at higher altitudes with the same impact on VIS, NIR

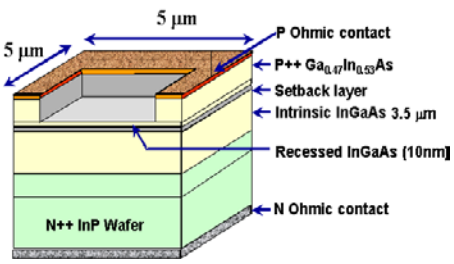
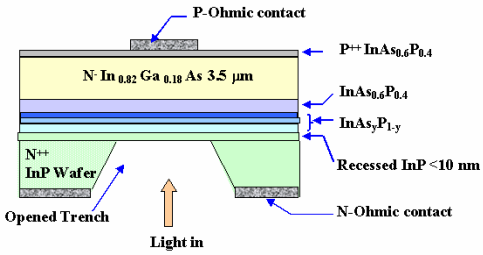
Figure 3: Comparison of VIS, SWIR & LWIR Imaging Capabilities.

and SWIR. However, NIR and SWIR exhibit an advantage over VIS in that they can image around clouds meaning demonstrating the ability to image through the gaps between clouds. Such gaps behave in the same way as haze with smaller particles than the clouds and therefore a marked benefit to SWIR imaging.



(a) Top-illuminated type photodetector



(b) Bottom-illuminated type photodetector

Figure 4: The schematics of a pin photodiode with recessed (a) top contact layer and (b) bottom contact layer for allowing penetration of incoming photons

III.5 Imaging Through Smoke: Smoke is a recognized obscurant used as a battlefield cloaking technique. It is also essential to be able to penetrate smoke as it is a common hazard in forest, industrial and residential fires. The optical densities of smoke are driven by smoke size particles with many approximately or less than 0.1 µm in diameter. The type of smoke also matters; smoke that appears white is mostly scattered light, for example in forest fires burning wood, whereas smoke that appears black is caused by both scattering and absorption of light, for example in burning oil. Due to the particle sizes, the advantage for imaging through smoke both white and black is for longer wavelengths. Black smoke has a higher optical density due to both scattering and absorption, while white smoke has a smaller optical density. Both white and black smoke optical densities reduces significantly with wavelength and a marked advantage and benefit is provided by SWIR sensors over NIR and VIS.

III.6 Imaging Camouflage, Background, and Target Contrast: Another area of interest and differentiation is background contrast, which is important for driving, navigation, pilotage, situational awareness and search. NIR and VIS reflectivity are quite similar; however material reflectivity is very different for SWIR and even further differentiated by environment whether urban or rural. In urban environments, while there are contrast differences between VIS and SWIR, they are overall very similar. On the other hand, in rural environments, vegetation has a much higher reflectivity in SWIR and most images look very bright with very few low reflectivity objects, suggesting contrast not as varied in SWIR as it is in VIS. Figure 3 summarizes the imaging capability at various wavelength bands.

IV. DEVICE STRUCTURES- SWIR

IV.1 Broadband Photodetector Structure: The SWIR imaging device structure consists of *InGaAs* (lattice matched to *InP*) as a absorption layer, and an ohmic contact layer which does not absorb significant number of photons, the photodetector can be used in wide spectral regions covering from near *UV to 1.7 µm*, and can be extended its detection capability to *2.5 µm* by varying the *InGaAs* composition. Figures 4(a) and 4(b) are the cross-sectional views of the top-illuminated and bottom-illuminated type devices, respectively. The devices can offer quantum efficiency (QE) of more than *90%* at *1.6 µm* wavelength. The diode can be designed in circular or square in shape. The buffer layers with graded composition of $InAs_yP_{1-y}$ are placed between absorption layer $In_{0.8}Ga_{0.2}As$ and the substrate *InP*. This dislocations bend at step interface of each graded layer and are disturbed to enter into the next layer. So it is very effective to reduce the dislocation density in the lattice mismatch materials [5], [6]. The epi-layer is grown on a highly doped *n-InP* wafer and the n-ohmic contact is placed at the bottom of *n+ InP* wafer. With varying the InGaAs composition, the proposed detector's sensitivity can be extended to UV to 2.5 µm. If we consider absorption of $In_{0.8}Ga_{0.2}As$ material is 5000 /cm at cut-off of 0.47 eV, this device is estimated to be > 80% at 2.5 µm of illumination for 3.5 µm thick absorption layer. This device can also have lower wavelength absorption into down to 0.4 µm. In effect the sensor device becomes a VIS-SWIR device with multispectral capabilities able to image in all lighting and weather conditions in a single monolithic device.

V. IMAGING DEVICES- MWIR/LWIR

Another alternative to the CCD/CMOS sensor is the capability to image beyond the capabilities afforded by a SWIR image by using materials that absorb longer wavelengths MWIR/LWIR. One such viable material is Mercury cadmium telluride (MCT), which is capable between 1 µm and 12 µm.

V.1 HgCdTe Device Structure: Planar or mesa schemes

are the most frequently used photodiode architectures in HgCdTe detectors for LWIR imaging devices (Figure 5). HgCdTe detectors are typically broadband, and by varying compound composition the spectral band can be selected. Further, if backside substrate is removed, potentially the detector could response to visible light. Generally however, HgCdTe detectors are designed as broad band sensors responding in NIR to VLWIR; 1.7 to 2.5 µm, 3 to 5 µm, 8 to 12 µm and 12 to 17 µm spectral bands. The base active layer generally doped n-type with a concentration ~ 1 x 10^{15} cm^{-3}. The cap layer is doped p-type ~ 5 x 10^{17} cm^{-3} and has a wider bandgap than the base layer (Δx ~ 0.06). Growth of a single type (n-type or p-type) HgCdTe layer permits the fabrication of planar diodes. If the base layer is grown n-type, a group V element such as Arsenic is then used to form the p-type region. Arsenic is implanted in selected regions and annealed to form a planar p+ on n diode architecture [7], [8]. To activate the As-pocket implants regions, annealing has to be done under Hg-overpressure [8]. When both n and p type layers are grown prior to diode delineation, the only diode architecture permitted is a mesa scheme. Speaking briefly to n-on-p cases, when the base layer is grown p-type, boron implantation is typically employed in selected regions to form n-on-p planar diodes [9]-[11]. In both cases, the device structure is known as double layer heterojunction structure (DLHJ).

The choice of detector architecture determines the type

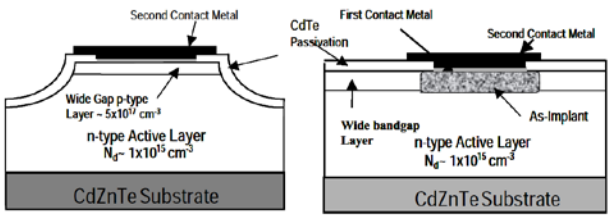


Figure 5: (a) (left) p+ on n mesa diode and (b) (right) p+ on n planar diode.

of dark currents that impact detector performance. The dominant current mechanisms for this specific case are diffusion current from the field-free bulk active layer side, generation-recombination current in the depletion region along with band-to-band or trap-assisted tunneling currents. The double layer heterostructure architecture coupled with recent improvements in passivation techniques have reduced the impact of surface tunneling currents and with the state-of-the-art quality MBE-grown HgCdTe have reduced G-R, tunneling currents [12], [13]. The R_oA product and QE(η) were taken as the figure of merit in order to maximize the detector parameters. Normally, detectors are AR-coated to reduce the reflection losses due to CZT back interface. The reflection loss from the back CZT interface is 21% while from the back of a Si substrate reflection loss is 30%.

VI. HIGH PEFORMANCE MULTISPECTRAL IMAGING SYSTEMS

We at Banpil established a long history of innovation in the optical imaging space having pioneered multispectral imaging through innovations in novel devices that combine visible and infrared imaging in the same monolithic sensor device. Our imaging device innovations and development progression towards next generation image sensors have previously been discussed [14]–[31]. We demonstrated linear arrays and 2-dimensional (2-D) array sensors including devices with micro-nano pillars (nano rods or wires) to increase sensitivity over standard image sensors as well as increased the absorption spectra. We have developed several generations of Focal Plane Array (FPA) with a wide spectral range from 0.35 µm to 1.7 µm, and as already discussed with a target to extend to 2.5 µm.

VI.1 Banpil Camera System Specifications: Banpil's high-performance camera [32] is an extended VGA 640x512 pixels imaging system. It consists of several innovations with foundations in our multispectral imaging technologies comprising of: (1) a high sensitivity FPA with low dark current; (2) a power-efficient multipurpose ROIC that is dynamically reconfigurable in supporting advanced high-sensitivity FPAs; and (3) an advanced reconfigurable multispectral camera with optics, electronics and embedded software**,** which by utilizing the innovations of the Banpil FPA and ROIC components could support applications with capabilities in both day and night without illumination, in all weather and visibility conditions, and all at optimally minimum SWaP-C. These characteristics and its attractive low-cost scheme position the Banpil camera system for dual-use applications in commercial and industrial sectors.

At the core of Banpil's low-cost VIS-SWIR camera is a fourth-generation Banpil developed high-performance InGaAs image sensor chip hybridized with a CMOS-based ROIC component chip with additional image processing functions integrated into the camera system specifically for use in high-performance applications. The Banpil camera provides features with emphasis on high sensitivity, high-speed (>1000 FPS), and high dynamic range (190 dB) that differentiate it from current SWIR cameras. It boasts a high-sensitivity over a broad spectral range (0.35 - 1.7 µm optionally extendable to 2.5 µm) with the ability to support poor visibility below 0.0001 lux and night vision (moonless night) as a VIS to SWIR camera. SWIR cameras today exclusively cover the SWIR region with the visible spectrum covered separately by conventional cameras. The Banpil VIS-SWIR camera has an exceptionally high dynamic range exceeding 190 dB, allowing unencumbered image processing capabilities in rapidly changing scenes e.g. from high brightness to darkness, and high quantum efficiency (>80%) consistently maintained well beyond the peak.

VII. EMERGING APPLICATIONS

The low-cost high-performance camera with its unique features and capabilities will enhance some existing applications as well as enable some emerging applications in commercial sectors. Multispectral imaging such as VIS-SWIR has significant advantages over conventional low light level imaging approaches, providing increased sensitivity and capturing unique target characteristics associated with the SWIR spectral band and thereby enhancing human vision. For instance, a SWIR camera exploits night glow to illuminate objects with great clarity on moonless nights. In addition to sensitivity advantages, SWIR imaging adds the capability to convert illumination outside the spectral range of conventional low light level devices; the capability to detect hidden and camouflaged objects as highlighted earlier.

A low-cost high performance Banpil camera that is optimized for small form factor, weight and power (SWaP-C), will open up a new class of sensors to the intelligence, surveillance, and reconnaissance (ISR) capabilities of the warfighter in defense applications. Due to a procurement-

friendly price-point, virtually every warfighter in the field will be able to exploit enhanced imaging without the burden and exclusivity that limits them today.

In commercial and industrial applications, it is already understood that security, automotive, and medical imaging are beneficiaries of multispectral imaging. The key to adoption remains cost. The autonomous vehicle of the future and even the passive and active driver safety and assistance features of the present will become more robust with VIS-SWIR sensors that overcome the limitations of CMOS-based imaging with a low-cost high performance camera. Finally, there are numerous emerging applications such as aerial photography for agricultural crop management, low earth orbit remote sensing for environmental monitoring, less destructive, cost effective, and safer natural resource exploration methodologies, and many others that are ideal applications, but would not be traditional users of the current high-priced multispectral imaging technologies. These applications collectively will support a symbiotic relationship with the low-cost high performance camera as they will be growth sectors in years ahead which will en masse help drive down costs to be competitive with CCD/CMOS.

VIII. Challenges and Opportunities

In our analysis of the cost structure of the camera and the trends we see emerging with rising applications and increased volume, image sensor hybridization stands out as an obstacle to cost reduction that is yet to be addressed fully. The hybridization cost component remains high even as we achieve significant cost advantages on key component costs. In fact, we estimated that successful achievement of transitioning to high density devices, such as a 5 µm pixel pitch VGA device, will reduce components cost so much so that the hybridization cost will exceed component costs on a percentage basis. Our own R&D into improving the hybridization process in conjunction with our hybridization partners reveals that it is ripe for more automation and additional innovation to bring down costs.

There is an opportunity also in smaller pixel and larger format arrays. Banpil is already conducting R&D into 5 µm devices [18]. Even with larger formats such as 1280x1024 pixels to provide higher resolution imaging over VGA, there are still an increased number of die per wafer which provides a cost advantage. Additional innovation is required to balance the tradeoffs to preserve functionality at the pixel level with such a tight pixel area to maintain high performance and SWaP-C.

IX. CONCLUSION

We explained various imaging devices which could extend human vision, mainly limited to the visible spectrum, which is where standard solid state image sensors (CCD/CMOS) operate. By capturing wavelengths such as NIR, SWIR, MWIR, and LWIR (beyond human vision), these imaging devices based on InGaAs and HgCdTe can provide visibility through different spectral signatures which could not be possible by human vision. The advantages and therefore the value of these imaging capabilities based on several environmental conditions have been shown. We at Banpil Photonics have been developing VIS-SWIR and LWIR image sensors and their imaging systems through innovating novel imaging devices to achieve high performance. By adopting the innovations, techniques and strategies presented, we have successfully developed a SWaP-C camera system with functionalities that will provide a path to broader commercial adoption, more emerging applications, and ultimately enable significant strides in enhancing imaging beyond human vision.

Abstract— **Slow light has always been a topic of extreme interest for researchers and scientists in order to utilize the full potential of light in switching, memory devices and in quantum optics. However, slow light phenomena and its potential applications in switching and memory devices by tunable graphene based hyperbolic metamaterial have not still been introduced in literature. Here we theoretically propose and numerically analyze a graphene based tunable slow light device from the concept of controlling the group velocity of light in hyperbolic metamaterials. In THz range, graphene-dielectric stack can behave as hyperbolic metamaterials and hyperbolic metamaterials can demonstrate slow light phenomena while being cladded by air. By utilizing the tunability option of graphene, proposed devices can be made tunable, which is the most important criteria to manage the full advantage of slow light. It ultimately paves a fully new way to find novel applications in photonic switch, optical buffers and memory devices. Interestingly, in such graphene based devices, voltage will play a vital role to control the group velocity of light from slow to fast and the carriers are photons instead of electrons.**

***Index Terms*—Graphene, Slow light, Hyperbolic metamaterial**

I. Introduction

Slow light has always been a topic of extreme interest for researchers and scientist in order to utilize the full potential of light in switching, memory and quantum optics, where the full control of the speed of light is necessary [1]. In such devices, the term 'slow light' means light with very small group velocity [1]. On the other hand, in last ten years, hyperbolic metamaterials (HMMs) [2] have shown their extreme aptness and applications in plasma physics[3], exhibiting negative refraction [4], negative index [5], sub-wavelength imaging [6], nano-scale wave guiding [7], light confinement [8, 9], nonlinearity enhancement [9], biosensing [10] etc. And recently HMM has been introduced in solar application by using the slow light concept [11, 12]. Graphene which is a single atom thick two dimensional plane of carbon atoms forming a hexagonal lattice layer with a lattice constant of 0.264 nm [13] has manifested some fascinating electrical properties and devices[14, 15]. Now graphene is getting seriously engaged in enthralling applications of photonics and plasmonics, last of them being inaugurated in constructing HMM replacing metal [16, 17]. Due to tunability option of graphene, all the fascinating properties supported by HMMs are supposed to be boosted by a marginal range, which in recent literature is already being reflected [16, 17, 18]. Surprisingly slow light phenomena and its potential applications in switching and memory devices by graphene based hyperbolic metamaterial have not still been introduced in literature to the best ofour knowledge. Here in this paper, we describe such an enthralling physics and working principle of a novel tunable slow light device, where the device is controlled by voltage and the carrier is photon instead of electron. Such a device may find exciting application in photonic switch and memory devices, where voltage will play the role to control the speed of light from slow to fast.

II. Theory

There are two ways to engineer hyperbolic metamaterial structure: a) Multilayer realization consisting of alternating sub-wavelength metal and dielectric layers. b) Metal nanowires in a dielectric host. Uniaxial anisotropic metamaterial can be identified by the permittivity tensor.

$$\boldsymbol{\varepsilon} = \begin{bmatrix} \varepsilon_{||} & 0 & 0 \\ 0 & \varepsilon_{||} & 0 \\ 0 & 0 & \varepsilon_{\perp} \end{bmatrix}$$

These uniaxial materials can show hyperbolic dispersion if they satisfy the condition $(\varepsilon_{||}\varepsilon_{\perp}) < 0$

For metal dielectric alternating metamaterial structure, as long as the length of one unit cell consisting of one metal and one dielectric layer is less than the wavelength of light used, we can employ effective medium theory.

By effective medium theory we get,

$\varepsilon_{\parallel} = f\,\varepsilon_m + (1-f)\varepsilon_d$ where $\varepsilon_{\parallel}$ is the effective permittivity in transverse palne and $\varepsilon_{\perp} = \left(\frac{f}{\varepsilon_m} + \frac{(1-f)}{\varepsilon_d}\right)^{-1}$ is the effeticve permittivity in propagation direction and $f = \frac{t_m}{t_d + t_m}$ is the filling ratio where t_m is the thickness of metal layer and t_d is the thickness of dielectric layer.

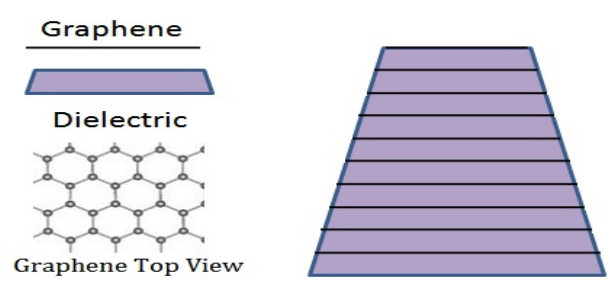

Fig. 1 Graphene-dielectric multilayer hyperbolic metamaterial considered in this work.

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

In case of graphene, at THz frequency range intra-band transition dominates. The effective permittivity of graphene can be obtained by two different ways. Frequency and chemical potential dependent conductivity of a monolayer graphene can be given by [16],

$$\sigma(\omega,\mu_c) = -\frac{j4\pi e^2 k_B T}{h^2(\omega - j2\mathcal{T})}\left(\frac{\mu_c}{k_B T} + 2\ln\left(e^{\frac{-\mu_c}{k_B T}} + 1\right)\right) - \frac{j4\pi e^2(\omega - j2\mathcal{T})}{h^2}\int_0^\infty \frac{f_D(-\xi) - f_D(\xi)}{(\omega - j2\mathcal{T})^2 - 16\left(\frac{\pi\xi}{h}\right)^2} d\xi \quad (1)$$

Where $f_D(\xi)$ is the Fermi Dirac function which can be given by, $f_D(\xi) = \frac{1}{e^{\frac{\xi-\mu_c}{k_B T}}+1}$

The permittivity of graphene dielectric metamaterial can be given by,

$$\varepsilon_\parallel = \varepsilon_\parallel' - j\varepsilon_\parallel'' = \varepsilon_d - j\frac{\sigma(\omega,\mu_c)}{\omega\varepsilon_o t_g} \quad (2)$$

$$\varepsilon_\perp = \varepsilon_d \quad (3)$$

Again the effective permittivity can be derived in following form effective medium approach,

$$\varepsilon_g = 1 - j\frac{\sigma(\omega,\mu_c)}{\omega\varepsilon_o t_g} \quad (4)$$

$$\varepsilon_\parallel = \frac{t_g\varepsilon_g + t_d\varepsilon_d}{t_g + t_d} = \varepsilon_d - j\left(\frac{\sigma(\omega,\mu_c)}{\omega\varepsilon_o t_d}\right);\ t_g \ll t_d \quad (5)$$

$$\varepsilon_\perp = \frac{\varepsilon_g\varepsilon_d(t_g + t_d)}{t_g\varepsilon_d + t_d\varepsilon_g} \cong \varepsilon_d;\ t_g \ll t_d \quad (6)$$

Where k_B is Boltzmann constant, T is temperature, μ_c is chemical potential of graphene , h is plank's constant, , ω is angular frequency, $\mathcal{T}$ is phenomenological scattering rate (.1meV) , t_g is the thickness of graphene layer, t_d is the thickness of dielectric layer and ε_d is the permittivity of dielectric. As we can see, in graphene based HMM, $\varepsilon_\perp$ is always positive, so to satisfy $(\varepsilon_{||}\varepsilon_\perp) < 0$ condition, $\varepsilon_\parallel$ has to be negative which can be obtained at THz frequency for graphene based HMM. So in the THz frequency range, we can expect graphene-dielectric stack to act as a hyperbolic metamaterial.

As conductivity of single layer graphene is dependent on frequency, chemical potential and temperature, permittivity of a single layer graphene and consequently the parallel permittivity of graphene-dielectric anisotropic metamaterial possess the same dependence.

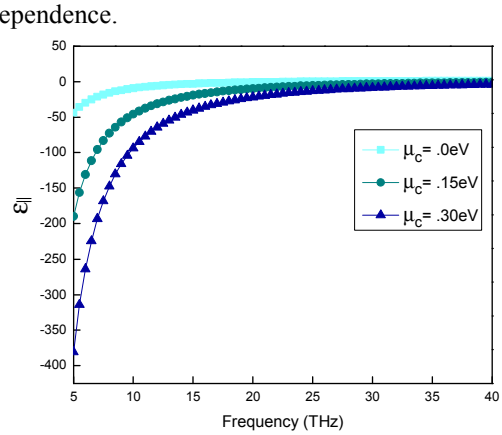

Fig. 2 Parallel permittivity (real part) of graphene-dielectric HMM for different chemical potential at different frequency.

Fig.2 shows the parallel permittivity of the anisotropic structure at different chemical potential vs different frequencies. As longitudinal permittivity of the structure is always positive, to obtain hyperbolic dispersion and also for securing slow light condition, parallel permittivity of the structure has to be negative. Fig.3 shows the permittivity of single layer graphene.

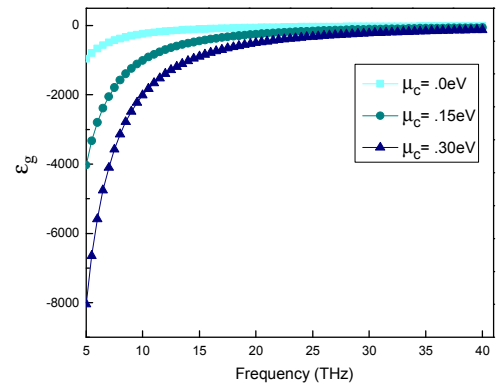

Fig. 3 Permittivity of graphene (real part) for different chemical potential at different frequency.

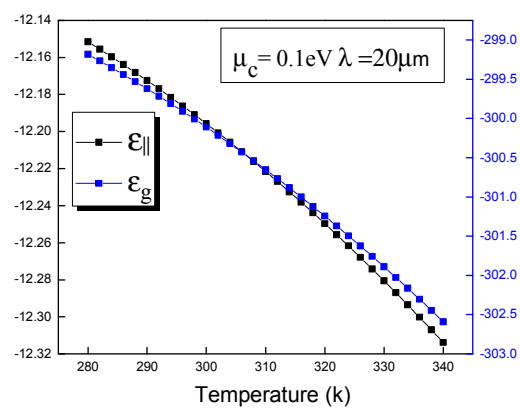

Fig. 4 Temperature dependent permittivity (real part) and parallel permittivity (real part) of graphene and graphene based HMM respectively.

Fig.4 shows the temperature dependence of parallel permittivity of the structure. To control slow light for switching effect, temperature might be used as a tuning mechanism but because of low temperature dependence of parallel permittivity, temperature controlled switch might not be possible. But for high temperature dependent signal generation, this structure might be used.

The most important parameter to change the parallel permittivity of the structure is chemical potential which can be changed by external dc field or gate voltage [18]. In this paper we will discuss the condition of slow light with respect to chemical potential; at last adopting the relation from [18] with gate voltage and chemical potential will show a relation of absorption and transmission with respect to gate voltage.

A waveguide filled with hyperbolic anisotropic metamaterial cladded by air [11, 12] or an air waveguide cladded by anisotropic metamaterial [19] can both exhibit slow light phenomena. It has been revealed that light can come to complete

standstill in hyperbolic metamaterial wave guide if the width of the waveguide is tuned to a certain value for a specific frequency or wavelength. This slow light phenomenon has been used to absorb ultra-broadband solar spectrum [11]. Necessary condition for complete standstill of light is identified by the condition when two propagating constants (forward and backward) come to a degeneracy point. For different wavelengths, the waveguide width at which light will be stopped will be modified. Solving a uniaxial anisotropic waveguide one can obtain the following equation for supporting even and odd TM modes respectively,

$$\frac{\varepsilon_{2z}k_1}{\varepsilon_1 k_2} = \tan\left(\frac{k_2 W}{2}\right) \; for\ even\ modes \qquad (7)$$

$$\frac{\varepsilon_{2z}k_1}{\varepsilon_1 k_2} = -\cot\left(\frac{k_2 W}{2}\right) \; for\ odd\ modes \qquad (8)$$

Where

$$k_1 = (\beta^2 - k_\omega^2 \varepsilon_{air})^{\frac{1}{2}}$$

$$k_2 = \left(k_\omega^2 \varepsilon_{2z} - \frac{\varepsilon_{2z}}{\varepsilon_{2\parallel}}\beta^2\right)^{\frac{1}{2}}$$

$$k_\omega = \frac{\omega}{c}$$

$\varepsilon_{air} = relative\ permeticity\ of\ air$, $\varepsilon_{2z} = \varepsilon_d\ from$ (6), $\varepsilon_{2\parallel} = \varepsilon_\parallel\ \ from$ (5), W is width of the waveguide.

In this work, we clearly show that slow light is not only dependent on the width of the waveguide but also the parallel and longitudinal permittivity. But why they were not mentioned so strictly in pervious works of slow light using hyperbolic metamaterial? Simply because using metal and dialectic, those values come naturally; there is no way to change to permittivity of the metal or dielectric at a certain frequency because every metal or dielectric has a specific permittivity at a specific wavelength. Though there is one option to tune the structure, which is the filling ratio of metal and dielectric but once the structure is fabricated there is no way to change the permittivity of metal or dielectric or width of the structure or filling ratio. So a hyperbolic structure built to stop light at a specific frequency or wavelength at a specific width will always stop light at that specific width of that specific wavelength or frequency. Light of that specific wavelength cannot simply pass through structure. But using graphene we can tune the permittivity of the structure after fabrication, why? Because permittivity of graphene is simply dependent on conductivity and that conductivity is dependent on chemical potential which can be tuned by external electric field or dc voltage. Though tuning the chemical potential might be difficult in this complicated structure (but by no means impossible [18]). In addition, we don't need a huge variation in chemical potential to disobey the condition for slow light. It means that a graphene-dielectric structure, which is tuned to stop light of specific wavelength, we can let that light to be a transmitting one by changing chemical potential. Thus we can make a photonic memory switch. So basically we can control slow light at our will.

III. Discussion and Results

Fig.5 demonstrates the temperature dependent slow light. It can be observed that the width of the waveguide which is required to achieve slow light is changed by temperature slightly. This is because the conductivity of graphene has weak temperature dependence which is indicated in fig.4 and consequently the parallel permittivity of the structure is also very slightly temperature dependent. So we conclude that temperature can't be a control mechanism for tuning slow light. So it is veritably not practicable to realize a photonic memory or switch with

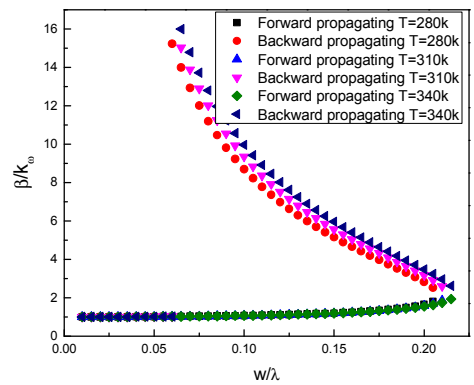

Fig. 5 Temperature dependent Slow Light , normalized propagation constant $\boldsymbol{\beta}$ as a function of waveguide width w for different temperature (T).

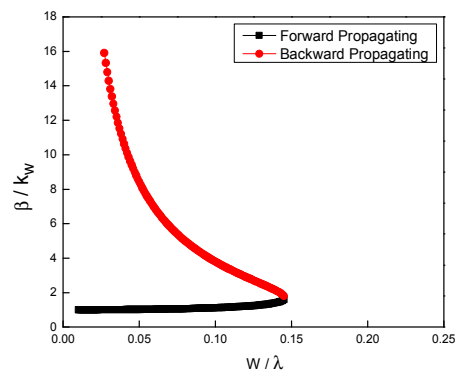

Fig. 6a Slow Light for Graphene based HMM, normalized propagation constant β as a function of waveguide width w. Light is stopped at a certain width where forward and backward propagating wave coincides, at zero chemical potential the permittivity of the structure is such that light stops at width $w = \sim.15\lambda$ where $\lambda =$ wavelength of the incident light.

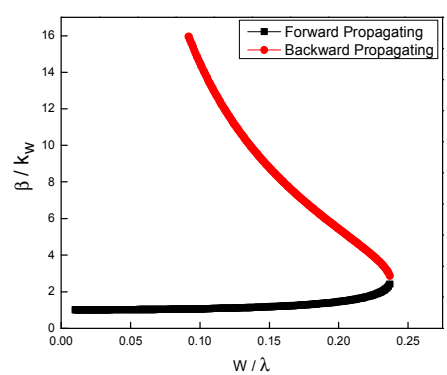

Fig. 6b Slow Light for Graphene based HMM, normalized propagation constant β as a function of waveguide width w. Light is stopped at a certain width where forward and backward propagating wave coincides, at .2eV chemical potential the permittivity of the structure is such that light stops at width $w = \sim.235\lambda$ where $\lambda =$ wavelength of the incident light ,thus violating the condition for slow light for zero chemical potential.

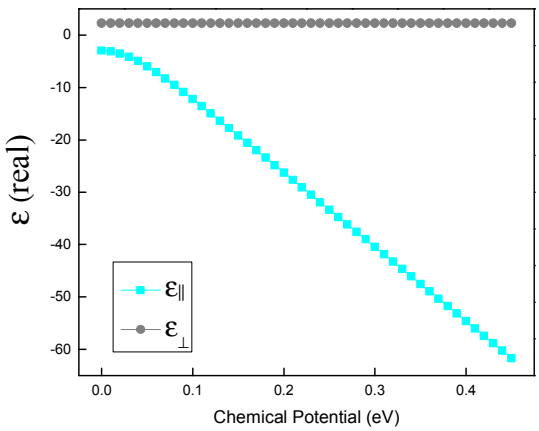

Fig. 7 Parallel and longitudinal permittivity (real part) of Graphene-dielectric metamaterial structure at different chemical potential.

temperature control but it may find application where temperature sensitive light device is obligatory.

Fig.6a and 6b clearly shows the chemical potential dependent slow light in graphene based HMM. At first we want to discuss the slow light mechanism for unbiased graphene or with zero chemical potential. In fig.5a the black and red line represents the forward and backward propagating waves respectively. When $\frac{\text{waveguide width}}{\text{wavelength of light}} = \sim.14$ light is stopped at that width. In the above example, we are using light of wavelength of $20\mu m$, then the width of the waveguide must be at least $20\mu m \times .14 = 2.8\mu m$ to achieve slow light condition. So now if we can change the permittivity of the structure then the width at which light would be trapped will be changed. Changing chemical potential of graphene will change the permittivity (parallel) (fig. 7) of the graphene-dielectric HMM structure. So the change of chemical potential will shift the trapped position to higher wave guide width. From fig.6b for .2eV chemical potential, for light to be trapped or stopped, the necessary condition is $\frac{\text{waveguide width}}{\text{wavelength of light}} = \sim.235$. So using previous wavelength of light of $20\mu m$, the width of the waveguide must be at least $20\mu m \times .235 = 4.7\mu m$

Now let us consider a rectangular waveguide which has the necessary width to trap light of a specific wavelength at 0 chemical potential. If we change the chemical potential from 0 to any higher value, then the waveguide doesn't have the required width to trap light. So the condition for light to be trapped is not satisfied and so light will be transmitted. Thus the device can act as a switch or photonic memory device.

IV. Conclusions

In this work, we have briefly pointed out the possibility of tunable slow light by using a graphene based hyperbolic medium. As graphene is actively tunable, the device is also tunable. Slow light is itself a fascinating phenomenon. Active tunability in order to achieve complete stopping of light and letting it transmit again via gate voltage may pave the way to future voltage controlled phonotic memory devices. The control mechanism will be gate voltage and the carriers will be photons. Group velocity of the photons will be controlled by gate voltage. In future, such devices may ultimately pave a fully new way to find novel applications in photonic switch, optical buffers and memory devices replacing current technologies.

***Abstract*—A quantum mechanical approach of first order born approximation is taken to numerically model AlGaAs/GaAs Quantum Well Infrared detector that operates at long wavelength region (8-9μm). Our numerical analysis of the photocurrent spectra as well as the broadening of the same at 8.31μm peak wavelength is found to be in close resemblance with the experimental result with 8.55μm peak wavelength as reported by Alves et. al. We have gone one step further by subsequently exploring the photo-response behavior of QWIP at the limit of strong electron-photon interaction and found that, besides the modification in photo-current spectrum in terms of relative magnitude and spectral shift, the strong non-linear photo-response enforced by light-matter coupling possesses the potential of accommodating multi-color detection mechanism under moderate bias and high optical density in active region.**

***Index Terms*—Quantum Well Infrared Detector, photo-current spectrum, electron-photon interaction, NEGF model**

I. Introduction

From thermal imaging to medical diagnostics, and in commercial and military application, infrared detection technology has been a vibrant topic for perpetual research. Since late '90s or so, Quantum Well infrared detector has successfully emerged to be one of the strongest competitors of the widely used HgCdTe (MCT) photodetector in this infrared detection regime [1]. An active research is going on to bring forth the high sensitivity, high selectivity and multispectral capability that the Quantum Well interband and intersubband detector promises for detection and identification of specific emission signatures. Among the different types of quantum well infrared photodetectors (QWIPs), the technology of GaAs/AlGaAs multiple-quantum-well (MQW) detectors is the most mature [2].

In this paper, we have formulated a numerical model to investigate the photocurrent spectrum of AlGaAs/GaAs intersubband Quantum Well photoconductor subjected to a widely varied degree of light-matter mutual coupling. The photoconductive response, which is considered to maintain a linear relation with the strength of incident light in some other previous work as in [3], may not remain linear when it experiences a continually increasing exposure to optical intensity. In this work, we have also peered into the non-linearity in electrical response and broadening in current spectra invoked by strong light-matter interaction.

The motivation of exploring the possibility of non-linear response of photoconductor primarily emanated from the fact that, researchers today has been showing an increasing interest in using plasmonic/ other mechanism of field enhancement for photodetectors in order to provide strong near-fields to increase light absorption and improve the detector performance in terms of NEDT, dark current and other figure of merits [4]. The behavior of the sensor exposed to condensed light can be significantly different, such is our conviction.

II. Device Description

In this paper, we have analyzed the photoconductive behavior of $Al_{0.26}Ga_{0.74}As/GaAs$ Quantum Well Infrared photodetector, which functions through intersubband transition for long wavelength light (8-9μm). The physical structure of the device is reported in [5], which comprises of 20 periods of active regions sandwiched between thick GaAs contact and buffer layer, as in Fig. 1. We have taken a cross section of the device along the vertical (growth) direction and perform our simulation over a single period of active region, as shown in Fig. 2.

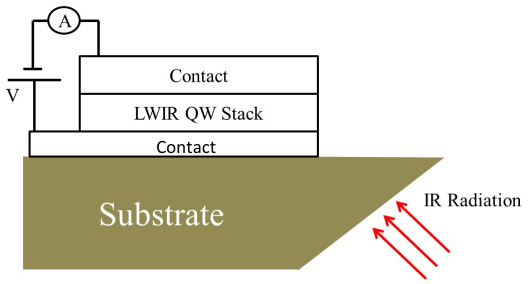

Fig. 1. Schematic diagram of Quantum Well Photo-detector with readout

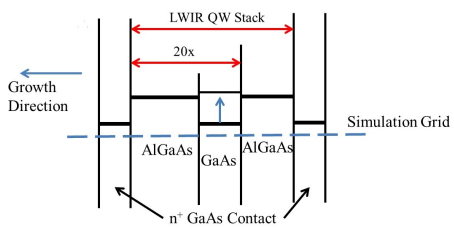

Fig. 2. Active region and the cross-section along which the simulation is performed. Thick lines indicate conduction band offset

III. Quantum Mechanical Modeling

A. Numerical Formulation

The fundamental unit of the periodic layer of active region of QWIP can be described by the Hamiltonian:

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

$$H = H_0 + H_{ep} \tag{1}$$

H_0 gives the description of ballistic transport; it includes the kinetic energy, the band structure and electric potential. H_{ep} contains scattering of electron by photon/ optical phonon. In our model, we adopted a single band tight binding effective mass approximation model [6] where we have kept aside all other kinds of possible scattering, i.e- scattering by acoustic phonon, ionized impurities, interface roughness etc since we would like to keep our interest more to the maxima of the photocurrent spectra and less to its broadening. The operator for electron photon interaction reads:

$$H_{ep} = \frac{e}{m_0} A \cdot p \tag{2}$$

Where the quantized photon field for monochromatic light under standard dipole approximation is given by [7]

$$A = \sqrt{\frac{\hbar\sqrt{\mu\varepsilon}\phi_\omega}{2N_\omega\omega\varepsilon_0}}\widehat{a}(be^{-i\omega t} + b^\dagger e^{i\omega t}) \tag{3}$$

$$\phi_\omega = \frac{N_\omega c}{V\sqrt{\mu\epsilon}} \tag{4}$$

Here $\widehat{a}$ is the polarization unit vector and A_0 is the incident photon flux, N_ω is the number of photon per unit absorbing volume. In the Plane Orbital Basis for a layered system, the Hamiltonian for electron-photon interaction is of the following form:

$$H_{ep} = \sum_{L,L'} M_{L,L'}(be^{-i\omega t} + b^\dagger e^{i\omega t}) \tag{5}$$

$$M_{L,L'} = \frac{e}{m_0} A_0 \langle L|p|L'\rangle \tag{6}$$

$$A_0 = \sqrt{\frac{\hbar}{2\epsilon_0 V\omega}}\widehat{a} \tag{7}$$

L indicates semiconductor layers, and A_0 is the solution of Maxwell's electromagnetic equation, where we take the electromagnetic field of a photon to be a single mode monochromatic plane wave [9].

$$\nabla^2 A_0(x) + \frac{\omega^2}{c^2} A_0(x) = 0 \tag{8}$$

Within the NEGF formalism, the steady state equation of motion for the Green's functions is given by the Dyson's equation [8], [11]:

$$G_R(E) = [(G_0^R)^{-1} - \Sigma_{ep}^R(E) - \Sigma^{RB}(E)]^{-1} \tag{9}$$

$$G_0^R(E) = [E + i\eta - H_0]^{-1} \tag{10}$$

$$G^<(E) = G^R(E)\Sigma^{<B}(E)G^\dagger(E) \tag{11}$$

In this paper, we have employed the numerical model proposed in [12] to accommodate a single inelastic scattering of electron inside the device due to photon absorption which is otherwise subjected to ballistic conduction.

$$(E - H_0 - \Sigma^{RB} - D \otimes G_1^R(E+\omega))G_0^R(E) = 1 \tag{12}$$

$$((E+\omega) - H_0 - \Sigma^{E+\omega})G_1^R(E+\omega) = 1 \tag{13}$$

The self-energy, $D \otimes G_1^R$ in the equation of motion for G_0^R accounts for the broadening and spectrum shift resulting from the out-scattering of state ψ_0 to ψ_1. The electron correlation functions are:

$$G_0^<(E) = G_0^R(E)\Sigma^{<B}(E)G_0^\dagger(E) \tag{14}$$

$$G_1^<(E+\omega) = G_1^R(E+\omega)[D \otimes G_0^<(E)]G_1^\dagger(E+\omega) \tag{15}$$

$$D^<(E) = 2\pi M_{L,L'}[N_\omega\delta(E+\omega)]M_{L,L'} \tag{16}$$

The physical explanation of the equations is as following: A plane wave,ψ_0 , injected from the contact at energy E propagates into the device and due to subsequent photon absorption, may scatter into another quantum state ψ_1 at some higher energy $(E+\omega)$ which have no phase coherence with ψ_0. This secondary wave ψ_1 then propagates ballistically until it exits through the barrier [12].

B. Model Manoeuvring

Determination of photo-induced current using the exact conduction band offset of $AlGaAs/GaAs$ hetero-structure poses a major computational problem. Photo-excitation process involves inelastic scattering of electron to higher electronic state; however, the ground state must be populated for proper functioning of the mechanism. Since the contact acts as the primary source of carrier to the device, no electron can get into any of the energy states that lie below the continuum level of the contact, unless tunnelling/ optical phonon or other types of elastic relaxation process is taken into account to populate ground state.

In this paper, we have made a careful maneuvering over the original hetero-structure conduction band profile so as to circumvent the inclusion of phonon relaxation process and still mimic the photoconductive behavior of the QWELL up to a satisfactory extent without introducing any possible computational artifact. We have lowered the extreme left and right corner of the conduction band effectively leaving a barrier between the QWELL and the extreme left (or right) lead. The width of the barrier is kept marginally enough so as to inject carrier into the ground state of the QWELL. Too wide barrier would completely seal the injection process whereas too thin barrier would result in an overbroadening of ground states and washing out of spectral peaks.

Once injected from contact, the carrier is assumed to be ballistically transported apart from the single inelastic scattering it undergoes for the appropriate wavelength of incident light. No consecutive/multiple scattering is taken into account.

IV. Result and Discussion

Fig. 3 shows the calculated local density of states of $Al_{0.26}Ga_{0.74}As$ Quantum Well structure simulated for unit cell period. It reveals two sharp peaks of energy states at 0.0654eV and 0.2159eV. The latter energy states are posited at the edge of the Quantum Well height ($Al_{0.26}Ga_{0.74}As$ has 0.2282eV band offset over GaAs QW) and hence are called quasi-bound state. The Local Density of States(LDOS) implicates that a sharp photo-absorption spectrum is likely to be found around 8.3 μm incident light wavelength, which is equivalent to the energy difference between two strong density of states (0.22eV-0.065eV=0.15 eV). It may be noted that, the Density of States does not appreciably alter within the applied low bias region.

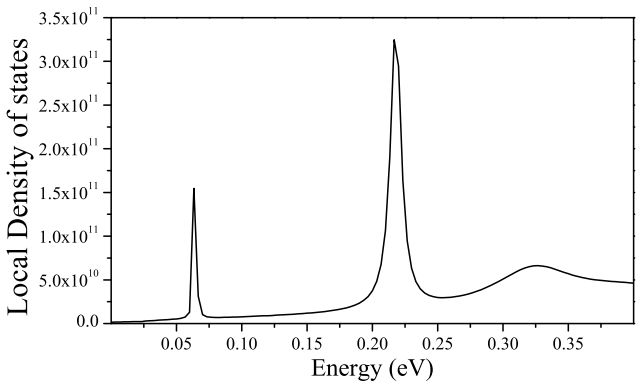

Fig. 3. Local density of states of the AlGaAs/GaAs QWELL structure

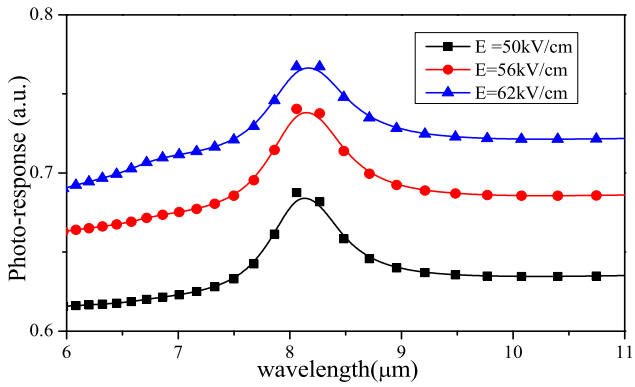

Fig. 5. Photo-current spectra of QWIP structure at various electric field and moderate photon density

A. Comparison between Calculation and Experimental Result

Fig. 4 is the comparison between photocurrent spectrum found by our calculation and that found by experiments in [5](and also in [10]). The close resemblance between the two both in terms of peak wavelength and the FWHM substantiates the validity of our numerical approach. The peak photocurrent from our calculation is found at 8.31μm for moderate photon density, which agrees with the experimentally found peak at 8.55μm within less than 3% deviation. It may be interesting to notice that, the experimental data shows a minor peak at 7.929μm, which is also echoed in our simulation at 7.793μm, with a bit exaggeration, although.

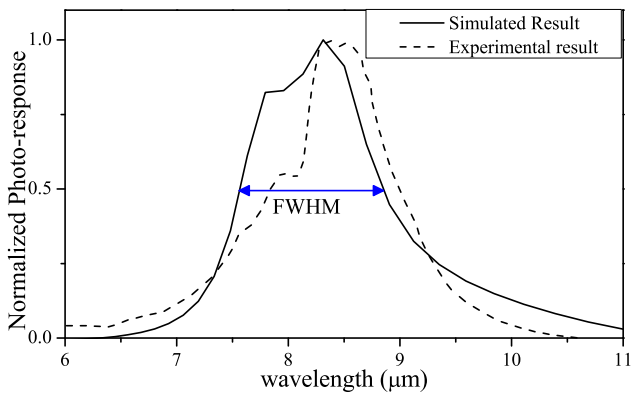

Fig. 4. comparison between our simulation and experimental result from [5]

Fig. 5 shows the photocurrent response of AlGaAs/GaAs QW detector resolved in spectrum under various bias. For moderate photon density, we observe that the position of peak wavelength at 8.3 μm does not get modulated appreciably by the bias voltage; apart from stepwise addition of an offset to the spectrum. Since AlGaAs/GaAs behaves as a photoconductor, the bias voltage is not kept too high, lest the peak of the spectrum should get flattened out.

B. Extrapolation of Model towards strong electron photon interaction limit

Fig. 6 shows the modification in photocurrent spectrum due to increasing amount of photon existing per unit absorbing volume of active region. Since availability of more photon per volume is a consequence of more incident light, the photocurrent peak gets enhanced accordingly. The point to be noted is, along with the rise is photocurrent peak response, the broadening, i.e. the FWHM of the photocurrent spectrum keeps increasing as well. This is certainly as expected, since the broadening of the spectrum indicates reduced lifetime of the carrier in the ground state.

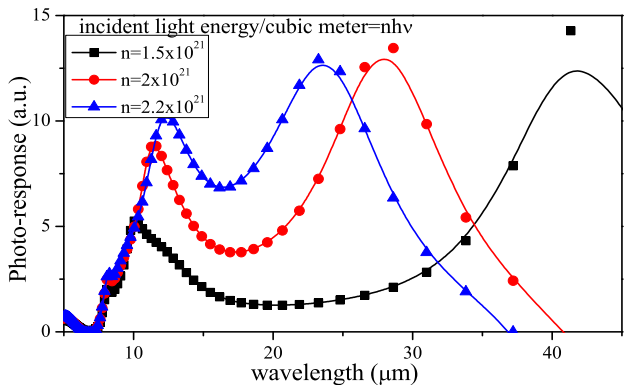

Fig. 6. Change in photocurrent spectra with the increasing number of photon available per unit absorbing volume in high photon density regime

The photo-response, for sufficiently increased amount of photon incidence, does no longer get increased at a proportionate rate, it rather undergoes saturation. What we find more intriguing is the spitting or bifurcation of photocurrent spectra into a major peak (in far-infrared region) and a minor peak (in long infrared region) and their tendency to come closer to each other (the minor peak undergoes red-shift while the major peak sees blueshift) with the increasing number of photon per absorbing volume. This phenomenon of spectral splitting is otherwise inexplicable if the dynamic re-structuring of energy bands inside the active region ensued by the change in optical density inside active device detector is not taken into account. If not operated under strong electron-photon interaction, this multi-color spectra could have never been obtainable otherwise in such a simple intersubband Quantum Well detector, since a two (or more) color detection scheme would have necessitated at least 3 bound/quasi-bound states.

Our simulation asserts that, even at moderate photon density, the spectra contains a secondary peak in far-deep infrared region. However, this far-infrared peak is not supposed to appear in experimentally found FTIR spectra until the corresponding photon energy of the secondary peak rises several order higher over thermal energy (kT). Interestingly enough, the device, if subjected to strong electron-photon interaction,

should re-orient its band-structure dynamically with the change in incident optical intensity so as to cause blue-shifting of the far-infrared peak (as well as red-shift of infrared peak) eventually resulting in two-color spectrum while still retaining a simple photo-sensing system.

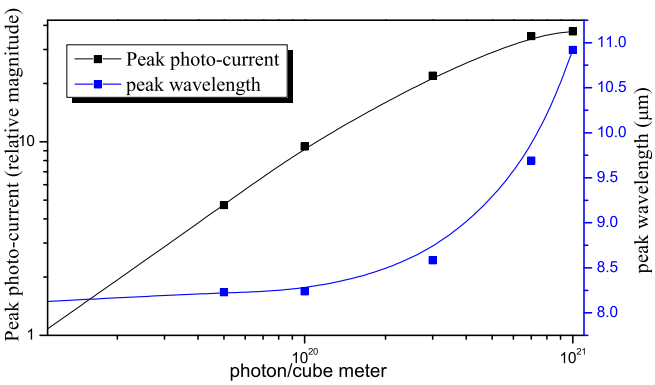

Fig. 7. Change in peak photocurrent and spectral maxima with increasing number of photon per unit volume (blue-shifting of far-infrared is not shown)

Fig. 7 shows that the photo-response keeps increasing almost linearly upto 10^{20} photon per m^3 of active region. Photon density exceeding this limit will cause the photo-response to get saturated. Moreover, the volume density of photon does not appreciably change the spectral maxima upto 10^{20} photon count per unit volume. Beyond that point, the spectrum sees a red shifting in peak wavelength for considerably large amount of optical intensity. At this limit of strong carrier-photon coupling, the band structure is not solely determined by device engineering, but also by the nature of light the device is responding to.

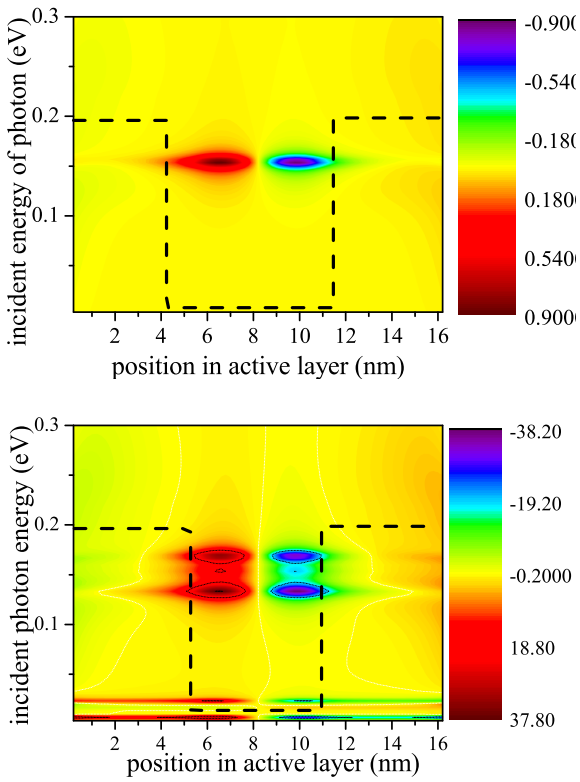

Fig. 8. Spatially resolved photocurrent spectrum at (top) low electron photon coupling, and (bottom) stronger coupling at thermal equillibrium

Fig. 8 contains spatially resolved photocurrent spectrum along the growth direction at thermal equillibrium. One can observe how the spectrum is gettting not only broadened but also splitted into a major and a minor peak around 15eV energy of photon incidence as the strength of electron photon coupling goes from moderate to stronger degree. An almost evanescent spectral line also appears near 0.035eV (corresponding to far-infrared line). Our simplified assumption of spatially invariant photon density along the structure gave rise to non-conservation of current; however, it has an added benefit of vividly depicting the QW region where photo-absorption does actually take place.

V. Conclusions

From the numerical analysis illustrated here, it can be asserted that the quantum mechanical description of a Quantum Well infrared Photo-detector we employed here with a careful computational manoeuvring with some straightforward assumption circumvents a considerable amount of computational burden and yet yields a satisfactory result which is in good agreement with that found experimentally by others within less than 3% error. Our simulation predicts the interesting possibility of multiple color detection mechanism in a two level system with the strong non-linearity in responsivity invoked by the intense coupling between electron-photon. Although we have mimicked the impact of strong electron-photon coupling by increasing photon volume density resulting from light incidence through the device aperture, it can effectually take place by few other and more plausible ways, i.e- plasmon assisted condensation of light. The model presented here is assumed to be excited by monochromatic beam; however, and modification in spectrum due to gaussian excitation beam is under our current investigation and will be published elsewhere.

I. Introduction

The electromagnetic wave phenomena can be represented using Maxwell's modern theory of electromagnetism. For the purpose of computer simulation, Maxwell's equations can be efficiently discretized using different methods like the Finite Volume Time-Domain (FVTD) method, Finite-Difference Frequency-Domain (FDFD) method, Finite-Difference Time-Domain (FDTD) method, Finite-Element Method (FEM), Discontinuous Galerkin methods, Spectral method etc [1] . Among them, the Finite-Difference Time-Domain (FDTD) method, first proposed by Yee [2] in 1966, is one of the most commonly used methods.

Some significant advantages of FDTD are – it is a fully explicit computational technique which uses nonlinear algebra and treats the impulse response of an electromagnetic system naturally. Thus it can provide wideband frequency response in a single simulation. Besides, modeling of a new structure can be simplified to a problem of mesh generation avoiding complex reformulation of an integral equation [1], [3–5].

The original formulations provided by Yee require that the constitutive parameters i.e. conductivity, permeability and permittivity of the materials must be independent of frequency [6]. Though perfect conductors, ideal dielectrics and free space can satisfy this condition, it is rarely true for real materials. For some materials, this approximation can be applied for a narrow range of frequencies only [4]. So, the wavelength (or frequency) range of interest can be divided into several narrow subranges such that the approximation can be applied to each subrange. But a significant drawback of this approach is that the FDTD simulation has to be performed separately for each subrange and then the results have to be merged together to get a complete solution. As a result, the simulation becomes computationally inefficient and cumbersome [7].

As FDTD does not accept data in tabular form [7], so for accurate and efficient simulation of real materials using FDTD method, it is very important to mathematically model the material in such a way that the model parameters are applicable for a wide frequency range. Mathematical models like the Debye model, Lorentz model, Drude Model, Lorentz Drude model etc. are available for this purpose [3]. Therefore, researchers have paid a great deal of attention towards finding new ways to optimize the optical parameters of different materials based on these models.

The modeling parameters of several materials have been reported till date to our knowledge. Deinega et al. [7] have reported the modified Lorentz model parameters for silicon applicable in the wavelength range of 300-1000 nm. Rakic et al. [8] have reported the parameters for 11 materials using Brendel-Bormann and Lorentz-Drude model. Sagor et al. [9] have reported the Modified Debye Model parameters for Nickel, Palladium, Iridium, Titanium and Hexagonal Cobalt. Saber et al. [10] determined the Modified Debye and Lorentz Model parameters for Cuprous Oxide and Silicon-Germanium alloy. Alsunaidi et al. [11] have reported the parameters for AlGaAs. M.A. Ordal et al. [12] have reported the modeling parameters for 14 metals applicable for the infrared and far-infrared region.

In this paper we present the Lorentz model parameters for 6 materials optimized using a nonlinear optimization algorithm based on the Hooke and Jeeves method [13]. The complex relative permittivity of each of these materials has been calculated using these parameters and the calculated permittivities are in very good agreement with the experimental data. The experimental data for Al_2O_3, AlAs, KBr, GaAs are taken from [14], ZnO from [15] and Graphene from [16].

The obtained parameters can be used to simulate electromagnetic phenomena involving these materials. Recent research in the field of electromagnetic phenomena has given rise to the study of Surface Plasmon Polaritons (SPPs). SPPs are electromagnetic waves which travel along metal-dielectric interface with the unique capability to propagate beyond diffraction limit [17]. This property can lead to miniaturization of integrated photonic devices to a great extent [18]. But due to high attenuation, plasmonic signals die out over a distance of a few micrometers in the visible frequency range [17]. So, it is important to find new materials which can guide SPP with

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

low attenuation.

Using the obtained parameters of AlAs and Al_2O_3 and the parameters of Ag reported in [8], we have simulated two Metal-Dielctric-Metal (MDM) waveguides for symmetric SPP mode propagation. We investigated the power propagation profile for both the waveguides. It was observed that Ag/Al_2O_3/Ag configuration gives better performance in terms of symmetric SPP mode power propagation.

II. MATERIAL MODEL

The frequency dependent complex permittivity function for Lorentz model with N number of pole pairs[3] is given by:

$$\varepsilon(\omega) = \varepsilon_\infty + \sum_{n=1}^{N} \frac{\Delta\varepsilon_n \omega_n^2}{\omega_n^2 + 2j\omega\delta_n - \omega^2}$$

where the infinite frequency relative permittivity is represented by ε_∞, the number of the Lorentz pole pair is represented by n, the change in relative permittivity due to the nth pole pair is represented by $\Delta\varepsilon_n$, the undamped frequency of the nth pole pair is represented by ω_n and δ_n is the damping factor for the nth pole pair.

III. OPTIMIZATION METHOD

A nonlinear optimization algorithm based on the Hooke and Jeeves [13] method has been developed in order to extract the parameters. To begin with, the experimental values of real (ε_{rex}) and imaginary (ε_{iex}) parts of complex permittivity of a material are taken from [14–16].

Then a group of guess values of the parameters which need to be optimized is provided. The complex relative permittivity is calculated by inserting the guess values into the mathematical model. An objective function is used to calculate the deviation of the calculated permittivity from the experimental one. This objective function is minimized by varying the parameters according to the Hooke and Jeeves method so that the deviation becomes smaller in successive iterations and ultimately comes down to a predefined tolerance level.

We defined the objective function as follows:

$$f(\varepsilon_\infty, \Delta\varepsilon_n, \delta_n, \omega_n) = \ x_1 + x_2$$

where

$$x_1 = \sum (\varepsilon_{rc} - \varepsilon_{rex})$$
$$x_2 = \sum (\varepsilon_{ic} - \varepsilon_{iex})$$

Where ε_{rc} is the real part of permittivity calculated using the obtained parameters, ε_{rex} is the experimentally obtained real part of permittivity, ε_{ic} is the calculated imaginary part of permittivity, ε_{iex} is the experimentally obtained imaginary part of permittivity.

IV. FORMULATION AND SIMULATION OF THE WAVEGUIDE

A two dimensional plasmonic waveguide simulator has been developed based on the FDTD method. The original FDTD algorithm ignores the frequency dependency of permittivity of materials. The simulator is designed to overcome this limitation by implementing the general auxiliary differential equation (ADE)-FDTD algorithm [19].

In order to prevent reflection from the waveguide boundaries we used the perfectly matched layer (PML) proposed by Berenger in 1994 [20]. The region for simulation is divided into small cells. The step size is taken as Δx = Δy = 2nm and the time step is chosen as

$$\Delta t = 0.95c^{-1}[\frac{1}{\Delta x^2} + \frac{1}{\Delta y^2}]^{-2}$$

where c=3×10^8 ms^{-1} is the speed of light. These values of Δx,Δy,Δt were found to be sufficient to ensure the stability of the algorithm as well as the Courant stability criterion [3]. The schematic diagram of the waveguide is shown in Fig. 2(a).

The symmetric SPP mode is modulated by a Gaussian pulse of width 3fs and 1550nm wavelength and is pumped into the waveguide. The normalized Ey profile pumped into the structure is shown in Fig.2(b).

V. RESULTS AND DISCUSSION

The parameters extracted using the nonlinear optimization algorithm are presented in TABLE I. and TABLE II. The curves for real and imaginary parts of the complex relative permittivity are shown for both optimized and experimental values in Fig. 1. From the tables we observe that the maximum RMS deviation is 0.0019 for Potassium Bromide. Besides, the figures also exhibit very good agreement between the experimental and optimized curves.

We have used double pole pairs for modeling graphene and gallium arsenide and all other materials have been modeled using single pole pair. So, the time required to run the FDTD algorithm using these parameters will be less compared to the FDTD algorithm that uses multiple pole pair models.

The distribution of the E_y field of the symmetric SPP mode propagating through the MDM waveguide is shown in Fig.2(d).

The normalized power curves for Al_2O_3 and AlAs are shown in Fig.2(c). From the curves we see that the attenuation of SPP is less if Al_2O_3 is used as a dielectric layer in the MDM waveguide compared to AlAs.

TABLE I: OPTIMIZED PARAMETERS FOR ALUMINA, ALUMINUM ARSENIDE, ZINC OXIDE AND POTASSIUM BROMIDE FOR SINGLE POLE PAIR LORENTZ MODEL

Parameters	**Materials**			
	AlAs	**Al_2O_3**	**KBr**	**ZnO**

VI. CONCLUSION

We have presented the Lorentz model parameters for alumina, aluminum arsenide, zinc oxide, potassium bromide, graphene and gallium arsenide. To the best of our knowledge, the Lorentz model parameters of these materials have not been presented in any work till date. The complex relative permittivities calculated using these parameters are in very good agreement with the experimental values. Since the obtained parameters are applicable for broad frequency ranges, broadband calculation can be performed in a single run of the FDTD algorithm. From the simulation of Ag/AlAs/Ag and Ag/Al_2O_3/Ag waveguides we can conclude that compared to AlAs, Al_2O_3 is a better choice as dielectric layer in MDM waveguide in terms of attenuation. In order to completely characterize the performance of AlAs and Al_2O_3 as dielectric layers in MDM waveguide we also need to consider the confinement factor which is left as future work . Using the same procedure, other materials and configurations can be simulated to compare their performance as SPP waveguides.

***Abstract*—We propose and present a semi-analytical model to study the interaction between surface plasmon polaritons generated by phase-matching structures in corrugated dielectric/metal interfaces. The proposed semi-analytical model calculates surface plasmon polariton dynamics that agree well with that found from the full-field vectorial finite difference time domain (FDTD) simulations. The proposed model takes almost no computational time in comparison with FDTD simulations. Therefore, the proposed model can be used instead of FDTD simulations to design and engineer sub-wavelength structures to enhance light confinement. In particular, the proposed model can save significant amount of time to efficiently predict the optimal structural parameters to achieve resonant absorption in metal/dielectric interface of a thin-film solar cell.**

***Index Terms*—Periodic corrugations, plasmonics, surface plasmon polariton, plasmonic solar cell, plasmonic light trapping.**

I. Introduction

With the ever increasing global population along with rapid technological development and increased demand of mechanizaton for comfort, global energy demand keeps on growing. It is predicted that with the current rate of growth of energy consumption, global oil reserve will be depleted within 50 to 100 years; natural gas reserve will be exhausted in 60 to 70 years; and coal reserve will be depleted in around 200 years [1]. Apart from the limited reserve of fossil fuels, the use of fossil fuels raises severe environmental concerns. At present, the burning of fossil fuels produces around 21.3 billion tonnes of carbon dioxide (CO_2) per year [2]. However, it is estimated that the natural processes can absorb only about half of that amount produced due to the burning of fossil fuels. Therefore, there is a net increase of 10.65 billion tonnes of atmospheric carbon dioxide per year [2]. Carbon dioxide is one of the greenhouse gases that enhances radiation trapping and contributes to global warming, which is strongly believed to cause major adverse effects on global climate in near future. This calls for urgent and rigorous exploration for alternative clean and environment-friendly energy sources.

Solar irradiation is the primary source of energy on earth. The amount of solar radiation striking earth is around 1.76×10^6 TW, which is orders of magnitude higher than the global energy demand [3]. Among all renewable energy sources, solar energy is the most promising, however, still has a higher cost relative to other sources as photovoltaic energy conversion is not very efficient. Reducing the cost per Watt by increasing the efficiency has been the driving force behind photovoltaic research till date.

Historically, crystalline Si (c-Si) has been the mostly used semiconductor for photovoltaics. In c-Si solar cells, approximately 50% of the total cost is due to the cost of the materials themselves, with the remainder due to cell production and module fabrication [4]. There are several advantages of using c-Si as a material such as its abundancy, low cost, and availablility of matured technology for fabrication. However, c-Si is a weak light absorber requiring a layer of several hundreds of microns to fully absorb the incident sunlight and thus increasing the cost. Alternative to bulk PV cells, i.e., thin-film PV cells have been developed, which have thickness of only a few microns. The thin-film PV cells have lower processing cost, but with lower efficiencies [5].

Incorporation of plasmonic design in thin-film cells increases effective absorption length that leads to increased light absorption which can significantly compensate for the lower active region thickness [6]–[8]. Plasmon is a quasi particle that represents macroscopic oscillation of free electron plasma. Free electrons in metals under proper excitation give rise to several forms of plasmons, i.e., volume plasmon, localized surface plasmon, and surface plasmon polariton (SPP). In this work, we have studied the dynamics of SPPs as a means to increase the efficiency enhancement of thin film PV cells. Recent studies have shown significant promise of corrugated dielectric/metal interfaces to support the excitation of SPPs for increased light confinement in sub-wavelength structures [9]. To optimize such a structure, thorough understanding of the underlying physics is very important. Several studies have been done to investigate the transmission and reflection properties of a groove to incident SPPs [10], [11]. The phase relation between SPPs excited by individual phase-matching structures depends on the detail geometry of the structure. Therefore, the dynamics of SPPs can be engineered by changing the geometry of the corrugated interface.

In this work, we present a semi-analytical model to characterize the interaction between SPPs coupled by finite or infinite number of periodic rectangular grooves in a dielectric/metal interface. We apply this model to calculate the field along a c-Si/Ag interface, which is often used in photovoltaic structures. We also calculate the field with full finite difference time domain (FDTD) simulation. We find good agreement between

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

the results found using the semi-analytical model with that found using the full FDTD simulation. The semi-analytical model is much faster than FDTD simulation, and therefore, can be used to design sub-wavelength structures such as thin film PV cells for increased light confinement.

II. Interaction of SPP with Unexcited Grooves

Periodic groove structure on the back contact of a PV cell is very efficient to confine light in SPP modes in the dielectric/metal interface, consequently enhancing absorption and photo-current [12], [13]. For efficient light-trapping, groove geometry, groove dimensions and pitch width of the periodic groove structure are important design parameters. Since resonances of plasmonic modes depend on all these parameters simulatenously, it poses a significant design challenge to find optimal values of these parameters. Parameter sweeps for different design parameters require considerable amount of time. The semi-analytical model that we propose in this work resolves this issue by calculating the response of a groove by its transmission properties.

We confine our study to rectangular groove geometry. To understand and predict the interaction of generated SPPs with adjacent grooves, it is important to study the response of an unexcited groove to an incident SPP mode. A proper insight of the reflection and transmission properties of an unexcited groove is helpful to develop understanding toward an improved structure design.

A. Simulation Setup

To simulate the response of an unexcited groove to incident SPP mode, we carry out FDTD simulation for a Silver/Silicon interface with only two grooves. Since our focus is to study the dynamics of grooves in confining light in plasmonic modes, we solve only for plasmonic modes and neglect other scattering and photonic modes. To cancel the photonic mode from the simulation, a layer of Silicon with semi-infinite thickness is placed on Silver substrate and the source is placed inside the Silicon layer. We model the materials, i.e., Silver and Silicon using optical constants obtained from Palik [14].

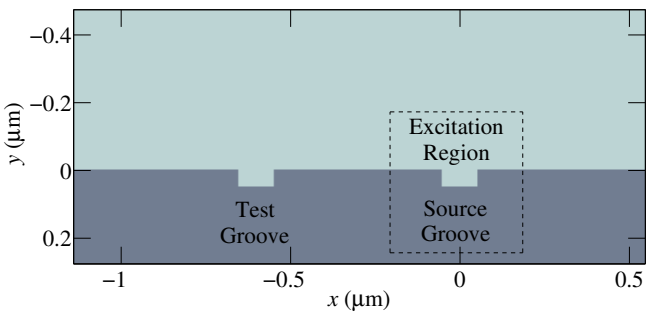

Fig. 1. Simulation setup for modelling response of unexcited groove to incident SPP wave.

In this setup, light is incident on only one of the grooves, which we identify as the "source groove." The incident light on the source groove excites SPP, which propagates and is incident on the sidewall of the second groove, which we identify as the "test groove."

Figure 1 shows the simulation setup where a rectangular source groove with width of 100 nm and depth of 50 nm was excited by normal incidence of a plane polarized monochromatic wave with free space wavelength of 1000 nm. In this particular case, test groove is separated from the source groove by 50 nm and has the same dimensions as the source groove.

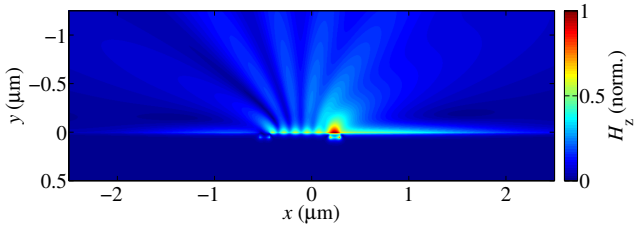

Fig. 2. Standing wave-like mode profile between the test and source groove. Both grooves have a width of 100 nm and a depth of 50 nm.

To model the response of an unexcited groove to incident SPP, we carry out another FDTD simulation to obtain the field amplitude profile for a system with only the source groove. Figure 2 shows the resulting normalized magnetic field amplitude for the simulation domain shown previously in Fig. 1 except when there is no test groove.

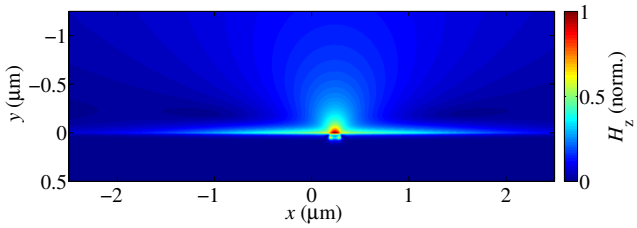

Fig. 3. Resulting normalized H_z field amplitude for the source groove in the absence of test groove

In Fig. 3, the magnetic field distribution shows the SPP mode profile excited by the source groove, which is essentially a reference quantity relative to which the transmission characteristics of the test groove will be determined. To calculate these transmission characteristics, we concentrate on the field distribution along the metal/dielectric interface. Figure 4 shows normalized H_z field along $y = 0$ for both of the output responses from Fig. 2 and Fig. 3. We determine three parameters, i.e., field transmission coefficient (T), field reflection coefficient (R), and transmission phase shift (ϕ_t) to quantify transmission characteristics of an unexcited groove of a specific dimension. These parameters will be employed to develop the semi-analytical model that we propose in this work.

B. Calculation of T, R, and ϕ_t

When SPP generated from the source groove is incident upon the test groove, part of it is transmitted through the test groove, part of it is reflected back toward the source groove, and the rest is decoupled from it to couple into the photonic mode. Field transmission coefficient T signifies the fraction of SPP mode that propagates through the test groove. To calculate T, first we determine the field amplitude at a point beyond the test groove along Ag/Si interface from the simulation with both grooves. Then we determine the field amplitude at the same point from the simulation with only the source groove. We define T as the ratio of these two field quantities. In the case of Fig. 4, we take the ratio of normalized magnetic field amplitudes at $x = -2$ μm to calculate T.

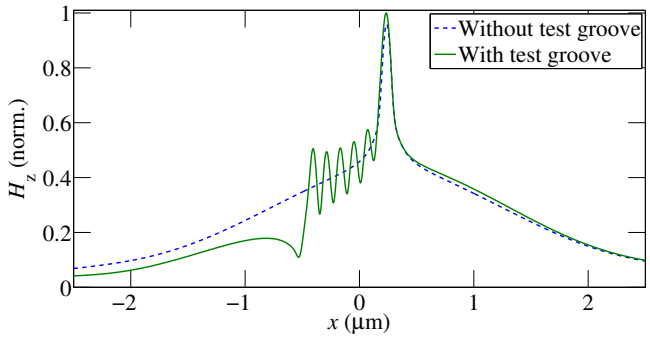

Fig. 4. Resulting normalized H_z field amplitude along $y = 0$ for the source groove with and without the test groove

Calculation of field reflection coefficient R is not straightforward. To calculate R, we use the observation that a standing wave-like mode is created in the region between two grooves as shown in Fig. 2. This mode shape is created due to superposition of the incident SPP from source groove and the reflected SPP from the sidewall of the test groove. If the exponential decay associated with the SPP mode is to be ignored over small propagation length, H_z at the maxima of the standing wave-like mode near to the test groove can be written as

$$\begin{aligned} H_{z,\text{maxima}} &= H_{z,\text{incident}} + H_{z,\text{reflected}} \\ &= H_{z,\text{incident}} + R H_{z,\text{incident}}. \end{aligned} \tag{1}$$

From Eq. (1), we can evaluate R at different groove dimensions. For the case shown in Fig. 4, local maxima at $y = -0.4075$ μm is considered for calculation of R.

Transmission phase shift, ϕ_t is calculated by comparing the relative phase difference between the SPP modes with and without the test groove at a point beyond the test groove. For this purpose, field profile at a fixed time step for both simulation domain is calculated.

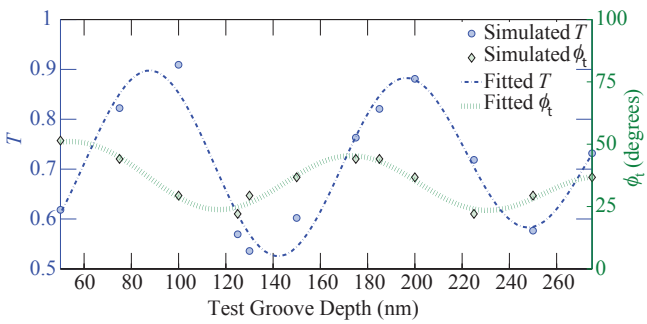

Fig. 5. Field transmission coefficient T and transmission phase shift ϕ_t versus the depth of test groove.

With the changes of groove dimensions, the parameters T, R, and ϕ_t show significant variations. Figure 5 shows the fluctuations of T and ϕ_t for a range of test groove depths while keeping groove width constant at 100 nm. These modeling parameters calculated from full-field simulations are pivotal for the semi-analytical model presented in the next section.

III. Semi-analytical Model

A. Formulation

The magnetic field of the SPP mode excited in a dielectric/metal interface is described as

$$H_z(x,t) = A e^{j(\beta_{\text{spp}} x - \omega t)}. \tag{2}$$

In Eq. (2), β_{spp} is the propagation constant that depends on the structure. In general, we can write $\beta_{\text{spp}} = -a + jk_{\text{spp}}$, where $a, k_{\text{spp}} > 0$ for $x > 0$ and $a, k_{\text{spp}} < 0$ for $x < 0$. The amplitude of the SPP mode in a region, which has N number of excited grooves either on the left or right side, is given by [15]

$$A = \sum_{m=0}^{N} A_m T^m e^{-amd} e^{jm(k_{\text{spp}} d - \phi_t)}, \tag{3}$$

where d is the pitch width between grooves. Now, if we have an interface with identical grooves, $A_0 = A_1 = ... = A_N$. In the presence of N grooves on both sides, superposition of two such modes gives us the SPP mode. When each of these two modes is incident on a groove, a part is reflected back. Therefore, the magnetic field between two grooves, $H_{z,\text{Left}}$ contributed by N grooves on the left side and $H_{z,\text{Right}}$ for N grooves on the right side can be described as

$$\begin{aligned} H_{z,\text{Left}} =& A\{\mathrm{e}^{-ax}\sin[k_{\text{spp}}x - \omega t] \\ &- R\,\mathrm{e}^{a(x-2d)}\sin[-k_{\text{spp}}(x-2d) - \omega t]\}, \end{aligned} \tag{4a}$$

$$\begin{aligned} H_{z,\text{Right}} =& A\{\mathrm{e}^{a(x-d)}\sin[-k_{\text{spp}}(x-d) - \omega t] \\ &- R\,\mathrm{e}^{-a(x+d)}\sin[k_{\text{spp}}(x+d) - \omega t]\}. \end{aligned} \tag{4b}$$

In Eq. (4), R is the field reflection coefficient, which is accounted only for the first stage. The SPP mode between two grooves is found as $H_z = H_{z,\text{Left}} + H_{z,\text{Right}}$. The values of T and ϕ_t presented in Fig. 5 are used to evaluate Eq. (4). The values of a and k_{spp} can be obtained from analytical calculation for a given metal/dielectric interface [16].

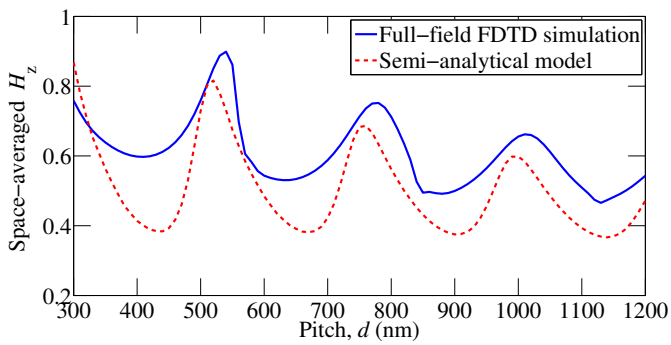

Fig. 6. Space-averaged H_z versus pitch of the corrugated interface from semi-analytical model and full FDTD simulation.

B. Results

We compare the results obtained from the semi-analytical model with that obtained from full FDTD simulation. In Fig. 5, we plot the field transmission coefficient and phase shift for varying test groove depth from FDTD simulation when the light is incident only on the source groove. We use the parameter values obtained from Fig. 5 in the semi-analytical model and calculate the space-averaged field between two adjacent grooves for a structure with $N = 1000$ grooves on each side of these two adjacent grooves of interest. The results obtained from semi-analytical model are given in Fig. 6 along with the results obtained from the full FDTD simulation with periodic boundary conditions. In Fig. 6, space-averaged H_z along the interface is plotted versus pitch of the grooves on the interface. We note that the semi-analytical results match well with full FDTD simulation results. The difference between the semi-analytical and full FDTD simulation results may occur due to the fact that the semi-analytical model does not take the field at the groove faces into account.

IV. Conclusion

The model presented here employs characteristic transmission properties of a single phase-matching structure to semi-analytically predict the field enhancement in periodic structures. The results closely match with that obtained from full FDTD simulations. Design and optimization of a sub-wavelength device requires numerous full FDTD simulations. By contrast, our proposed model presents a design rule, which could easily be used to calculate optimum parameter values, such as the groove depth and pitch, for a sub-wavelength geometry for enhancement and engineering of the confined field along a dielectric/metal interface.

[*]niaz.eee04@gmail.com

Abstract— **In recent years, optical manipulation has been emerging as a powerful technique in a wide range of applications, especially in the field of biological sciences. It is a mechanism to handle micrometer sized particles without mechanical or thermal damage or contamination. Lately, the use of VCSELs (vertical-cavity surface-emitting lasers) as light sources in optical manipulation has got significant attention because of their various advantages compared to conventional lasers. Particularly, their small dimensions with typical active diameters of less than ten micrometers, the possibility of simple and inexpensive formation of two-dimensional VCSEL arrays and their integration capability have made them convenient for optical manipulation applications. Another field of interest in biological research is microfluidics, which studies the manipulation and analysis of fluids in microscale. In this paper, we combine these three basic elements – VCSELs, optical manipulation, and microfluidics – to form VCSEL-based miniaturized optical trap array modules. In our previous work, the fabrication of VCSEL arrays and their characterization results were presented. In this paper, the integration of the VCSEL arrays into the module will be presented. Optical deflection experiments with microparticles will also be shown.**

Index Terms— **VCSEL, miniaturization, integration, optical manipulation, microfluidics.**

I. Introduction

Optical manipulation is a technique of manipulating particles using light. It is based on the phenomenon that micrometer-sized particles can be moved by the radiation pressure of light. The concept of laser-based optical trapping was first suggested by Arthur Ashkin in 1970 [1]. He observed in an experiment with a weakly focused laser beam that particles were moving along the beam axis and towards the beam center. The working principle of optical trapping is based on the light-matter interaction. When light hits a dielectric particle, there is a momentum transfer between the particle and the light. This effect is illustrated in Fig. 1, where a transparent particle with a diameter of several wavelengths and a refractive index higher than that of the surrounding medium is located off-axis in an unfocused Gaussian beam. Two exemplary parallel rays A and B are considered. When these rays are incident on the particle, they are refracted as well as reflected at the particle surface. Considering only refractions, we see a change in the directions of the rays. This change causes a change in momentum of the incident rays and gives rise to two forces F_A and F_B oriented orthogonal to the respective ray. With ray A having a higher intensity than ray B, the force F_A is larger than the force F_B. This leads to a net force that pulls the particle towards the intensity maximum, or towards the beam center.

Today, optical manipulation has found numerous applications in different branches of science and technology. Particularly, it has gained much interest in the field of biological sciences and chemistry because it offers the advantage of manipulating biological material without contamination, mechanical or thermal damage [2].

Microfluidics, another emerging field in today's biological research has expanded very rapidly because it has the merits of miniaturization, portability, and high throughput with reduced sample volume [3]. VCSELs, another component of our module, have attained significant attention as laser sources in almost all areas where miniaturization is an important issue [4]. Because of their versatile properties, they are highly suited for optical manipulation in microfluidics. Their emission in the near-infrared region falls in the transparency window of biological material, i.e., biological material shows low absorption in this wavelength range, minimizing the risk of thermal damage [5]. Moreover, their surface emission eases the fabrication of two-dimensional laser arrays, which enables the formation of multiple optical lattices. This would otherwise require extensive beam splitting or steering setups [4]. Besides, their compact size with typical dimensions of some ten micrometers facilitates the realization of a drastically miniaturized module. Hence, by the integration of VCSEL arrays with microfluidic channels, a portable, inexpensive particle manipulation device is feasible.

II. Vertical-Cavity Surface-Emitting Lasers

Fig. 2(a) depicts the schematic of a surface-relief VCSEL structure emitting its light perpendicular to the surface. Epitaxially grown on a GaAs substrate using an AlGaAs-based molecular beam epitaxy system, the structure is targeted for an emission wavelength of 850 nm. The laser resonator is formed by sandwiching an active region by two mirrors, namely the top and the bottom DBR (distributed Bragg reflector). To enable back-side n-contacting, both the bottom DBR and the GaAs substrate are n-doped. The top DBR is p-doped and has a

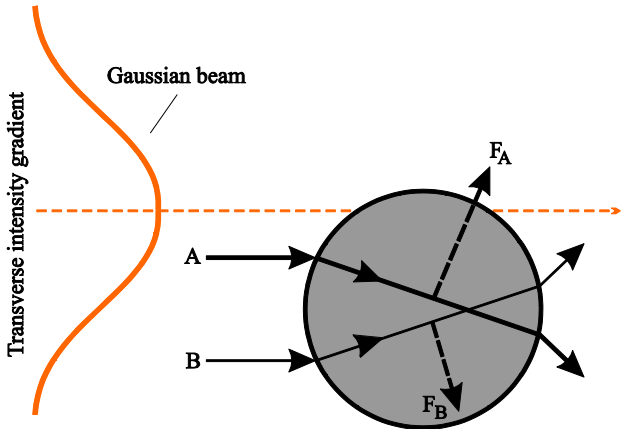

Fig. 1. Working principle of a two-dimensional optical trap.

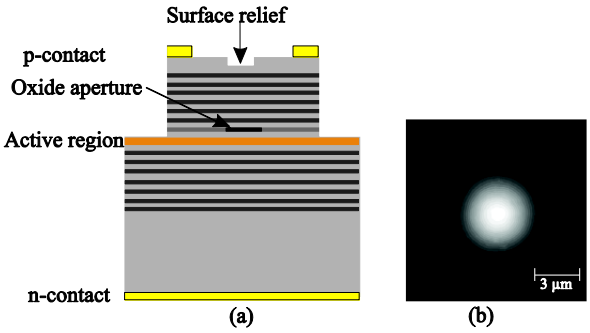

Fig. 2. Schematic of a surface-relief VCSEL structure (a) and its measured Gaussian-like near-field intensity pattern (b).

reduced number of mirror pairs compared to the bottom DBR to enhance light outcoupling from this side. In contrast to a conventional VCSEL structure, the p-doped DBR is followed by an additional antiphase layer on top, with a thickness of one quarter of the material wavelength. During fabrication process, the antiphase layer is selectively etched in the center of the laser facet to form a so-called surface-relief. This laser structure favors the emission of a Gaussian-like beam profile as in Fig. 2(b), in contrast to ring-like beam profiles from conventional VCSELs with the same aperture diameter. A ring-like emission is unfavourable for the targeted miniaturized trapping scheme because it leads to an offset between beam and trapping center [6]. Besides, lower beam quality increases the beam diameter at the focal point.

To enable light emission from the top side, the top p-contact is structured as a ring on top of the VCSEL mesa. Sandwiched between the bottom and the top DBR, the active region consists of three 8 nm thick GaAs quantum wells that are separated by 10 nm thick barriers. Undoped spacer layers are inserted on both sides of these quantum wells in order to make the active region one wavelength thick, which improves the longitudinal carrier confinement [7]. Above the active region is the oxidation layer with high aluminium content (typically 98–100%). During the fabrication process, this layer is selectively oxidized to form an oxide aperture. The aperture provides both carrier and current confinement in the transverse direction on the p-doped side.

III. Integration Approach of the Miniaturized Trap Array Module

The miniaturized trap array module targeted for our experiments requires densely packed surface-relief VCSEL arrays and the integration of the microfluidic chip directly above the VCSEL facets [8]. The integration is a critical consideration for the fabrication of the module. Electrical accessing of the p-contact in the conventional way by bond wires hinders this close integration of the microfluidic chip. Therefore, the p-contacting is done by bondpad metals placed in 30 to 40 µm deep bonding grooves. The integration

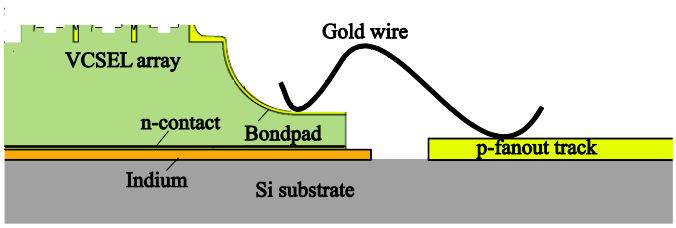

Fig. 3. Cross-sectional schematic view of a wire-bonded VCSEL chip on a chip carrier with fanout tracks.

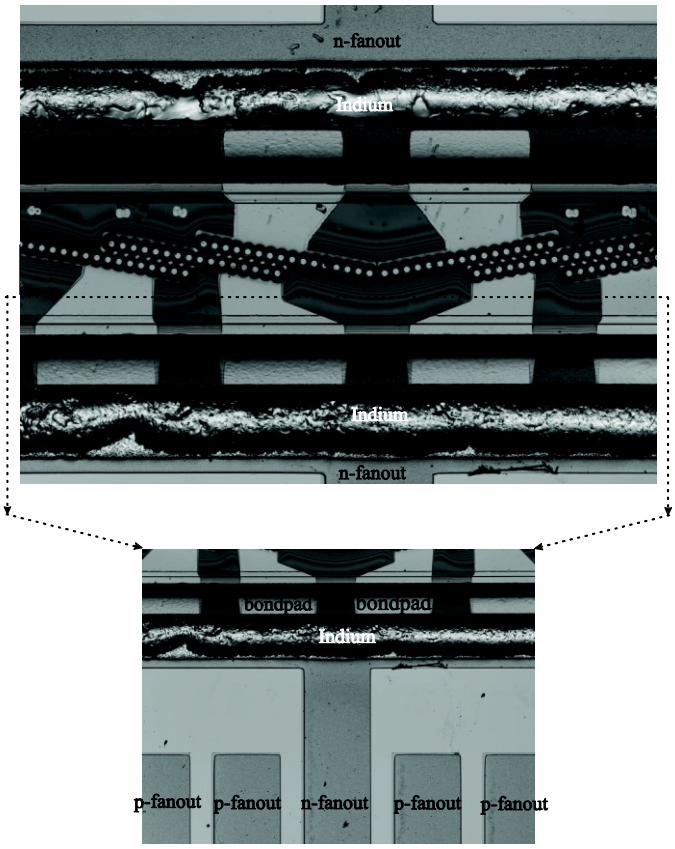

Fig. 4. Laser microsocopic image of the top side of the chip carrier with an integrated VCSEL chip (top) and enlarged view of the metal fanout tracks (bottom).

concept is illustrated in Fig. 3. A VCSEL chip soldered to a structured chip carrier can be seen. The heat sink contains several fanout tracks. For accessing the p-contact of the VCSEL arrays, the fanout tracks are connected to the bondpads by gold wires. It is clear from the figure that because of the deep bonding groove, the gold wire will not create an obstacle for the microfluidic chip to be placed close above the VCSEL facets.

IV. Fabrication of the Module

For the module, integration-capable top-emitting VCSEL arrays are required. The fabrication process of the arrays is presented in Ref. [8]. After the fabrication, the fabricated VCSEL sample is sawed into 1.8 mm × 0.6 mm chips. Then the chips are soldered on a silicon chip carrier with a size of 20.7 mm × 2.53 mm. To form the fanout tracks, first a seed structure of titanium and gold is deposited on the wafer, then thick gold is electroplated on this seed structure. Later indium is evaporated for soldering of the VCSEL chips. A top view of a chip carrier with a VCSEL is partially visible in Fig. 4. The heat sink has five fanout tracks on each side – one fanout track for the common n-contact and four tracks for four p-contacts. The p-fanout tracks are connected to the bondpads by wire bonding. The characterization results are presented in section V.

In the next step, the optoelectronic chip is integrated with the microfluidic chip. It is glued and then treated with ultraviolet curing [9]. The chip contains a microfluidic channel (Y-junction) with one inlet and two outlets. The channel is fabricated from a polymer called Topas® COC (Cyclic olefin copolymer) and has a width of 60 µm. During

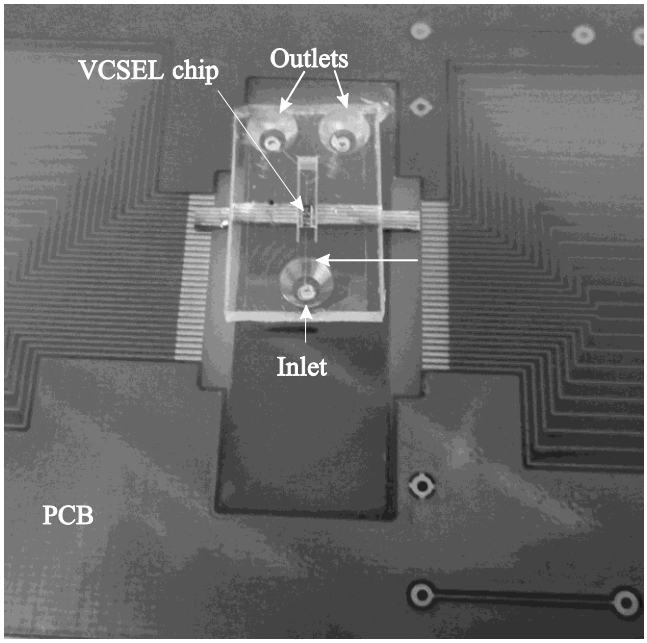

Fig. 5. Photograph showing the assembled VCSEL chip integrated with the microfluidic chip on a printed circuit board.

the integration, the channel is aligned to the VCSEL arrays. The chip is then assembled on a printed circuit board (PCB) using glue. Figure 5 shows the assembled chip on the PCB.The inlets and outlets of the channels are connected via tubes to a syringe containing a particle solution. Electrical

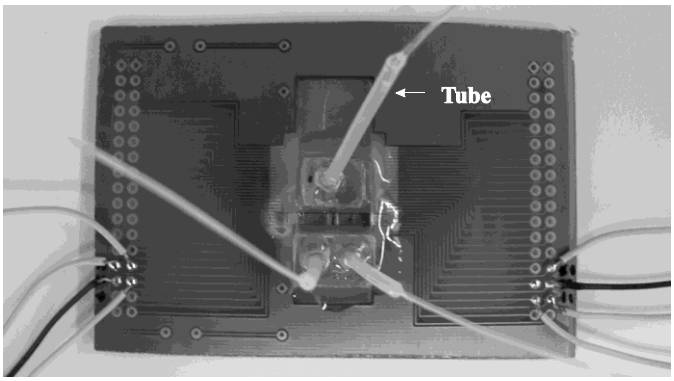

Fig. 6. Photograph of a fully functional VCSEL-based miniaturized trap array module.

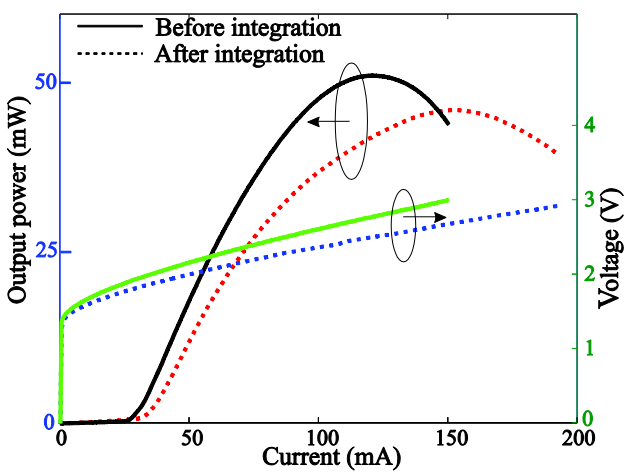

Fig. 7. LIV characteristics of a surface-relief laser array consisting of 13 emitting VCSELs with an individual active diameter of 10 µm.

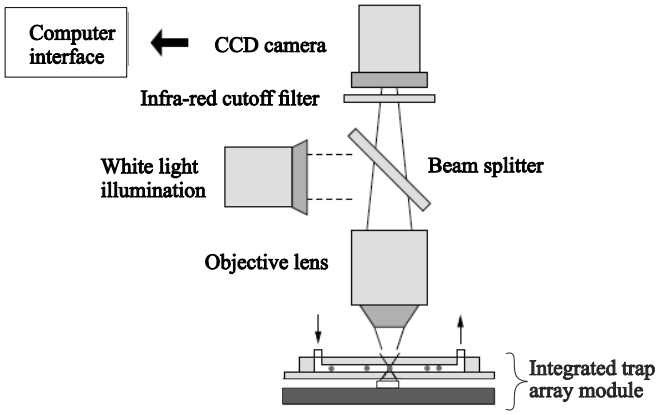

Fig. 8. Schematic of the experimental setup used for the observation of the optical deflection experiment.

wires are then attached to the PCB. The fully functional miniaturized VCSEL array module can be seen in Fig. 6.

V. Characterization After Heat Sink Integration

Figure 7 shows the LIV (light-current-voltage) curves of a fabricated VCSEL array before and after integration with the chip carrier. The array consists of 13 emitting VCSELs with an individual active diameter of 10 µm. A threshold current of around 26 mA, which increases slightly after integration, can be observed. The maximum power decreases from 52 mW to around 42 mW. This reduction of power might be caused by the increased leakage current after the soldering of the VCSEL chip to the carrier.

VI. Trapping Experiments

A. *Experimental Setup*

To observe the experiment, a CCD camera is used in combination with a beam splitter and white light illumination. An IR-cutoff filter is used to block the laser light so that the particle movement during laser operation is visible in the CCD camera. Therefore, the laser beams cannot be seen in the images. The schematic of the experimental setup is displayed in Fig. 8. The flow of the liquid is regulated by a computer-controlled syringe pump. Figure 9 shows the laser arrays just under the channel. The output power is 3 mW per laser.

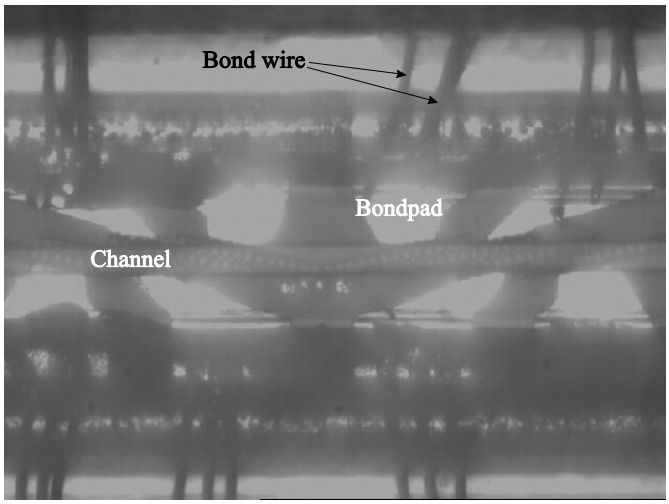

Fig. 9. Photograph of the laser arrays just under the microfluidic channel. The laser arrays are tilted by about 12° with respect to the channel edge.

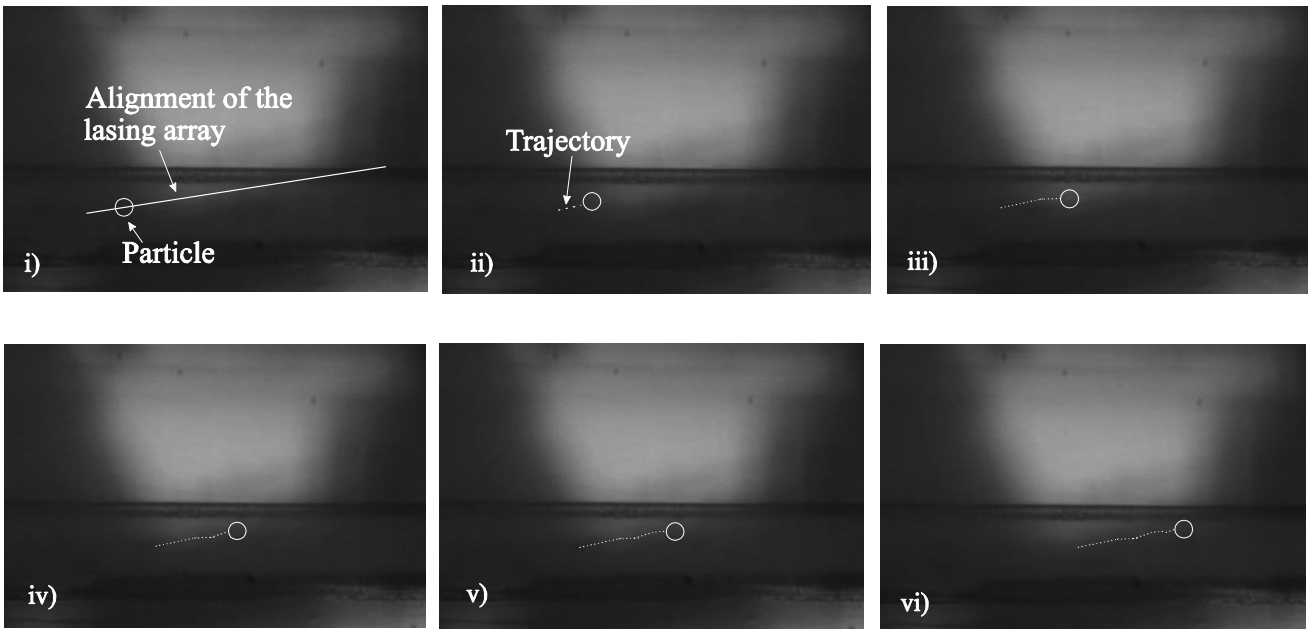

Fig. 10. Snapshots of a continuous deflection experiment with a 10 µm polystyrene particle. The particle is slowly redirected to the upper part of the channel while passing through the channel.

B. *Experimental Results*

The experiment is performed with 10 µm diameter polystyrene particles. Figure 10 depicts the trajectory of the particles when the laser array is in operation. The alignnment of the laser array is indicated. The particles are moving from left to right with a certain velocity. In Fig. 10 (i), a 10 µm particle approaches the laser array and it is attracted by the laser beams. As the particles flows forward, it is further deflected (Figs. 10 (ii)-(vi)) by the attraction of the tilted laser arrays. As a result, the particles are deviated from their initial path.

VII. Conclusion

In this paper, the fabrication of a VCSEL-based miniaturized module for microparticle manipulation has been presented. The module requires the fabrication of single-mode integration-capable VCSEL arrays. Single-mode emission is realized by the surface-relief technique and the integration capability is achieved by deep bonding grooves. Moreover, the VCSEL arrays are fabricated as densely packed arrays to enable continuous optical deflection experiments. After the fabrication of the VCSEL arrays, they are sawed to form VCSEL chips. Then the chips are soldered on silicon chip carriers containing heat sinks. Next, the p-fanout tracks of the heat sink are connected to the bondpads by wire bonding. A microfluidic chip is then integrated with the laser module by fixing it directly above the VCSEL facets. Next, the chip is assembled on a PCB, which is soldered with wires for electrical connection to an external current source. In this way, the miniaturized module is realized.

After the fabrication of the module, optical deflection experiments are performed with 10 µm polystyrene particles and particle deflection is successfully observed. The final goal is to use the module for biological cell sorting.

Acknowledgment

We would like to thank the Institute of Optoelectronics for providing the materials and equipment which allowed to do this research at Ulm University.

***Abstract*—Quantum cascade laser (QCL) is a promising candidate for comparatively less developed terahertz spectral range. GaN based QCLs provide significant advantages over traditional GaAs based QCLs due to their higher LO phonon energy. Multiple wavelength hetero active region cavity offers various advantages like multiple emission wavelength for spectroscopy, nonlinear optical phenomena, and second harmonic generation. In this paper, we propose and design a multiple wavelength hetero cavity terahertz GaN based QCL emitting at 1.7 THz, 4.3 THz, and 7.2 THz. We present detail modeling of the system and final gain spectrum. We observe high gain (~ 250 cm^{-1}) with multiple wavelength output emission. We also observe the sensitivity of the emission on temperature and find that the gain decreases sharply with increase in the temperature.**

***Index Terms*—Quantum Cascade Laser, Hetero Cavity, Multiple Wavelength, Terahertz QCL**

I. Introduction

The terahertz frequency range, loosely defined as the frequencies from 300 GHz to 1 THz has historically been immature as it lacks suitable radiation sources, detectors, and transmission technology [1]. However, terahertz technology is important for its potential applications, including astrophysics and atmospheric science, biological and medical sciences, security screening and illicit material detection, nondestructive evaluation, communications technology, and ultrafast spectroscopy. Due to significant application potentials, many researchers have explored ways to find sources for Terahertz emission. Photonic approaches to direct terahertz generation are limited due to the lack of appropriate materials with sufficiently small bandgaps, e.g., the longest wavelength lead salt laser diodes do not extend below 15 THz [2]. Unlike the conventional bandgap structure of semiconductor lasers, in quantum cascade lasers (QCLs), quantum confinement splits the conduction band into a number of distinct subbands [2]. The energy spacing of the lasing subbands determines the radiation frequency, allowing in principle to produce light at arbitrarily long wavelengths and even extend into the terahertz frequency range [2]. Terahertz QCL was first demonstrated in 2002 and remarkable progress on terahertz QCLs has been made since then [3].

In QCLs, the emission wavelength can be chosen over a very wide wavelength range by choice of the quantum well thicknesses in the active regions. Typically 30–50 periods of alternated active and injector regions are cascaded to make the laser core. As electrons transport through the cascade, active regions are pumped sequentially. Thus, as the various active regions do not compete for pumping energy, the combination of wavelength agility and cascading principle can advantageously be used for multi-wavelength emission [4]. Heterogeneous active regions, i.e., periods emitting at different wavelengths have been employed to obtain broadband tunable lasers for spectroscopic applications [4]. Straub et al. proposed a two-wavelength QCL with heterogenous cascades emitting at 8 μm and 9.5 μm. They have used traditional InGaAs/AlInAs material system for operating in the mid-IR range. No work has been reported on heterogenous cascade in terahertz frequency range.

In this work, we have proposed a novel GaN based heterogeneous active region QCL design, which will emit in three distinct frequencies, namely 1.7 THz, 4.3 THz, and 7.2 THz. GaN based active region enables us to operate in the terahertz frequency range. With its comparatively higher LO-phonon resonance energy, QCL can operate at comparatively higher temperature. We have done detail modeling of GaN based QCL systems. We also have calculated detailed electronic transport for the system. We have calculated the gain for each of the emission wavelengths and also observed the effect of change of temperature on the output emission. The remaining of this paper is organized as follow: Section II describes the mathematical modeling required for the simulation of various parameters. Section III presents the proposed design and its various aspects. Section IV describes the characterization for the proposed design. Section V concludes the paper and discusses the scope for further extension of the work.

II. Theoretical Modeling

We want to calculate the gain spectrum of a GaN based Quantum cascade structure. To find the the output emission wavelength, first we must find the mode that will lase. The axial modes that are supported by a laser cavity of length L are given by [5]

$$f = m\frac{c}{2nL}, \tag{1}$$

where c is the speed of light, n is the index of refraction, and m is an integer that denotes mode number. In practice, a number of axial modes lie within the gain linewidth of QCLs. However, in QCLs, which have a homogenously broadened gain medium, the mode that first experiences gain greater than loss becomes the sustained mode in the cavity.

Now, we need to calculate the gain of the axial mode. The peak modal gain of a QCL for radiative transition from subband j to subband i is given by [6]

$$G_M = \frac{4\pi q^2}{\varepsilon_0 n\lambda}\frac{z_{ij}^2}{2\gamma_{ij}L_p}(n_j - n_i), \tag{2}$$

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

where q is the charge of an electron, ε_0 is the permittivity of free space, n is the index of refraction, λ is the transition wavelength, $2\gamma_{ij}$ is the full width at half maximum (FWHM) linewidth, z_{ij} is the dipole matrix element, L_p is the length of a period, Γ is the confinement factor, and n_i, n_j are the carrier densities in subbands i and j, respectively. The gain spectrum is found by multiplying the peak modal gain by the Lorentzian lineshape, L_{ij}, given by

$$G = G_M L_{ij}. \tag{3}$$

The calculation of the gain spectrum using Eq. (2) requires the determination of the dipole matrix element z_{ij} between the levels i and j, the FWHM linewidth γ_{ij} for the transition from level i to level j, and the carrier densities in the subbands i and j. The methods for calculations of z_{ij} and γ_{ij} can be found in Ref. [6] and Ref. [7], respectively. The carrier density in each of the subbands is calculated using the rate equation approach as discussed in ref. [8].

Next, we have considered electrical and optical properties of GaN based materials. The temperature dependent bandgap energy E_g can be found by methods described in [9]. The polarization, which is responsible for internal electric field of GaN based materials consists of spontaneous and piezoelectric components. The spontaneous polarization in C/m^2 for the $Al_xGa_{1-x}N$ alloy as function of the Al content x can be approximated by [10]

$$P_{spAlGaN}(x) = -0.090x - 0.034(1-x) + 0.021x(1-x) \tag{4}$$

Wurtzite group III nitrides exhibit an additional piezoelectric polarization P_{piezo} when stress is applied. The piezoelectric polarization can be written as

$$P_{piezo} = 2\frac{a-a_0}{a_0}\left(e_{31} - e_{33}\frac{C_{13}}{C_{33}}\right) \tag{5}$$

The parameters used for the calculation of polarization are taken from references [9] and [11].

The existence of both built-in polarization fields in wurtzite III Nitride semiconductors leads to energy band bending. The electrostatic fields in each layer j-th as a result of total polarization fields can be expressed as [12],

$$E_j = \frac{\sum_k (P_k - P_j)\frac{l_k}{\epsilon_k}}{\epsilon_j \sum_k \frac{l_k}{\epsilon_k}} \tag{6}$$

where P is the total macroscopic polarization, ϵ is the static dielectric constant, and l is the thickness of each layers (k-th, j-th). The subscripts k and j correspond to the k-th and j-th layers.

To ensure zero average electric field in the layers, note that the electric field expression in (6) needs to satisfy the periodic boundary conditions as follows [12]

$$\sum_j l_j E_j = 0. \tag{7}$$

III. Design

We propose to use a GaN-based system with large LO-phonon energy of 90 meV for THz QCLs. The advantages are threefold. First, the large LO-phonon energy in a GaN-based system can reduce the thermal population of the lower laser state. Second, ultrafast LO-phonon scattering in GaN/AlGaN QWs can be used for the rapid depopulation of the lower laser state. Third, the large LO-phonon energy can also increase the lifetime of the upper laser state by reducing the relaxation of electrons with higher in-plane kinetic energy via emission of a LO-phonon [13].

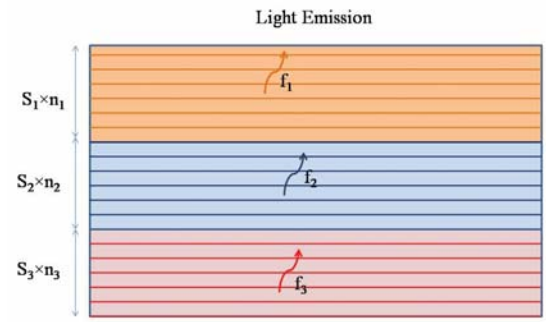

Fig. 1: Schematic of the overall design structure. Here, structures S_1, S_2, and S_3 periods are repeated n_1, n_2, and n_3 times respectively and emit f_1, f_2, and f_3 frequency respectively.

In our design, three structures S_1, S_2, and S_3 each emitting a different wavelength are stacked together as schematically shown in Fig. 1. The active waveguide core consists of 30 period of each structures. S_1 is designed to emit at 7.2 THz, S_2 is designed to emit at 4.3 THz, and S_3 is designed to emit at 1.7 THz. We use GaN for the quantum wells and ternary $Al_{0.2}Ga_{0.8}N$ alloys for the barriers. Each structure is so designed that they satisfy the periodic boundary conditions explained by Eq. (7).

All three structures S_1, S_2, and S_3 consist of four quantum wells. The layer sequence for one period of S_1 is (in nm) 5.7/**0.62**/6.18/**0.73**/2.85/**0.52**/3.6/**0.83**, beginning from an injection layer for a depopulation layer. The layer sequence for one period of the S_2 is (in nm) 5.7/**0.62**/6.18/**0.73**/2.8/**0.52**/4.2/**0.83**, beginning from an injection layer for a depopulation layer. The normal and bold scripts denote the GaN wells and the AlGaN barriers, respectively. In both S_1 and S_2, the 6.18 nm thick GaN wells are n-doped to 2×10^{11}cm^{-2}.

S_1 and S_2 are variation of a same structure, differing only in active region. The active region of S_1 consists of two quantum wells of 2.85 nm and 3.6 nm, whereas the two quantum wells in S_2 are of 2.8 nm and 4.2 nm. The wider active region results in a lesser energy difference between two energy levels and hence we get a smaller frequency output in S_2 than in S_1. The slight modification of the other active region layers results in better electron transition to create sufficient population inversion.

The layer sequence for one period of the structure S_3 is (in nm) 7.1/**0.8**/7.6/**0.8**/2.8/**0.8**/3.6/**0.9**, beginning from an injection layer for a depopulation layer. The 7.6 nm thick GaN well is n-doped to 5×10^{10}cm^{-2}. Here, S_3 has a different design for injector region than that of S_1 and S_2. We also note that the barrier width is changed. The injector wells are 7.1 nm and 7.6 nm in S_3, instead of 5.7 nm and 6.18 nm in S_1 and S_2. The active region barrier is also changed to 0.8 nm from 0.52 nm. These changes result in a much smaller emission frequency than that of the other two structures.

As S_2 and S_3 will have different structures and hence dif-

ferent current density, we need a special transitional structure for electron transition from last period of S_2 to first period of S_3. We have designed a special injector region as the basic structures' energy levels do not match. The injector level layer sequences are 2.85/**0.7**/3.8.

IV. Characterization

In this section, we will discuss the characteristics of the proposed structures. Figures 2, 3 and 4 show the simulated bandstructures and moduli squared of wavefunctions for an applied bias of 67.4 kV/cm for one and a half period of structures S_1, S_2, and S_3, respectively, at temperature 100 K.

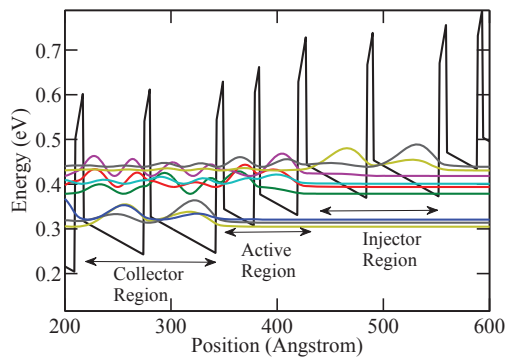

Fig. 2: Bandstructure and the moduli squared of the relevant wave functions for three periods of S_1 structure

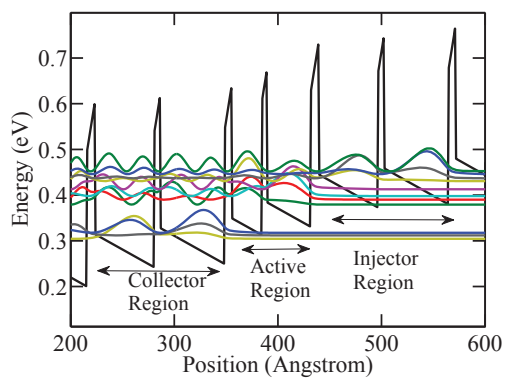

Fig. 3: Bandstructure and the moduli squared of the relevant wave functions for three periods of S_2 structure

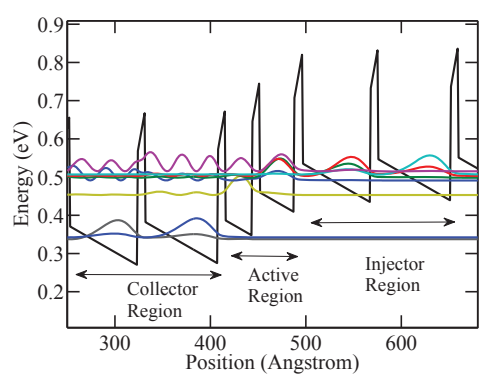

Fig. 4: Bandstructure and the moduli squared of the relevant wave functions for three periods of S_3 structure

The structures are grown on one substrate and on top of each other. This means all the structures are connected together like a series circuit. Therefore, same current runs through the structures and the current is limited by the smallest current produced by any structure [14]. To ensure current matching between the structures, we have calculated the current densities in individual structures for different biases, which is shown in Fig. 5. As S_1 and S_2 are similar structures varying only in active regions, currents in S_1 and S_2 are close to each other. Here, the collector levels and injector level energy levels closely match. So, injector level of S_2 can act as the collector level of S_1. Hence, carrier transition from S_1 to S_2 can be made directly without the need of any special injector region. We can see that current density in S_3 is significantly different from S_2. As S_2 and S_3 varies in the injector regions, injector region of S_3 can not work as the collector level of S_2. So, we have designed a special injector region for transition between S_2 and S_3, which consists of two quantum wells of 2.85 nm and 3.85 nm, separated by a barrier of 0.7 nm. This special injector region matches the energy levels of active region of S_2 to energy levels of injector level of S_3. As a result, we have a closely matched current levels in the combined structure, which is shown in Fig. 6.

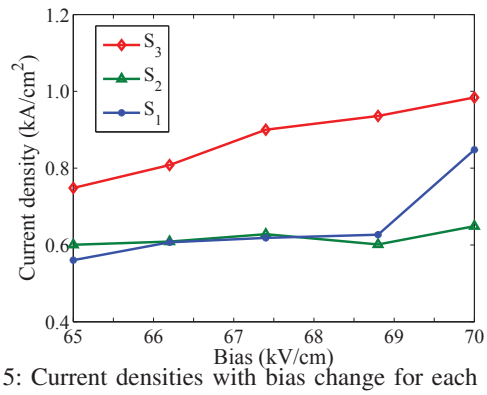

Fig. 5: Current densities with bias change for each structure

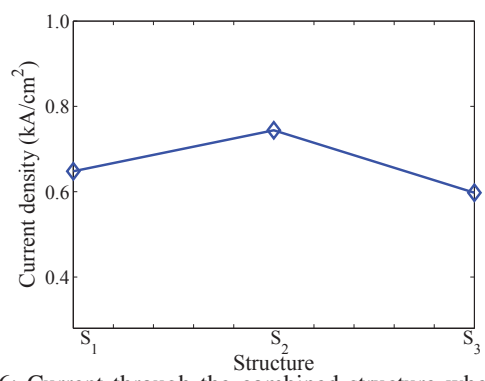

Fig. 6: Current through the combined structure when S_1, S_2, and S_3 are cascaded and biased at 67.4 kV/cm

We have calculated the population density in each of the structures. The population densities for S_2 is shown in Fig. 7. Here, we note that significant amount of population inversion was achieved in this structures. From Eq. (2) we can see that population inversion is directly proportional to the gain of the laser. As a result, we will be able to achieve high gain from the design. Again, Eq. (2) shows that modal gain is inversely proportional to wavelength. At terahertz range, the wavelength is significantly less than mid-IR range wavelength. So, this fact will also result in higher gain. Overall gain spectrum shown

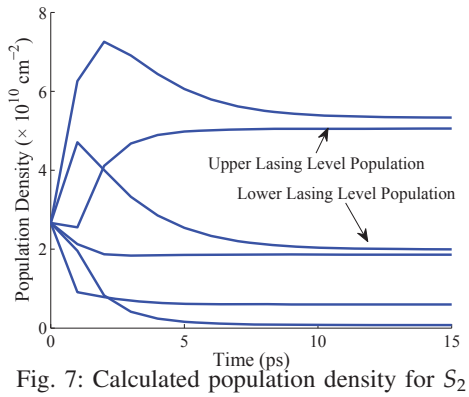

Fig. 7: Calculated population density for S_2

in Fig. 8 agrees with these result. This higher gain will enable the emission to overcome the loss in the extended cavity and will result in sustained high power emission.

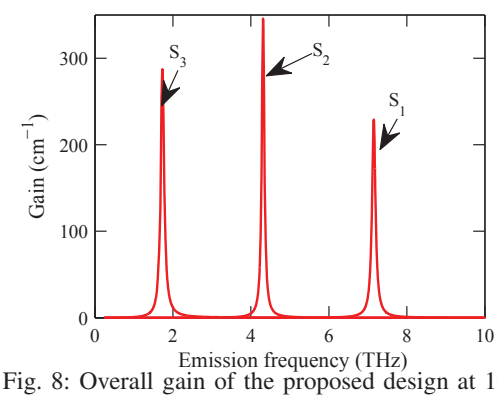

Fig. 8: Overall gain of the proposed design at 100 K

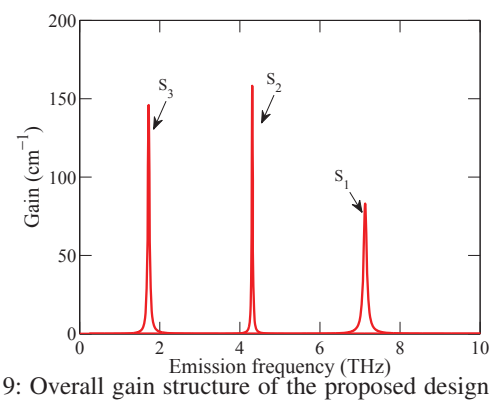

Fig. 9: Overall gain structure of the proposed design at 150 K

We have also performed the simulation at higher temperatures. Figure 9 shows the output emission of the laser at a higher temperature of 150 K. At this temperature, we note that the emission has significantly lower gain than the emission at 100 K temperature. This lower gain can be attributed to the thermal backfilling of electrons in the lower lasing level, which lowers the population inversion approximately by 40%. As the gain is directly proportional to the population inversion, gain also reduces by the same amount. If we further increase the temperature to 200 K the laser fails to lase, as the gain decreases more and becomes less than loss.

V. Summary

We have proposed a novel multiwavelength heterostructure GaN based Terahertz design. The proposed design simultaneout detail carrier transport calculation and found significant population inversion in each structure. The current between the structures is matched so that the gain of one structure will not suffer for the other. We have shown that output emission of this laser will have significantly high gain in the range of ~250 cm^{-1}. This high gain will result in higher output power. This can be very useful in terahertz imaging and spectroscopy applications. We also found that higher temperature results in lower gain due to thermal backfilling of electrons into the lower lasing level.

Improved texture retrieval by combining different variants of Local Binary Patterns

Nabeel Mohammed,[1,*] Sohel Rana,[2]
[1,2]Department of CSE, University of Asia Pacific
Dhanmondi, Dhaka, Bangladesh
*nabeel.mohammed@uap-bd.edu

***Abstract*—This paper proposes the combination of different variants of local binary patterns for texture retrieval. Recent studies have shown that LBP features extracted at multiple resolutions give the best performance for a standard texture retrieval collection. Techniques have been proposed to create a multi-dimensional histogram of these features. In this study we use a simpler approach. We hypothesize that the different variants of LBP may actually extract slightly different but useful image information. If this were the case, then using them in combination will result in further improved performance, compared to using each one independently. We demonstrate this by using LBP, LBP^{ri}, and LBP^{u2} features in combination. We take ideas from the GNU Image Finding Tool (GIFT), and use separate normalisation to ensure the different feature vector lengths do not bias the system towards one of the features. We performed experiments on the two standard texture collections. Our results demonstrate that combining the different LBP features do indeed result in improved performance. In fact, for one of the collections (Outex_TR_00000) collections, using our method give better performance than the current state-of-the-art.**

***Index Terms*—Image retrieval, Local binary patterns, Separate normalisation**

I. Introduction

This work is inspired by the research reported in [1] and [2], where the authors extract LBP features at multiple resolutions, and apply them to an image retrieval task. Both these studies report their results on the Outex_TR_00000 texture collection [3]. [1] tried 16 variants of local binary patterns (LBP) along with Gabor filters, Tamura features, and two different GLCM features to find the most effective texture feature for the Outex_TR_00000 image collection. In reality the numbers are even more extensive, as they tried the LBP variants in different combination of resolutions, for a total of 38 LBP features. These were tested using three different distance measures: the Bhattacharya, chi-squared and L_1 distances. The non-LBP features were only tested using the chi-squared distance. There was in total 118 different attempts to find the best performing texture feature. After this thorough search, they found the best performing texture feature for this collection was a concatenation of $LBP_{1,8}$, $LBP_{3,8}$ and $LBP_{5,8}$, which gave an accuracy of 63.74% when using the L_1 distance.

In [2], the authors wanted to address the shortcomings of a scheme which concatenated the feature vectors, and proposed a multi-dimensional LBP descriptor, which they state performs better than the concatenated version. However, there is some confusion at this point. In the first paper [1], the authors report that the average retrieval rate (ARR) of $LBP_{1,8} + LBP_{3,8} + LBP_{5,8}$ is 63.74% . However in their latter paper [2], when reporting the results of the multi-dimensional LBP feature, they report the ARR of $LBP_{1,8}+LBP_{3,8}+LBP_{5,8}$ as 58.85% and the ARR of the multi-dimensional LBP feature as 63.04%. In our experiments we could found an ARR of 63.12% for $LBP_{1,8} + LBP_{3,8} + LBP_{5,8}$.

Whichever may be the correct number, what is noticeable in both the papers is that the authors concentrated on using the same type of LBP feature (whether it be LBP, LBP^{ri}, LBP^{u2} etc.) in different resolution combinations. Given that they found a combination of $r = 1, 3$ and 5 to perform best, we don't want to repeat their work. Instead the contribution of this study is to try to see whether a combination of the different types of LBP features, extracted at these resolutions, can give better performance.

The following section gives a brief description of LBP. We follow this with a description of our experiments. We then describe our results, which justify our claims.

II. Background

Local Binary Patterns (LBP) were first proposed in [4]. Some variants were then presented in [5]. Since then it has become a widely used texture features and has gained wide acceptance due to good performance in different image processing applications and also through simplicity of calculation. Here we will discuss the version presented in [5].

LBP features are calculated over a circular neighbourhood around a central pixel. The size of the number of pixels in the neighbourhood (P) and its radius (R) can be varied. For this discussion we will assume that the images are grey scale.

The authors begin by defining a texture T in a local neighbourhood of an image as the joint distribution of the gray scale pixel values of $P, (P > 1)$ pixels

$$T = t(g_c, g_0, ...g_{P-1}) \tag{1}$$

Where g_c is the grey level value of the central pixel in the neighbourhood and $g_p(p = 0, ..., P - 1)$ are the grey level values of P equally spaced pixels at a distance of radius R, forming a circular neighbourhood. The grey level values which do not correspond to an actual pixel can be found by interpolation. To achieve invariance to luminance the value of the center pixel g_c is subtracted from the neighbourhood pixels G_p, giving

$$T = t(g_c, g_0 - g_c, ...g_{P-1} - g_c) \tag{2}$$

Assuming that the differences $g_p - g_c$ is independent of g_c, Equation 2 can be refactored to

$$T \approx t(g_c)t(g_0 - g_c, ...g_{P-1} - g_c) \tag{3}$$

As $t(g_c)$ here describes the overall luminance in the image, and as LBP features want to gain invariance to luminance, the

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

g_c components is dropped and the texture of the neighbourhood is approximated by

$$T \approx t(g_0 - g_c, ...g_{P-1} - g_c) \tag{4}$$

This data can be used to produce a P dimensional histogram which can be used as a feature. But to achieve invariance to scaling of the grey scale values just the sign of the differences are considered.

$$T \approx t(s(g_0 - g_c), ...s(g_{P-1} - g_c)) \tag{5}$$

where

$$s(x) = \begin{cases} 1 & x \geq 0 \\ 0 & x < 0 \end{cases} \tag{6}$$

Incorporating a binomial factor operator 2^p for each sign, Equation 5 can be converted to a number. This number can be used as a representation of local texture. [5] and other works have referred to this in terms of P and R as $LBP_{R,P}$.

$$LBP_{R,P} = \sum_{p=0}^{P-1} s(g_p - g_c)2^p \tag{7}$$

This process is illustrated in Figure II, showing how the LBP pattern can be calculated for an image region with the following grey scale values:

30	25	10
85	50	120
70	60	100

The calculation is performed around the central pixel, with a grey scale value of 50, with $R = 1$ and $P = 8$. Three neighbours have a pixel value less than 50, resulting in a corresponding 0 in the pattern entry. The others pattern entries have a value of 1, as their pixel value is larger than that of the central pixel. The order of how the pattern is read is immaterial as long as it is read consistently. In this example, we can start reading from the top right in a clockwise manner to get 01111100 as the pattern with $LBP_{P,R} = 124$ using Equation 7.

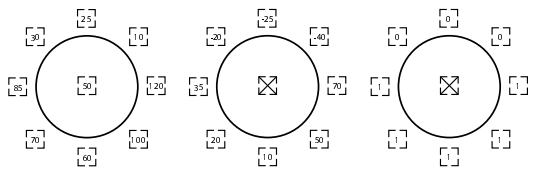

Fig. 1. Illustration of the LBP calculation.

An extension to this is presented by the authors based on the observation that certain binary patterns occur frequently in texture images. These "uniform" patterns have a small number of spatial transitions in their circular neighbourhood. These can be thought of as templates which can help identify microstructures in an image such as bright spots, dark spots and edges. Equation 8 is used to measure the uniformity of a region.

$$U(LBP_{R,P}) = |s(g_{P-1} - g_c)| + \sum_{p=1}^{P-1} |s(g_p - g_c) - s(g_{p-1} - g_c)| \tag{8}$$

In a scheme which is called LBP^{u2}_{PR}, patterns which have a U value of less than or equal to 2 are placed in a bin corresponding to their number. Other patterns are all placed in one bin. So, for a an $LBP_{R,P}$ value which has 8 bits, there are 58 uniform patterns, resulting in a histogram of 59 bins when using LBP^{u2}_{PR} .

$LBP_{R,P}$ is easily transformed into its rotation invariant version $LBP^{ri}_{R,P}$ by rotating the pattern to maximise the number of 0s in the most significant bits starting from g_{p-1}. So, the pattern 01111100 found from the illustration in Figure II would become 00011111. Using equation 9 each uniform $LBP^{riu2}_{R,P}$ pattern gets a unique label assigned to it, which depends on the number of 1s in the pattern. Every non-uniform pattern gets the label $P + 1$. This scheme produces $P + 2$ unique values. The image feature is calculated as a histogram of $LBP^{riu2}_{R,P}$ values, summed over a texture region.

$$LBP^{riu2}_{R,P} = \begin{cases} \sum_{p=0}^{P-1} s(g_p - g_c) & if\ U(LBP_{R,P}) \leq 2 \\ P + 1 & otherwise \end{cases} \tag{9}$$

Although LBP^{ri}, LBP^{u2} and LBP^{riu2} can all be calculated from LBP, upon reflection it is clear that each of them represent different image information, however slight the difference may be. The classic LBP histogram is simply a histogram of texture patterns. In achieving rotation invariance LBP^{ri} will also help identify similar texture patterns, even if they are rotated. The uniform patterns are interesting in that they do not claim to find similar patterns, but instead it can be thought of as a statistic of patterns which fulfil the uniform criteria. LBP^{riu2} would then be a the rotation invariant version of this statistic. Once we think of the different LBP features in this light, we hypothesize that using them in combination will give better overall performance, compared to using just one. Also, as they can all be extracted from LBP, the computational overhead is not significant. In this next section we describe the experiments we conducted to test our hypothesis.

III. Experiments

A. Texture collections

We present our results using two texture collections. The Outex_TR_00000 collection is used to facilitate comparison with [1] and [2].

We also present results using the VisTex collection, to show that the findings of this study can be repeated on other texture collections. The version of the VisTex collection is one used in [6], [7], [8], which has 1670 texture images in 124 relevance classes.

B. Features extracted

As mentioned previously, a large number of extensions and variants of LBP have been proposed over the last few years. Showing the performance of these variants in combination is a mammoth task and not required to establish our claim. We use the variants proposed in [5], as it is sufficient to make our case. Each of the variants were extracted at resolutions of

$1, 3$ and 5 pixels, as this resolution combination was found to be the best by [1] and [2]. Table I lists the features we have extracted. As writing the full details is space consuming, we have decided to label them for future reference in this paper.

Feature combinations	Feature Vector length	Label
$LBP_{1,8} + LBP_{3,8} + LBP_{5,8}$	768	LBP-Doshi
$LBP^{ri}_{1,8} + LBP^{ri}_{3,8} + LBP^{ri}_{5,8}$	108	LBP-Doshi-ri
$LBP^{u2}_{1,8} + LBP^{u2}_{3,8} + LBP^{u2}_{5,8}$	177	LBP-Doshi-u2
$LBP^{riu2}_{1,8} + LBP^{riu2}_{3,8} + LBP^{riu2}_{5,8}$	30	LBP-Doshi-riu2

TABLE I
THE DIFFERENT TYPES OF LBP FEATURES EXTRACTED TO BE USED IN COMBINATION. THE '+' INDICATES CONCATENATION.

C. Distance Measurement

[1] and [2] report that the multi-resolution LBP features performed best when used with the L_1 distance measure, as defined in equation 10, where V_p and V_q are two feature vectors of n dimensions, and j is the index into the vectors.

$$d_1(V_p, V_q) = \sum_{j=1}^{n} |V_p(j) - V_q(j)| \tag{10}$$

All results reported in this paper use this distance measure to judge the similarity between two images.

D. Combining features

Combining features by using simple concatenation is problematic. One reason for it has been discussed in [2], however that is not the main concern of this study. We have a different problem, where we are looking to combine features, whose feature vector lengths are quite different. Table I lists the length of the feature vectors of each feature extracted for this study.

If we were to use a simple concatenation scheme, the larger feature vectors would dominate in the distance measurements, giving results biased towards certain features.

To implement a more sensible system, we take ideas from the GNU Image Finding Tool (GIFT) system [9], which uses separate feature normalisation as a default setting. This has been cited as one of the reasons why it was shown to be the best of seven CBIR systems tested by [10]. Our normalisation scheme is much simpler than GIFT's, but the main theme is to ensure features are given their due weight. Our normalisation scheme shown in Equation 11, where the distance between images I_p and I_q are calculated using k features $V_{p,1}..V_{p,k}$ and $V_{q,1}..V_{q,k}$. The distance is calculated as the sum of the distances of the individual normalised features.

$$distance(I_p, I_q) = \sum_{j=1}^{k} d_1 \left(\frac{V_{p,j}}{sum(V_{p,k})}, \frac{V_{q,k}}{sum(V_{q,k})} \right) \tag{11}$$

The following features combinations have been used for this study.

- LBP-Doshi
- LBP-Doshi-ri
- LBP-Doshi-u2
- LBP-Doshi-riu2
- LBP-Doshi and LBP-Doshi-ri
- LBP-Doshi,LBP-Doshi-ri and LBP-Doshi-u2
- LBP-Doshi, LBP-Doshi-ri, LBP-Doshi-u2 and LBP-Doshi-riu2

E. Evaluation

[1] use a measure of the average percentage of relevant images retrieved in the top 20 retrieved images. In this case, all the images in the database are used as query images. This is no different from calculating the average retrieval rate (ARR) used by [11] and [12] to report results for a subset of the VisTex collection. The recall rate (RR) for a query image I_q calculated for the first N images retrieved is calculated as

$$RR_N(I_q) = \frac{number\ of\ relevant\ images\ retrieved\ by\ N}{N} * 100 \tag{12}$$

and ARR for a set of query images Q is then simply

$$ARR_N = \frac{\sum_{q \epsilon Q} RR_N(I_q)}{size(Q)} \tag{13}$$

We will report ARR_N results, using all the images in the database as queries, where N is the number of images per relevance class in the collection. Also, we present precision-recall (PR) graphs [13] where for each unique recall value, the precision values are averaged over all query images. Again, for these graphs every image in the collection is used as a query.

IV. RESULTS

Table II and III lists the ARR of the different combinations of features tried in this study. Using LBP-Doshi, LBP-Doshi-ri together in combination also improves performance, compared to using just LBP-Doshi. However adding the information gathered from LBP-Doshi-u2 consistently improves the performance, and the best results are obtained when using LBP-Doshi, LBP-Doshi-ri and LBP-Doshi-u2 together in combination. In fact for the Outex_TR_00000 collection, the results obtained using a combination of the three features IS 65.30% is better than the currently reported state-of-the-art results of 63.74% by [1].

Features	ARR
LBP-Doshi	63.12%
LBP-Doshi-ri	62.1%
LBP-Doshi-u2	62.28%
LBP-Doshi-riu2	58.816%
LBP-Doshi and LBP-Doshi-ri	**64.7%**
LBP-Doshi,LBP-Doshi-ri and LBP-Doshi-u2	**65.3%**
LBP-Doshi, LBP-Doshi-ri, LBP-Doshi-u2 and LBP-Doshi-riu2	62.78%

TABLE II
PERFORMANCE FOR THE OUTEX_TR_00000 COLLECTION. THE RESULTS IN BOLD SHOW THE BEST RESULTS.

In Figures 2 and 3 we see that the improved performance is also reflected in the precion-recall graphs. Again combining LBP-Doshi,LBP-Doshi-ri and LBP-Doshi-u2 gives the best performance.

Features	ARR
LBP-Doshi	77.10%
LBP-Doshi-ri	75.05%
LBP-Doshi-u2	76.52%
LBP-Doshi-riu2	71.73%
LBP-Doshi and LBP-Doshi-ri	**78.13%**
LBP-Doshi,LBP-Doshi-ri and LBP-Doshi-u2	**78.59%**
LBP-Doshi, LBP-Doshi-ri, LBP-Doshi-u2 and LBP-Doshi-riu2	76.18%

TABLE III
PERFORMANCE FOR THE VISTEX COLLECTION. THE RESULTS IN BOLD SHOW THE BEST RESULTS.

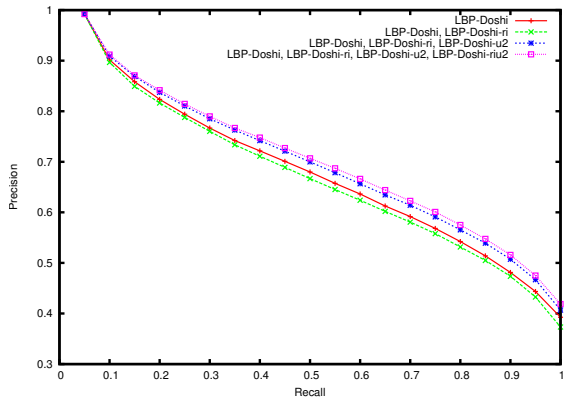

Fig. 2. Precision-Recall graphs comparing the performance of the different combinations of LBP feature types for the Outex_TR_00000 collection.

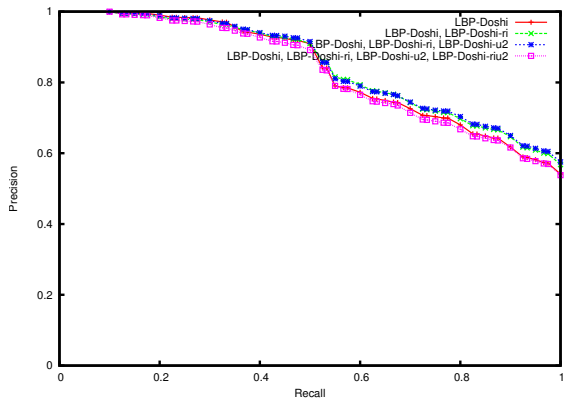

Fig. 3. Precision-Recall graphs comparing the performance of the different combinations of LBP feature types for the VisTex collection.

For both texture collections we see that adding LBP-Doshi-riu2 to the combination reduces performance. This may be understood by studying the LBP^{riu2} feature. LBP^{ri} rotates the LBP pattern so that there is a maximum number of zeros in the most significant bits, thus causing some texture patterns to be mapped to a single LBP. Applying the uniformity criteria (Equation 8) causes a further merging of texture patterns. This two step loss of image information can be a cause of degraded performance.

V. CONCLUSION

This paper explored the possibility of using different variants of LBP in combination, based on the hypothesis that if each variant extracts different but useful image information, then using them in combination will give better performance, compared to using a single variant. We have conducted our experiments on two standard texture collections. We extracted four variants of LBP features at multiple resolutions. We have shown that combining LBP, LBP-ri, and LBP-u2, through separate normalisation, gives improved performance compared to just using these features individually, for two standard texture collections. In fact for the Outex_TR_00000 collection, our method outperforms the current state-of-the-art.

In conclusion, we believe it is a flawed approach to claim one individual feature type outperforms another individual feature type, as done in [1] and [2]. It is possible, as we have demonstrated, that each individual feature extracts useful but different image information. It is through using such features together we can achieve better performance. We have demonstrated this using different variants of LBP, but it can be reasonably concluded that such combined approach can be beneficial when using other features.

***Abstract*—The implementation of an adaptive Volterra filter to compensate for speaker non-linearity using a pipelined recurrent neural network based architecture is demonstrated. The proposed architecture consists of two stages: nonlinear stage performing a nonlinear second order Volterra (SOV) mapping from the input space to an intermediate space and a linear combiner performing a linear mapping from the intermediate space to the output space. The filter design is tested by implementing it on a dataplane processing unit configured for audio processing. The implemented algorithm is adjusted for Xtensa Processor and uses HiFi-2 DSP standard. The collected data confirms smaller error of the output with the speaker and also a very low settling time.**

***Index Terms*—Volterra, JPPSOV, Xtensa, adaptive filter, non-linearity.**

I. Introduction

The Volterra Series filter is one of the most widely used non-linear systems. The ease with which existing linear adaptive filters can be extended to fit this model makes it a popular non-linear filter. The Volterra Series expansion can be interpreted as a Taylor Series expansion with memory [1]. A major disadvantage of the filter is the computational complexity arising when the complete series has to be implemented. One key reason is that the number of the Volterra coefficients increases geometrically as the delays (or memory) and orders increases.

There are a number of methods applied to reduce the computational complexity. These include iterative factorization technique [2], the fast Kalman algorithm [3], multi memory decomposition [4]. With these strategies, the computational complexity can be reduced significantly compared with the SOV filter, but the stable performance is not guaranteed. Again, in Volterra filter using the normalized least mean square (NLMS) the output of the system becomes a nonlinear function of the filter coefficients [5].

However, a novel architecture based on Pipelined Recurrent Neural Network (PRNN) [6], [7] provides a more computationally efficient way to approximate non-linear systems in a modular approach. In this Xtensa processor [8] based implementation, the novel adaptive Joint Process filter using Pipelined Second Order Volterra (JPPSOV) architecture is followed. The attractive attribute of such pipelined architecture is that the capability of such realizations to efficiently approximate nonlinear systems using less computational burdens. Moreover, the combination of the two stages, nonlinear and then linear, makes the output dependent on the filter coefficients linearly.

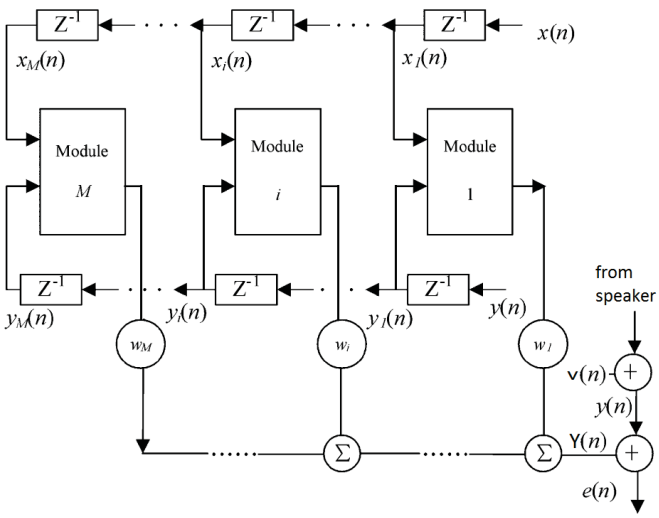

Fig. 1. Block diagram of modified adaptive Joint Process filter using Pipelined Second Order Volterra architecture.

II. Theory

The algorithm effectively splits the system into two subsystems, one is nonlinear and the other is linear. The nonlinear subsystem contains M number of SOV cores (Fig. 1). It performs nonlinear mapping from a input space to an intermediate space which linearizes the nonlinear signals. Each module takes one of the external inputs and the noisy output from the speaker as inputs. The benefit of this arrangement is in the uniformity of numbers of inputs and outputs and the synaptic weight matrix.

For the i-th module, the input can be written as:

$$X_i(n) = [X_{i,1}(n), X_{i,2}(n)] \tag{1}$$

where, the column $X_{i,1}(n)$ is vector of previous external input at the n-th time point and is described by:

$$X_{i,1}(n) = x(n-i)$$

and $X_{i,2}(n)$ contains the noisy output from the speaker,

$$X_{i,2}(n) = y(n-i)$$

At the n-th time point, input signal vector $X_i(n)$ is expanded to a row vector $XX_i(n)$ by the SOV series (2) where the number of columns of the matrix is defined by $L = 6$ which is much less compared to $(N+1)(N+2)/2$ of the ordinary Volterra theory.

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

$$\begin{aligned} XX_i(n) &= [XX_{i,1}(n), XX_{i,2}(n), \ldots, XX_{i,L}(n)] \\ &= [1, X_{i,1}(n), X_{i,2}(n), X_{i,1}^2(n), \\ &\quad X_{i,1}(n)X_{i,2}(n), X_{i,2}^2(n)] \end{aligned} \tag{2}$$

Since the weight vectors are same for all the modules, the synaptic weight vectors of the SOV series of each module is denoted by the column vector $H(n)$, whose length is also L.

$$H(n) = [h_1(n), h_2(n), ..., h_L(n)]^T \tag{3}$$

Thus, the output $y_i(n)$ of the i-th modules is defined by:

$$y_i(n) = XX_i(n)H(n) \tag{4}$$

The linear subsystem simply performs a mapping from the intermediate space to the output. The outputs of the nonlinear subsystems are combined in a ratio provided by a weight vector to produce an estimation of the original signal. The weight vector is given by:

$$W(n) = [w_1(n), w_2(n), ..., w_M(n)] \tag{5}$$

If the outputs of the previous non-linear modules are

$$YY(n) = [y_1(n), y_2(n), ..., y_M(n)]^T \tag{6}$$

the outputs of the linear subsystem would simply be the inner products of these two vectors.

$$Y(n) = W(n)YY(n) \tag{7}$$

The error between the desired signal and estimated signal is given by

$$e(n) = y(n) - Y(n) \tag{8}$$

Under the assumption that the coefficient vector $H(n)$ of the nonlinear subsection is time variant, the adaptation of $H(n)$ is similar to the classical case. Therefore, the normalized least mean square (NLMS) equation driving the update of the nonlinear subsection finally becomes

$$H(n+1) = H(n) + \eta_2 e(n)\frac{U(n)}{||U(n)||_2^2} \tag{9}$$

where $U(n)$ is defined by,

$$U(n) = W(n)XX_i(n)$$

Similarly, the NLMS equation driving the update of the linear filter is

$$W(n+1) = W(n) + \eta_1 e(n)\frac{YY(n)}{||YY(n)||_2^2} \tag{10}$$

where $||YY(n)||_2^2$ is the L_2 norm.

Here, η_1 and η_2 are the two learning rates. A necessary condition for the mean convergence is [9],

$$0 < \eta_1 < 2 \qquad \text{and} \qquad 0 < \eta_2 < 2$$

The values of the learning rates are very crucial for steady response of the filter. In this work, $\eta_1 = \eta_1 = 1/8$ is used.

TABLE I
THE VALUE OF THE NON-LINEARITY COEFFICIENTS FOR SIMULATING DIFFERENT SPEAKERS

Co-efficient	b	c
Speaker-1	-0.1	0.1
Speaker-2	0.05	0.05

III. OPTIMIZATION TECHNIQUES

As illustrated in [10], the filter with only 4-5 modules ensures lowest mean square error (MSE). As the Xtensa processor gives an opportunity of two parallel multiplication operation, 4 modules are used in this implementation. Moreover, the inputs of each module is also modified in order to decrease the no. of memory operations.

According to (9), $U(n)$ has to be divided by $||U(n)||_2^2$ and then η_1 is multiplied to obtain the change of the vector H. The filter converges as long as $0 < \eta_1 < 2$. The performance of the filter does not change much within this range of η_1. If η_1 is kept constant on the other hand, the division result can be allowed to vary to mimic the change of η_1. Since doing complete division using any DSP processor like Xtensa is inefficient, the division is replaced with an efficient bit shift operation. This bit shift can be modeled by,

$$q = \left\lfloor \frac{2^{\lfloor \log_2 a \rfloor}}{b} \right\rfloor \tag{11}$$

where a is the dividend, b is the divisor and q is the quotient. It can be observed that the quotient can be off by only one fourth of its intended value. Since $\eta_1 = 1/8$, the division can be replaced with the bit shift operation, effectively making $\eta_1 = 1/32$ in the worst case scenario.

It can be seen from (10) that, the computation of the change of the vector W can be done in a similar manner to improve efficiency.

IV. TEST STRATEGY

The Xtensa instruction set simulator (ISS) has been used to test the performance of the algorithm. From the tests run in the simulator, various performance characteristics like the time required to process each sample and the residual error are obtained.

The audio for the speaker input and the audio output obtained from the microphone both are required during run-time for the filter. Both the audios are assumed to be mono channel with 16 kHz sampling rate and each sample was assumed to consist of 16 bits. The errors in output are obtained as 16-bit values as well.

For the actual testing of the adaptive filter algorithm, the microphone input signal is modeled from the speaker input signal. Furthermore the speaker input is considered to be non-linearly distorted by,

$$z = \frac{x + bx^2 + cx^3}{1 + |b| + |c|} \tag{12}$$

where the non-linear terms are assumed to be less than or equal 10% of the linear term. A random noise has also been added to the microphone input. The noise is within 1% of the feedback signal at most.

Using the speaker input and the modeled microphone input, the filter is tested for various different scenarios. Three different audio samples each 1 second in length are used to test the

TABLE II
THE REQUIRED CYCLES & MINIMUM PROCESSOR CLOCK SPEED FOR THE DIFFERENT SCENARIOS

Audio type	Speaker	Total cycles	Cycles per sample	Minimum clock speed (MHz)
Human voice	Speaker-1	17238241	1077	17.24
	Speaker-2	17238871	1077	17.24
Instrumental music	Speaker-1	17564397	1098	17.56
	Speaker-2	17642333	1103	17.64
Periodic signal	Speaker-1	17995837	1125	18.00
	Speaker-2	18049309	1128	18.05

TABLE III
THE SETTLING TIME AND THE RESIDUAL NOISE AT DIFFERENT SCENARIOS

Audio type	Speaker	Residual Noise (dB)	Settling Time (ms)
Human voice	Speaker-1	-41.0048	8.75
	Speaker-2	-39.0622	7.50
Instrumental music	Speaker-1	-28.7217	12.50
	Speaker-2	-27.9533	9.38
Periodic signal	Speaker-1	-45.1022	32.19
	Speaker-2	-44.0620	25.00

filter. These audios are: human voice, instrumental music and simple triple frequency audio. All of the audios are of 1 second in duration. Different values of the non-linearity coefficients in the microphone input model are tested to simulate different speaker types. The used coefficients, b and c, are summarized in Table I.

The processor has been configured in the built-in 'HiFi-2 standard' mode [11] for the particular implementation. In this configuration, the processor can handle audio signal processing like multiplication and addition of 24-bit numbers very efficiently. Hence for this implementation, the 16-bit integers from the input are shifted left in order to convert to 24-bit. Processor's parallel multiplication instruction is utilized whenever possible to reduce the number of cycles required per audio sample.

V. RESULTS AND DISCUSSION

The number of instructions required by the processor to operate on the audio samples of 1 second and minimum clock frequency required to do the processing in real-time is given in Table II. Since the processor can operate at frequencies well above the obtained minimum required clock frequency, it will be possible to use the processor for real-time operation with ease. As illustrated in Fig. 2, use of only four modules shows the lowest Mean Square Error (MSE).

The average error in decibels was calculated with respect to the input signal. As the settling time is negligible, the residual noise was calculated as the average of all the error values in decibel (dB). The time after which the error becomes less or equal to the mean error was considered to be the settling time. The mean local error vs. sample plots for the human voice sample, music sample and the simple periodic audio signals through different speakers are shown in Fig. 3 and Fig. 4 respectively. Again, the settling time and the residual noise is presented for the six scenarios in Table III.

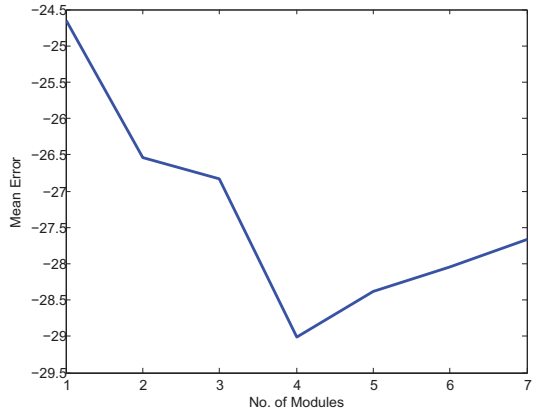

Fig. 2. relation between the MSE and the number of modules for speaker-1.

VI. CONCLUSION

An implementation of a novel adaptive joint process filter employing the pipelined architecture is presented in this paper. It is seen that the algorithm can easily be implemented using the Tensilica Xtensa dataplane processing unit. The obtained residual error was very low and the settling time was very small. Furthermore, size of the code and the required processor clock speed was within desired levels for the implementation indicating the efficiency of the algorithm.

ACKNOWLEDGMENT

The authors would like to thank Cadence Design Systems, India for providing the software, license and samples required for the work.

***Abstract*—In this work we proposed a new variant of spectral clustering using double spectral analysis which proved to be able to achieve better clustering results. The present work focuses on the special case of 3D videos and the implication of their use. Various improvements are introduced including the use of stereo over mono videos, the use of double spectral clustering over spectral clustering and the use of multiple representative images per trajectory for more robust trajectory representation. Extended experiments have been conducted in three 3D full feature commercial films which revealed the power of stereo face clustering in comparison with single channel face clustering.**

***Index Terms*—3D, stereo facial image clustering, Spectral clustering, Ncut, HSV color space, facial image clustering**

I. Introduction

Clustering is one of the fundamental topics in computer science. It has been studied at a great degree but even at present day it is not considered solved. Clustering deals with dividing an existing set of objects $\mathcal{P}$ (in our case, images) into a number of subsets (clusters) $\mathcal{C} = \{C_i | C_i \subseteq \mathcal{P}\}$. Those subsets have to fulfill the following conditions: $\bigcup_{C_i \in \mathcal{C}} C_i = P$ and $\forall C_i, C_j, i \neq j \in \mathcal{C} : C_i \bigcap C_j = \oslash$. Essentially clustering assigns each sample of a data set to a cluster, although there are exceptions to this rule like in the fuzzy c-means algorithm.

This paper deals with facial image clustering applied on 3D commercial feature films, where the goal is to separate face images into groups, for which within-cluster similarity is high whereas between-cluster similarity is smaller. There is some work with single channel feature films like [1] but similar work on 3D films is quite limited. Also, in [1] these films there is limited variance in optical effect, illumination, or special features of the images in the used test films. The film used in [1] has just 1 shots with consistent clothing, the film focuses on character development rather than visual effect etc. There are also various works with facial image clustering not deriving from videos like [2], [3] but focusing on still images. in this case the requirements are different. On the other hand, even in mono videos, often the dataset derives from much shorter videos as in [4] or is confined as in [5]. Spectral clustering has also been used in previous works [6],[7].

The rest of this work is organized as follows: Section 2 contains a short presentation of Mutual Information and its normalized version used in this work as similarity measure among images. Section 3 provides the problem statement and prior work on the field while Section 4 introduces the double spectral clustering and the improvements proposed. Section 5 contains the experimental results and finally Section 6 concludes the paper.

II. Mutual Information

Mutual Information (MI) is used in this work as the similarity measure between facial images, thus we will briefly present some related important definitions. the interested reader may refer to [6] for details on MI.

Mutual Information is defined as the common information of two distributions. Entropy of a random variable X is defined as:

$$H(X) \triangleq -\sum (p(x) log(p(x))) \tag{1}$$

while joint entropy of two random variables X, Y is defined as:

$$H(X,Y) \triangleq -\sum (p(x,y) log(p(x,y))) \tag{2}$$

where $p(x)$ is the probability density function and $p(x,y)$ is the joint probability density function of random variables X and Y respectively. The normalized mutual information used is:

$$D(X,Y) = \frac{H(X) + H(Y)}{2H(X,Y)} \tag{3}$$

as in [8]. In this work the HSV color space of images was used for calculating similarity as it has been proved to be more robust in illumination changes compared to RGB color space. More specifically we will follow the approach of [6] where only Hue (H) and Saturation (S) are used. According to this approach, a 4D normalized MI is used:

$$D(X,Y) = \frac{H(H_1) + H(S_1) + H(H_2) + H(S_2)}{2H(H_1, S_1, H_2, S_2)} \tag{4}$$

where H_i is the Hue and S_i is the Saturation of each image respectively. For the 4D joint histogram an approach similar to [6] was used.

III. Problem statement and prior work

In order to use spectral clustering techniques we define our face clustering problem as an undirected graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ cut problem. We consider each facial image to be a graph vertex and then we construct a similarity matrix $\mathbf{W}$ in which each element w_{ij} represents the edge that connects the two images (vertices), which has a weight representing the similarity of the corresponding image pair and has an assigned value of $1/d_{ij}$.

We can then use different spectral approaches to solve the problem. Crucial to all approaches is the definition of the Laplacian matrix $\mathbf{L}$. The normalized Laplacian is defined as:

$$\mathbf{L} = \mathbf{D}^{-1/2}\mathbf{L}\mathbf{D}^{-1/2} = \mathbf{I} - \mathbf{D}^{-1/2}\mathbf{W}\mathbf{D}^{-1/2} \tag{5}$$

where $\mathbf{D}$ is the Degree matrix. The normalized Laplacian $\mathbf{L}$ has been used in our case since it has been proven to have greater merits than the unnormalized one [9].

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

Having defined the Laplacian matrix $\mathbf{L}$ different approaches for clustering can be used. One possible solution could be the use of Normalized Cuts (Ncut) [10] described in subsection III-A while another solution could be the approach introduced in [11] and summarized in subsection III-B below.

A. Normalized cut

Ncut is defined primarily for bipartition, namely for splitting the graph into two parts, and it attempts to find the cut that minimizes the edge weights (connections) between the two clusters while simultaneously maximizing the edge weights within the two clusters.

The problem the Ncut algorithm tries to solve is defined as $\text{argmin}_{\mathbf{y}} \frac{\mathbf{y}^T(\mathbf{D}-\mathbf{W})\mathbf{y}}{\mathbf{y}^T\mathbf{D}\mathbf{y}}$ subject to $\mathbf{y}^T\mathbf{D}\mathbf{1} = 0$ which uses the matrices defined in section III. The Ncut problem is usually solved by relaxing the solution using eigen-analysis [10].It is proven in [10] that the eigenvector corresponding to the second smallest eigenvalue is the optimal graph cut for the given criterion. More eigenvectors or an iterative eigen-analysis can be applied in order to derive more than two clusters.

B. Spectral clustering

While Ncut solves a binary problem, the spectral clustering approach proposed in [11] solves a multiclass clustering problem. This solution also uses the Laplacian matrix $\mathbf{L}$ defined in (5). The solution applies eigen-analysis in $\mathbf{L}$ and uses the first k eigenvectors $\mathbf{u}_2, ..., \mathbf{u}_{k+1}$ excluding the first one. A new matrix containing those eigenvectors is defined as $\mathbf{U} \in \mathbb{R}^{N\times k}$ (N being the number of images). New samples are defined as the rows of this matrix after being normalized to norm 1. The final step is to use k-means [12] to these new samples.

IV. Introducing double spectral analysis

The two approaches briefly mentioned in sections III-A and III-B although have proved quite efficient in various cases, have some drawbacks. In this Section, we list these drawbacks and also propose ways to overcome them while preserving their merits.

At first, Ncut is designed to solved two-class problems which can have some implications when applied to multi-class problems. One simple example is demonstrated in figure 1(a). In this example a simple similarity matrix $\mathbf{W}_{sample}$ is used, created by inverting the Euclidean distance of each pair of points $\mathbf{x}_{ij}$.

Assume that we cluster the samples using the Ncut algorithm and matrix $\mathbf{W}_{sample}$. We plot the elements of the second smallest eigenvector in Figure 1(b) which is the optimal solution for the Ncut problem according to [10] and also choose to use the simplest threshold, namely zero. While there are 4 easily distinguishable classes, shown in Figure 1(a), Ncut fails to separate correctly the classes as it is obvious in Figure 1(b). More specifically, class #1 is split in two by using this threshold. By observing the elements of the eigenvector corresponding to each sample we see that all elements corresponding to samples of the same class obtain similar values. That observation led us to use a more flexible threshold, the greatest gap threshold (GG threshold) as explained in section IV-B.

The main drawback of the spectral clustering approach [11] is the use of k-means as the main clustering algorithm. It is well known that k-means has various limitations; such as the assumption of spherical clusters, the effect of initialization on its performance and the possible convergence to a local minimum. Thus, we opted for a more efficient clustering algorithm. Since Ncut does not assume the above we opt to use it instead of k-means, as described in the next Section.

A. Double spectral clustering

The proposed approach is similar to the one in [11]. Assume that we have a dataset with N facial images. We then calculate the similarity matrix $\mathbf{W} \in \mathbb{R}^{N\times N}$ as described in Section II, III and the normalized Laplacian matrix $\mathbf{L} \in \mathbb{R}^{N\times N}$ in (5).

We apply eigen-analysis to $\mathbf{L}$ and create a new matrix $\mathbf{U}$ containing the k first eigenvectors of $\mathbf{L}$ as columns. The eigenvectors are ordered using their corresponding eigenvalue in ascending order. Furthermore, the first eigenvector corresponding to the trivial solution is not taken into consideration. Thus, $\mathbf{U} = \{\mathbf{u}_2, ..., \mathbf{u}_{k+1}\}$.

We create new samples $\mathbf{Y} = \{\mathbf{y}_1, ..., \mathbf{y}_N\}$ that correspond to the rows of matrix $\mathbf{U}$. Those new samples have dimension k which equals the number of eigenvectors being used. It must be noted that we do not normalize the samples $\mathbf{y}_i$ as in [11], in order to keep as much discriminality as possible. Normalization using L_2 norm would mean projecting all samples to the unitary circle which obviously reduces the distance among samples.

The general idea is to create new samples that benefit from the eigen-analysis of the Laplacian matrix $\mathbf{L}$ which tends to gather together samples with high similarity score in $\mathbf{W}$ and to distanciate samples with low similarity score in $\mathbf{W}$.

From this point we create a new similarity matrix $\mathbf{W}'$ considering as initial data set the $\mathbf{Y} \in \mathbb{R}^{N\times k}$ and using the inverse of the Euclidean distance of similarity score:

$$[\mathbf{W}']_{i,j} = \frac{1}{(\mathbf{y}_i - \mathbf{y}_j)^T(\mathbf{y}_i - \mathbf{y}_j)} \tag{6}$$

Then, we proceed by creating the correspoding Laplacian matrix $\mathbf{L}'_{sim}$ and apply the Ncut algorithm in order to split the dataset into 2 subclusters. In order to get the desired number of clusters we recursively apply the Ncut algorithm to those subclusters until this number has been reached.

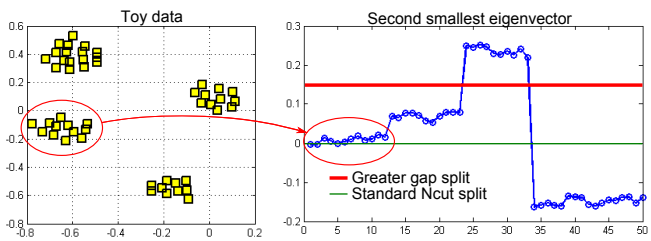

Fig. 1. Ncut unsuccessful clustering in toy example

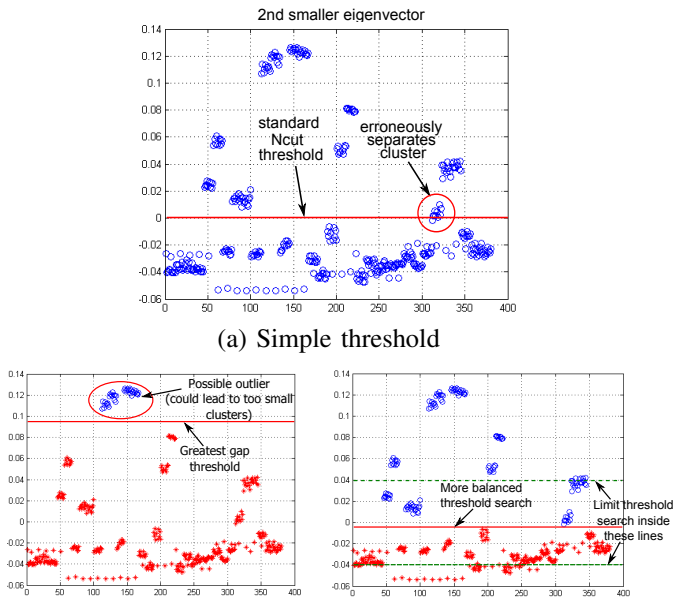
B. Greater gap threshold

As it has been previously mentioned and also shown in Figure 1 the simple thresholding approach that uses a threshold equal to zero on the eigenvector elements often fails when used with multi-class problems. For this reason we propose a new approach which uses a more flexible threshold that has been proven to be more reliable. Figure 2 plots the elements of the eigenvector of a real problem that corresponds to the second smallest eigenvalue and their relative position with



(a) Simple threshold

(b) Overall greatest gap threshold

(c) Limited greatest gap threshold

Fig. 2. The effect of using different thresholds

respect to the zero axis. One possible problem with a fixed zero threshold has already been mentioned and concerns the separation of clusters which get values around zero, as the one shown in Figure 2(a) inside the red circle. Those clusters could have samples which correspond to very similar elements of the eigenvectors (and thus they should not be split) but the a fixed zero threshold does not take into account this similarity.

Thus, instead of using a fixed threshold, we first sort the elements of the second eigenvector and then search for the greatest difference between two consecutive elements. Then the threshold is set as the mean value of these two consecutive elements having the greatest gap. Thus we get a different threshold in each application of the Ncut algorithm.

One problem with this approach is that it tends to first separate the outliers from the other samples (Figure 2(b)) which may not be an optimal approach. For this reason we restrict the threshold search inside some limits as shown in Figure 2(c). The restriction limits are usually defined with respect to the greatest value v occurring in each eigenvector, that is as a proportion of this greatest value v: $Limits : \pm av,\ a \in (0, 1]$.

V. Experiments

A. Mono and stereo dataset creation

We applied our proposed method in three full length 3D feature films of different duration, size of cast and genre. For the creation of the facial image dataset, face detection and tracking was applied. Two different approaches were tested, in an effort to highlight the advantage of using stereo data. In the first approach, the face detection [13] is performed every n frames in one channel (video) of the stereoscopic video, followed by a face tracker [14], [15] at the same channel. In the second approach, face detection [13] was applied on both channels, mismatches between the two channels were rejected and a stereo tracking algorithm [15] was applied in both channels. By using the above approaches we end up with a number of facial trajectories, namely series of consecutive facial images.

As can be observed in Table I the trajectories generated by the stereo face detectors and trackers are fewer in number and longer (in number of frames). This has the advantage of fewer facial images to be clustered and better representation of the actor appearances. Another observation that can be made in Table I is that the number of clusters (that equals the cast size) is quite high. The cardinality of actor clusters varies significantly with some actors having many facial images while others have very few appearances.

Usually, each tracking trajectory is represented by one (usually detected) facial image. Another approach for dataset creation examined was the inclusion of multiple facial images per trajectory. We used all detected images as well as each middle image between two sequential detections belonging to the same trajectory. For 2 trajectories represented by 2 sequences of k and m images respectively, T_k and T_m we calculate the similarity between them as:

$$\text{Similarity Score} = \max_{ij} MI(x_i, x_j) \quad x_i \in T_k, x_j \in T_m$$

where x_i is an image belonging to the sequence T_k. The extreme values for the size of T_i is 1 (as the usual case) to the whole set of images belonging to each trajectory. By this way a robustness in variation in pose, illumination etc is applied. It can be seen that with multiple images the number of images is increased but the similarity matrix used in clustering is of the same size as before (having the size of the number of trajectories) because only one score per trajectory is finally used. Experiments have been conducted using this new approach and revealed an increase in performance.

B. Experimental results

Experiments were conducted in three 3D feature films with varying duration, size of cast, special effect etc. Some characteristics of each film are shown in Table I where it can be seen that stereo dataset are fewer in number and bigger (in number of frames). This has the advantage of fewer facial images to be clustered and also larger trajectories which signifies better representation of the films. Experimental results confirm this also in the performance. In Table I it is obvious that the number of clusters (that equals the cast size) is quite high while another fact is the unbalanced classes; with some persons having many images and also some persons having very few appearances.

Results have been accumulated in Table II where it can be observed that there is a significant improvement over Ncut by using both double spectral clustering and double spectral clustering with constrained greatest gap. Of the two latter methods best results were achieved using the double spectral clustering in combination with greatest gap in all 3 films. The use of stereo video also improves the performance and provides an extra way to further improve the results. There is a significant advantage in using both channels in comparison with a single channel.

For the evaluation of the clustering a variation of F-measure was used. Since the number of clusters is quite high the standard F-measure tends to punish the splitting of classes into more clusters. In our case, and taking into consideration the complexity of the facial image clustering task, a different clustering measure was used. This new measure evaluates more

the purity of clusters, which is one of the desired criteria, while on the same time validates the overall clustering as well. The new approach included oversplitting the set to more than the clusters needed and then merged them in a way a user would merge them; that is by merging all clusters having the majority of their elements derive from the same class.

VI. CONCLUSION

In this work we proposed a new variant of spectral clustering using double spectral analysis which proved to be able to achieve better clustering results. We also focus mainly on 3D films and the special issues regarding their use, like the possible improvement by the use of stereo video compared to mono ones, but also in other aspects of films like the use of multiple images per trajectory for further improving the results. Finally a more flexible threshold was introduced that also proved more efficient. Further work will include more extensive research on the use of 3D films for clustering purposes.

***Abstract*—In this paper, we propose a method for video characterization based on activity description information. We employ a state-of-the-art video representation in order to learn human activity concepts, i.e., video groups formed by videos depicting similar human activities. In order to exploit the enriched visual information that is available in multi-view settings, we propose the use of the circular shift invariance property of the coefficients of the Discrete Fourier Transform (DFT) that leads to a view-independent multi-view action representation. In the test phase, in order to assign a test video to one (or multiple) activity groups, we perform temporal video segmentation in order to determine shorter videos depicting simple actions. Experimental results on 2 multi-view action databases denote the effectiveness of the proposed approach.**

***Index Terms*—Video characterization, Activity clustering, Multi-camera setup, Temporal video segmentation.**

I. Introduction

Understanding human activities in video sequences is a challenging problem due to the large variability in temporal scale and the periodicity of human actions, the complexity of articulated motion, the prevalence of complex backgrounds, variations in observation angles, etc. It has been primarily approached by applying action/activity recognition techniques that are able to exploit visual information coming from one [1] or multiple [2], [3] cameras. The adoption of multiple cameras gives the advantage of exploiting information related to scene geometry and, thus, leads to higher classification performance in general. However, this performance gain is accompanied by a higher computational cost, since in multi-view methods multiple video streams should be processed and analyzed [2], [3].

One of the disadvantages of the above-described approach is that in an action recognition setting, the set of all possible actions should be a priori defined. In addition, an adequate number of (labelled) videos should be employed in order to train classifiers that will be subsequently used for action video characterization [4]. Given the complexity of such a task due to the aforementioned reasons, the cardinality of the training set required in order to achieve satisfactory performance in an unrestricted application scenario would be enormous. This in turn generates several problems, the most important being the underlying financial and computational costs of such an approach.

In several application scenarios, e.g., in movie production/post-production and content-based video retrieval, the objective is the determination of similar action/activity patterns, rather than to perform a strict characterization (i.e., recognition) of the performed actions. In this way, several treatments, e.g. filters, can be applied to similar video segments. This can, obviously, been addressed by applying action recognition techniques and determine video groups depicting the same action/activity. In addition, in an attempt to address the above-described issues relating to human action recognition, an alternative approach can be exploited that involves unsupervised learning. Unsupervised learning of human actions in this sense is a relatively new research topic [4] and it is expected to receive considerable research interest in the next years.

In this paper, we propose a method for video characterization that exploits activity description. We employ the Dense Trajectory-based video description [5], that has been shown to provide state-of-the-art performance on a related task, i.e. action recognition, and combine it with the Bag-of-Words (BoW) model [6] in order to represent videos depicting actions. Furthermore, it does not suffer from background subtraction problems [7], as is the case with silhouette-based action recognition methods [8]. Finally, there is no need to track particular body parts, e.g., arms, feet [9] for action recognition. In an offline process, we determine K action video groups by clustering training action videos depicting simple actions. During the test phase, a Dense Trajectory-based video representation is obtained in order to represent a new (unknown) video, which is subsequently assigned to the label of the group formed by the most similar to it videos. Since test videos are not guaranteed to depict simple actions, we also propose a method that exploits the same video description and is able to perform automatic temporal segmentation of a test video to shorter ones, each depicting a simpler action. Finally, we extend both methods in order to be able to exploit multi-view information that is available in the cases where actions are observed by using multi-camera setups. Experimental results denote that the adoption of multi-view information provides considerable performance gains, when compared to the single-view case, confirming the findings that have come from other relating studies [8], [10].

The rest of the paper is structured as follows. Section II describes the proposed methods. Experimental results conducted in order to evaluate its performance are described in Section III. Finally, conclusions are drawn in Section IV.

II. Proposed Method

Let us denote by $\mathcal{U}$ a video database containing videos depicting N_I videos, e.g., a walking instance. In the case where the action instances have been recorded by using one camera, these action instances are depicted in N_I action instances, while in the case where a multi-camera setup formed by N_C cameras has been used, each action instance is depicted in N_C videos and $\mathcal{U}$ is formed by $N_T = N_I N_C$ videos. We would like to determine K video groups $\mathcal{U}_k$, $k = 1, \ldots, K$, where $\bigcup_{k=1}^{K} \mathcal{U}_k = \mathcal{U}$, each of which will (ideally) be formed by videos depicting the same activity type.

We employ the Dense Trajectory-based video representation [5] in order to represent each video by five vectors, describing two video properties: motion and shape. The shape of various subjects appearing in the scene is described by the Histogram

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

of Oriented Gradient (HOG) descriptor, while motion is described by the remaining four descriptors, i.e., Histogram of Optical Flow (HOF), two channels of Motion Boundary Histogram (MBHx and MBHy) and the (normalized) interest point trajectory coordinates. Even though the four latter descriptors describe the depicted motion, each of them describes a different property of motion. This is important in order to distinguish different activity types [5], [11]. In addition, the adopted video description, by describing local properties of videos, is robust to occlusions [5]. By adopting such a video description, each video in $\mathcal{U}$ is represented by five vectors $x_i^v \in R^{D_v}, v = 1, \ldots, V$ $(V = 5)$, D_v being the dimensionality of each descriptor, obtained by using the BoW model on each descriptor type.

In order to determine the K video groups in $\mathcal{U}$, we apply clustering on the previously determined video representations $\mathbf{x}_i^v, i = 1, \ldots, N_I$. These will serve as train samples. Since BoW-based video representations are better combined with kernel methods, we employ kernel K-Means algorithm [12] to this end. In order to combine the different activity properties described in different BoW-based representations $\mathbf{x}_i^v$, we employ the RBF-χ^2 kernel, where different descriptor types are combined in a multi-channel approach [13]:

$$[\mathbf{K}]_{ij} = \exp\left(-\frac{1}{v}\sum_v \frac{1}{A^v} D(\mathbf{x}_i^v, \mathbf{x}_j^v)\right), \quad (1)$$

where $D(\mathbf{x}_i^v, \mathbf{x}_j^v)$ is the χ^2 distance between the BoW-based representation of videos i and j with respect to the v-th channel. A^v is set equal to the mean value of χ^2 distances between $\mathbf{x}_i^v$ for the v-th channel. After the determination of the cluster labels for the vectors $\mathbf{x}_i^v$, each video i is assigned to the corresponding cluster label.

In the test phase, when a new video depicting an unknown activity appears, we want to assign it to a video group formed by videos depicting the same activity. Thus,we want to characterize its content in terms of the performed activity. To this end, we employ the Dense Trajectory-based video representation in order to represent it by using five vectors $\mathbf{x}_t^v$. Subsequently, we assign the video to the group that provides the minimal χ^2 distance from the corresponding cluster center (in the feature space).

In the case where action instances are depicted in multiple (N_C) videos, each captured by a different viewpoint, we can exploit the available multi-view information in order to obtain a view-independent action representation. This can be achieved by exploiting the circular shift invariance property of the coefficients of the Discrete Fourier Transform (DFT) [10]. In order to avoid confusion, let us denote by $\mathbf{x}_{i,c}^v$, $i = 1, \ldots, N_I$, $c = 1, \ldots, N_C$, $v = 1, \ldots, V$ the N_C vectors representing action video i by exploiting the v-th descriptor type. By using the camera labeling information that is available for both the training and test videos, we define a multi-view action representation by concatenating $\mathbf{x}_{i,c}^v$, i.e., $\mathbf{x}_i^v = [\mathbf{x}_{i,l_i=1}^{v\,T}, \mathbf{x}_{i,l_i=2}^{v\,T}, \ldots, \mathbf{x}_{i,l_i=N_C}^{v\,T}]^T$. In order to obtain a view-independent action representation $\mathbf{y}_i^v \in \mathbb{R}^D$, where $D = N_C \sum_v D_v$, we calculate the coefficients of the DFT by using $\mathbf{x}_i^v$, i.e.,:

$$y_i^v(k) = |\sum_{n=0}^{D-1} x_i^v(n) e^{-i\frac{2\pi k}{D}n}|, \quad k = 1, ..., D-1. \quad (2)$$

After the calculation of the multi-view action representations $\mathbf{y}_i^v$, we can proceed by following the above-described unsupervised learning process for action video group determination. Accordingly, a test action instance can be represented by employing a view-independent action representation $\mathbf{y}_t^v$ and assigned to the corresponding cluster label.

A. Temporal Video Segmentation

As has been previously described, test videos are not guaranteed to depict simple actions. Thus, the assignment of such videos in video groups containing simple actions would be wrong. In order to address this issue, we propose a method for automatic temporal video segmentation that exploits the Dense Trajectory-based video description.

Let us assume that a test video appears. We employ the Dense Trajectory-based video description in order to calculate descriptors $\mathbf{d}_i^v, i = 1, \ldots, N_d, v = 1, \ldots, V$ on the trajectories of densely-sampled video frame interest points. N_d is the number of interest points detected in the test video. We concatenate the five descriptor vectors $\mathbf{d}_i^v$ in order to fuse the local shape and motion information appearing in each trajectory, i.e., $\mathbf{d}_i = [\mathbf{d}_i^{1\,T}, \ldots, \mathbf{d}_i^{5\,T}]^T$. Subsequently, we apply K-Means clustering [14] on $\mathbf{d}_i$ in order to calculate a set of descriptor prototypes (codebook). By using this codebook, which is exclusively derived from the video under consideration, and the video frame indices corresponding to each trajectory, we create BoW-based representations of (overlapping) video segments, each consisting of T video frames and succeeding its neighbor by one frame. In all our experiments we have used the value $T = 20$. Let us denote the number of the resulting video segments by M. Let us also denote by $\mathbf{v}_j, j = 1, \ldots, M$ the BoW-based representations of the resulting video segments. By exploiting the video segment temporal relationship, we create two sets of video segment representations $\mathcal{S}_i$, $i = 1, 2$, each consisting of M_i, $i = 1, 2$ vectors $(M_1 + M_2 = M)$. By employing $\mathbf{v}_j, j = 1, \ldots, M$ and the corresponding set labels c_j, the within-set and total variance can be measured by:

$$s_w = \sum_{i=1}^{2} \sum_{j, c_j = i} (\mathbf{v}_j - m_i)^T (\mathbf{v}_j - m_i), \quad (3)$$

$$s_T = \sum_{j=1}^{M} (\mathbf{v}_j - m)^T (\mathbf{v}_j - m), \quad (4)$$

where

$$m = \frac{1}{M}\sum_{j=1}^{M} \mathbf{v}_j = \frac{1}{M}\sum_{i=1}^{2} M_i m_i, \quad (5)$$

$$m_i = \frac{1}{M_i}\sum_{j, C_j = i} \mathbf{v}_j. \quad (6)$$

After calculating s_w, s_T, we can calculate the so-called *Fisher criterion* $J = s_w/s_T$. Since $\mathbf{v}_j$ represent the video segments in the test video, the minimization of J leads to the maximization of the compactness of the two video segment sets $\mathcal{S}_1, \mathcal{S}_2$. In order to determine an optimal temporal segmentation of the test video, in terms of J minimization, we follow a line search strategy for the determination of the best parameter value N_1. The above-described process is illustrated in Figure 1.

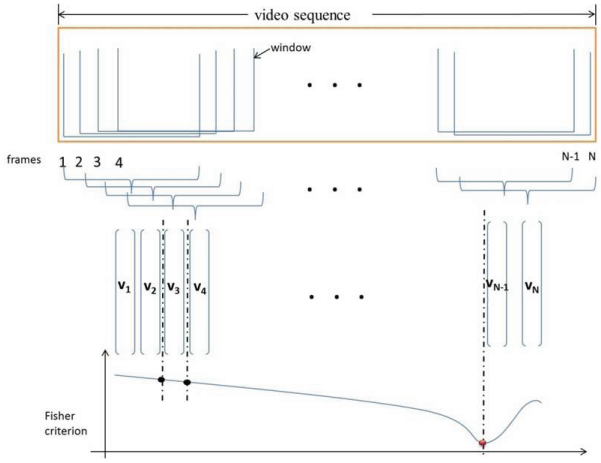

Fig. 1. Example of the temporal criterion.

An example of the above described temporal video segmentation process on a video sequence of the i3DPost database that depicts actions "walk" and "sit" is illustrated in Figure 2.

In the case where action instances are depicted in multiple (N_C) synchronized videos, each captured by a different viewpoint, we can exploit the available multi-view information in order to enhance temporal segmentation performance. Since all the N_C synchronized videos depict the same action instance, we expect that they should be temporally segmented at the same video frame index. We apply the above-described process on each of the N_C videos independently and determine the video frame cuts for each of them. Let us denote by t_i, $i = 1, \ldots, N_C$ the video frame indices determined for each of the N_C videos. We determine the action instance cut frame to be the mean video frame cut, i.e., $t = \frac{1}{N_C} \sum_{i=1}^{N_C} t_i$. In order to avoid taking into account outlier video frame cut values in the determination of the action instance cut, we can discard the α smaller and α larger t_i values before t calculation (α-trimming).

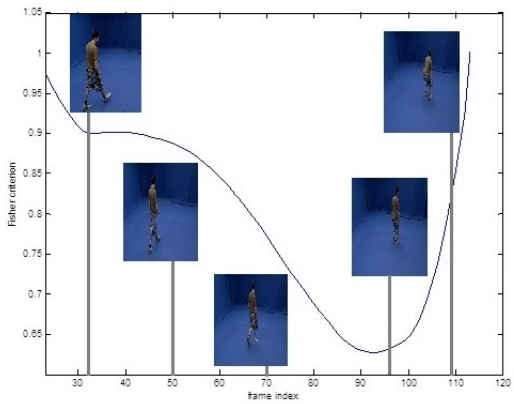

Fig. 2. Example of a video correspondence.

III. Experiments

In this Section we describe experiments conducted in order to evaluate the performance of the proposed methods. We have employed the i3DPost multi-view action database [15] and a new multi-view action database (that has been recorded for the needs of the FP7 EU project IMPART) [16] in order to evaluate both the temporal video segmentation and the video characterization methods. i3DPost action videos are captured in a constrained environment with blue background, while the IMPART database has complex background and periodical occlusions or interfering irrelevant movements. The i3DPost database contains 7 simple actions, specifically *run*, *walk*, *jump*, *jump-in-place*, *handwaving*, *bend* and *sit-standup*. It also contains video sequences containing complex actions, which are *run-fall* and *walk-sit* (2 actions) and *run-jump-walk* (3 actions). All actions are performed by 8 persons and are captured by 8 cameras, uniformly arranged inside the studio. We use 448 train samples (7 $actions \times 8\ persons \times 8\ cameras$) and 448 test samples, i.e., 256 2-action test samples (2 $instances \times 8\ pers. \times 8\ cam. \times 2\ segments$) and finally 192 3-action test samples (1 $instance \times 8\ pers. \times 8\ cam. \times 3\ segm.$). In multiview clustering, all N_C synchronized videos are combined, and thus the number of available samples is divided by the number of cameras. So, for this experiment we have 56 train and 56 test samples. The IMPART database is similar, with the difference that the actors are 7 and some of them perform the same action either in front of a scattered background or a blue one. Moreover, the cameras are 16 in this database. Here, train videos are 1024 and test ones are 848 in singleview setting. In the multiview setting, the training and test action sequences are equal to 64 and 53, respectively.

A. Temporal Segmentation experiments

The codebook cardinality was set equal to 50 for the i3DPost, and 70 for the IMPART datasets, since it was observed that for more complex environments a bigger codebook is preferable in encoding descriptors. Values larger than these gradually deteriorate the results. If S is the starting frame of the window presenting a minimum in the *Fisher criterion* J minimisation, the exact cut frame is set to $S + 0,4\,T$. Here we have to note that the diagram depicting obtained J values always presents a minimum. This is because the initial as well as the last values of the diagram are computed from degenerate clusters, one containing just a few histograms while the second containing all the others. This separation is not at all discriminative and gives high criterion values. As the cluster member number divergence gradually decreases, this problem is eliminated.

To decide whether a temporal segmentation is valid, we have manually determined action transition zones for each of the action sequences. A value of N_1 determined by the algorithm that falls inside the action transition zone was regarded to be a correct cut, while values of N_1 not belonging to the action transition zone were regarded to be incorrect. Transition zone is set by the ground truth cut frame allowing a tolerance of 10 frames, i.e. [t_i-10 t_i+10]. The obtained results are illustrated in Table I. As can be seen in this Table, by segmenting each of the available videos independently, classification rates equal to 75.78% and 76.71% have been obtained for the i3DPost and IMPART datasets, respectively. Multiview fusion enhances performance, since these classification rates are increased to 84.37% and 90.84%, respectively. Qualitative results on an action sequence of the i3DPost database can be seen in Figure 2.

TABLE I
2 & 3 action segmentation accuracy.

Database	Singleview (%)	Multiview(%) ($\alpha - trim$)
i3DPost	75.78	81.25 ($\alpha = 1$)
		84.37 ($\alpha = 2$)
IMPART	76.71	87.78 ($\alpha = 4$)
		90.84 ($\alpha = 6$)

B. Video Characterization Experiments

Clustering is performed either for each camera or in a multi-view setting. We have used a value of $D_v = 500, v = 1, \ldots, 4$, for video representation in all the experiments, employing all descriptors except *HOF*. We observed that it is better to use only the other 4, possibly due to their higher discriminative power in activity tasks, like this. In order to evaluate the clustering performance we need an appropriate metric. Let N be the number of labeled samples, ($N = N_I$ for the singleview case and $N = N_T$ for the multiview case), $C = \{c_1, c_2, \ldots, c_k\}$ be the clusters found by the clustering algorithm, $W = \{w_1, w_2, \ldots, w_c\}$ be the classes of the labeled objects, c_k be the objects composing cluster k and w_c the objects composing class c, $|C_k|$ be the cardinality of cluster k and $n_j^i = |w_i \cap C_j|$ be the number of objects of cluster i being in class j. We have chosen the F-measure as the evaluation metric, which combines the precision and recall measures [17]. The recall of cluster j with respect to cluster i, $r(i,j)$ is defined as $\frac{|c_j \cap w_i|}{|w_i|}$, where $||$ denotes the set cardinality. The precision of cluster j with respect to cluster i, $p(i,j)$, is defined as $\frac{|c_j \cap w_i|}{|w_j|}$. The F-measure combines both values as follows:

$$F_{i,j} = \frac{2}{\frac{1}{p(i,j)} + \frac{1}{r(i,j)}} = \frac{2p(i,j)r(i,j)}{p(i,j) + r(i,j)}. \quad (7)$$

The overall F-measure of clustering is given by:

$$F = \sum_{i=1}^{C} \frac{|w_i|}{N} max_{j=1,\ldots,K} F_(i,j). \quad (8)$$

The results of singleview-multiview segmentation and clustering are shown in Tables II and III for train and test videos, respectively. Clearly, multiview segmentation improves accuracy and also contributes to the enhancement of video characterization performance. We observed that in the singleview setting, the clustering algorithm finds it difficult to distinguish between similar actions, such as *walk-run* or *bend* and *sit-standup*. This is reasonable, since actions are quite different when observed from different viewing angles. However, by exploiting the enriched multiview visual information, discrimination is increased, achieving an F-measure value equal to 1 for the i3DPost train samples. Strangely enough, the same value for IMPART database is quite low and smaller than singleview, because samples in this case are much fewer and the problem becomes more difficult. However, test performance is much better in both databases. It is also remarkable that the method assigns more than 50% of test samples of an unknown class (*fall*) in a separate cluster, which indicates that the algorithm can recognize and group together new test samples of new concepts (action classes).

IV. CONCLUSION

In this paper, we proposed an efficient method for video characterization based on activity information. The method employs a state-of-the-art video representation in order to determine human activity concepts. A view-independent multi-view action representation is achieved by exploiting the circular shift invariance property of the coefficients of the DFT transform, while temporal video segmentation is performed as a pre-processing step in order to determine shorter videos containing simpler actions. Experimental results on two multi-view action databases denote the effectiveness of the proposed approach.

Optimal Multichannel Equalization for Robust Speech Dereverberation

Abdullah-Al-Maruf* and Mohammed Ariful Haque

Abstract—**Ideal acoustic multichannel equalization technique based on multiple-input/output inverse theorem (MINT) aims to completely invert the estimated room impulse responses (RIRs) between the source and microphone arrays. However, the method is known to be very sensitive to the estimation errors of the RIRs. In order to increase robustness, regularized MINT (R-MINT) has been proposed that overcomes the limitation by decreasing the energy of the equalization filters. In this paper, we analyze the solution of the R-MINT method and introduce a number of different ways to increase the robustness of the MINT method. Recently, regularized partial MINT (RP-MINT) method has been proposed that provides better perceptual speech quality compare to the R-MINT method. We also propose a new regularized optimal partial MINT (ROP-MINT) method which aims to optimize the equalized impulse response (EIR) between the source and output of the system. Simulation experiments conducted in various reverberant environments demonstrate that performance of our proposed ROP-MINT is better than that of the RP-MINT method.**

Index Terms—**speech dereverberation, multichannel equalization, regularization, optimization.**

I. Introduction

Speech signal recorded in an enclosed space by the microphones placed at a distance from the source is corrupted by its delayed and attenuated copies, which is known as reverberation. Reverberation decreases the speech intelligibility and degrades the performance of speech recognition systems. So, efficient dereverberation techniques can enhance the performance of many speech communication systems such as hands-free telephony, hearing aids and automatic speech recognition [1].

Dereverberation methods developed so far can be classified into single and multichannel techniques depending on the number of microphones used to record the speech signal [2]. Multichannel techniques are usually preferred than the single channel counterparts since spectro-temporal and spatial processing of the received microphone signals are possible. Acoustic multichannel equalization techniques, which aim to cancel out reverberation effect by inverse filtering, offer the most attractive approach to speech dereverberation. It is the only approach that offers perfect speech dereverberation in theoretical point of view.

The pioneer work in multichannel equalization approaches was done by Miyoshi and Kaneda [3] by proposing an elegant method commonly known as multiple-input/output inverse theorem (MINT). But the MINT method has a serious drawback in practice since it is extremely sensitive to the channel estimation errors and additive noise. In order to increase robustness of MINT, it has been proposed to reduce the energy of the equalizing filters by incorporating regularization [4]. The idea is to add equalizing filter energy by a regularization constant in the cost function which has to be minimized.

Besides regularized MINT (R-MINT) method, there is another way to increase the robustness of multichannel equalization techniques. It is reported in the literature that early reflections are not harmful for speech intelligibility [5], [6] and the late reverberation (defined as part of the room impulse response (RIR) after 50-80 ms) is the major reason of degrading speech quality. It has been experimentally shown that equalization of the late reflections is more robust than complete equalization in the presence of channel estimation errors [7]. Hence, more robust multichannel equalization techniques such as relaxed multichannel least-squares (RMCLS) [7] and channel shortening (CS) [8] are proposed that suppress the late reflections alone. Since any constraint is not imposed on the early reflections of the equalized impulse response (EIR), RMCLS and CS generally lead to undesired perceptual effects. Recently, a partial MINT (P-MINT) method has been proposed which aims to achieve both robustness and better perceptual speech quality [9]. It has been shown in [9] that by using the first part of one of the estimated RIRs as the early reflection part of the EIR, the regularized P-MINT (RP-MINT) can outperform all multichannel equalization techniques.

In this paper, we first analyze the solution of the R-MINT method and demonstrate how the regularization constant increases the robustness of the MINT method. We also present different ways to formulate robust MINT method other than the regularization approach. Secondly, we propose a new partial multichannel equalization technique that optimally determines the early reflection part of the EIR to increase perceptual quality while suppressing the reverberant tail of the RIRs. Our proposed regularized optimal partial MINT (ROP-MINT) is compared with the RP-MINT through simulation experiments in various reverberant conditions. Simulation results show that the dereverberated speech using the ROP-MINT method has better perceptual quality than that using the RP-MINT method.

II. Problem formulation

Consider a speech signal is recorded using M microphones in a reverberant environment. The ith microphone signal can be written as

$$x_i(n) = s(n) * h_i(n), \qquad i = 1, \dots, M \tag{1}$$

where $s(n)$ is clean speech signal, $h_i(n)$ is the RIR between the source and ith microphone and $*$ denotes convolution operation.

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

The output signal of multichannel equalized system is given by the sum of the equalized microphone signals which can be written as

$$\hat{s}(n) = \sum_{i=1}^{M} x_i(n) * g_i(n) \tag{2}$$

$$= s(n) * \sum_{i=1}^{M} h_i(n) * g_i(n) \tag{3}$$

$$= s(n) * d(n) \tag{4}$$

where $g_i(n)$ is the equalization filter for the ith microphone, $d(n)$ is the EIR between the source and output of the systems. In matrix form, $d(n)$ can be written as

$$\mathbf{d} = \mathbf{Hg} \tag{5}$$

$$\mathbf{H} = [\,\mathbf{H_1}\ \mathbf{H_2} \dots \mathbf{H_M}\,] \tag{6}$$

$$\mathbf{g} = [\,\mathbf{g_1^T}\ \mathbf{g_2^T} \cdots \mathbf{g_M^T}\,]^T \tag{7}$$

where $\mathbf{H}$ is the multichannel convolution matrix and $\mathbf{g}$ is the stacked equalization filter vector.

The equation (5) is used to obtain the equalizing filters, $\mathbf{g}$. Since true RIRs are not available in reality, $\mathbf{g}$ is evaluated using the estimated multichannel convolution matrix, $\hat{\mathbf{H}}$ instead of using true convolution matrix, $\mathbf{H}$. Here, $\hat{\mathbf{H}}$ is constructed from estimated RIRs, $\hat{h}_i$, which can be written as

$$\hat{h}_i(n) = h_i(n) + e_i(n) \tag{8}$$

where $e_i(n)$ is the estimation error.

Our aim is to obtain the dereverberated speech signal $\hat{s}(n)$, which is perceptually close to the clean speech signal $s(n)$.

III. Improving the Robustness of the MINT Method

To make the MINT less sensitive to channel estimation errors, the energy of the equalizing filters needs to be reduced. So in the cost function for R-MINT, the energy of $\mathbf{g}$ is added by a regularization constant. Hence, the cost function that is to be minimized is given by

$$J(\mathbf{g}) = \left\|\hat{\mathbf{H}}\mathbf{g} - \mathbf{d}\right\|_2^2 + \delta\|\mathbf{g}\|_2^2 \tag{9}$$

where δ is a parameter known as regularization constant. Here, $\mathbf{d}$ is the expected EIR which can be written as

$$\mathbf{d} = [1\ 0\ 0 \dots 0] \tag{10}$$

The closed form solution for (9) can be written as

$$\mathbf{g} = \left(\hat{\mathbf{H}}^T\hat{\mathbf{H}} + \delta\mathbf{I}\right)^{-1}\hat{\mathbf{H}}^T\mathbf{d} \tag{11}$$

where $\mathbf{I}$ is an unity matrix. Applying eigenvalue decomposition, we get $\hat{\mathbf{H}}^T\hat{\mathbf{H}} = \mathbf{USU}^T$, where $\mathbf{U}$ is the eigenvector matrix and $\mathbf{S}$ is a diagonal matrix with eigenvalues s_i in the diagonal entries. Now, (11) can be rewritten as

$$\mathbf{g} = (\mathbf{USU}^T + \delta\mathbf{UU}^T)^{-1}\hat{\mathbf{H}}^T\mathbf{d} \tag{12}$$

$$= \mathbf{UTU}^T\hat{\mathbf{H}}^T\mathbf{d} \tag{13}$$

where $\mathbf{T}$ is a diagonal matrix with $\frac{1}{(s_i+\delta)}$ in the diagonal entries.

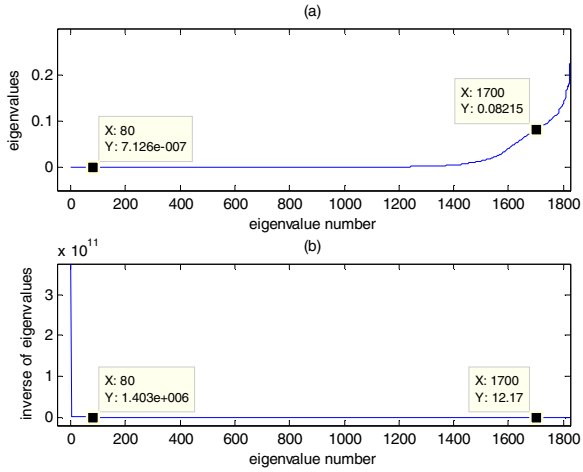

Fig. 1 (a) eigenvalus of $\hat{\mathbf{H}}^T\hat{\mathbf{H}}$, (b) inverse of the eigenvalues of $\hat{\mathbf{H}}^T\hat{\mathbf{H}}$

Initial few eigenvalues for any estimated channels are observed to be nearly zero which give extremely large values in inversion as it is shown in figure 1. In MINT, these extremely large inversed values get multiplied by entries of $\mathbf{H}$ instead of corresponding nearly zero valued entries of $\hat{\mathbf{H}}$. A small difference between $\mathbf{H}$ and $\hat{\mathbf{H}}$ creates undesired peaks in the EIR making MINT very sensitive to channel estimation errors. It is clear from (13) that R-MINT method actually adds regularization parameter δ with each eigenvalues s_i which prevents getting extremely large values in inversion. This lessens distortion in the EIR significantly making MINT more robust.

So instead of shifting eigenvalues with a constant amount δ, it is possible to incorporate regularization a number of different ways to make MINT less sensitive to channel estimation errors. Here we introduce some new ways to incorporate regularization.

A. Clipping the extremely large inverse of eigenvalues

Since extremely large inversed eigenvalues are the reason of distortion, it is not required to change all the inversed eigenvalues. Only the values over a threshold are needed to be changed while keeping intact the other inversed eigenvalues. Hence we propose the clipping method where only the inversed eigenvalues over a threshold will be changed and replaced by a moderate large value. Hence, for proposed clipping method the equation (13) becomes as

$$\mathbf{g} = \mathbf{UP}\,\mathbf{U}^T\hat{\mathbf{H}}^T\mathbf{d} \tag{14}$$

where $\mathbf{P}$ is a diagonal matrix. The diagonal element, p_i is computed as

$$p_i = \begin{cases} b, & if\ (1/s_i) \geq b \\ 1/s_i\,, & else \end{cases} \tag{15}$$

Here b is a threshold parameter which can be set to different values to get optimal performances for different reverberant environments.

B. Using variable regularization parameter

It is not required to use constant value of δ for each eigenvalue. Suitable value of the regularization parameter δ_i can be used for each eigenvalue s_i instead. Hence, we propose variable δ method for regularization which uses different value δ_i suitable for each eigenvalue s_i. So, for proposed variable δ method the equation (13) becomes as

$$\mathbf{g} = \mathbf{U}\mathbf{V}\,\mathbf{U}^T\hat{\mathbf{H}}^T\mathbf{d} \tag{16}$$

where $\mathbf{V}$ is a diagonal matrix with $\frac{1}{(s_i+\delta_i)}$ in the diagonal entries. So, the original R-MINT method is actually a special case of the variable δ method when all the δ_i become same.

C. Taking roots of the eigenvalues

In order to make MINT robust, we need to prevent getting extremely large values in the inversion of eigenvalues which can be done by increasing the small value of the eigenvalues. Since taking root increases the value of positive number less than 1, the eigenvalues can be replaced by their roots. Hence, we propose our root method for regularization where we replace each eigenvalues with their root in (13). So the equation (13) becomes as

$$\mathbf{g} = \mathbf{U}\mathbf{W}\,\mathbf{U}^T\hat{\mathbf{H}}^T\mathbf{d} \tag{17}$$

where $\mathbf{W}$ is a diagonal matrix with $\frac{1}{s_i^{1/\rho}}$ in the diagonal entries. The power constant ρ has to be selected for optimal performance like the regularization constant δ. Variable values can also be used for ρ which may improve performance but increases complexity.

IV. Proposed Regularized Optimal Partial MINT Method

The cost function of RP-MINT method [9] is given by

$$J(\mathbf{g}) = \left\|\hat{\mathbf{H}}\mathbf{g} - \hat{\mathbf{h}}_\mathbf{p}^\mathbf{d}\right\|_2^2 + \delta\|\mathbf{g}\|_2^2 \tag{18}$$

where $\hat{\mathbf{h}}_\mathbf{p}^\mathbf{d}$ is the desired EIR for RP-MINT. It contains one of the estimated RIRs in its early reflection part as long as the estimated RIRs are perceptually close to the true RIRs. So, $\hat{\mathbf{h}}_\mathbf{p}^\mathbf{d}$ can be written as

$$\hat{\mathbf{h}}_\mathbf{p}^\mathbf{d} = \left[\,\hat{h}_p(0)\;\; \hat{h}_p(1) \ldots \hat{h}_p(L_s-1)\; 0\; 0 \ldots 0\right] \tag{19}$$

where L_s is the length of the direct path and early path reflections in number of samples which is typically 50-80 ms.

When the environment is highly reverberant and estimated RIRs include large estimation errors, RP-MINT gives perceptually poor performance. It would be better to find an optimal equalization target rather than using a fixed $\hat{\mathbf{h}}_\mathbf{p}^\mathbf{d}$ as defined in (19). In order to find an optimal EIR we treat $\mathbf{d}$ as variable. So we propose a new least square cost function for our method as given below

$$J(\mathbf{g},\mathbf{d}) = \left\|\hat{\mathbf{H}}\mathbf{g} - \mathbf{d}\right\|_2^2 + \delta\|\mathbf{g}\|_2^2 + \gamma\|\mathbf{d} - \mathbf{d_0}\|_2^2 \tag{20}$$

where γ is a new constant, and $\mathbf{d_0}$ is an impulse function which is the ideal value for the EIR. Note that, in the cost function the last term $\|\mathbf{d} - \mathbf{d_0}\|_2^2$ tries to make EIR to be an impulse function and thus avoids EIR from taking any undesired value.

If we solve $\mathbf{g}$ and $\mathbf{d}$ after partially differentiating the cost function with respect to $\mathbf{g}$ and $\mathbf{d}$ and setting them to zero, we will get

$$\mathbf{g} = \left(\hat{\mathbf{H}}^T\hat{\mathbf{H}} + \delta\mathbf{I}\right)^{-1}\hat{\mathbf{H}}^T\mathbf{d} \tag{21}$$

and

$$\mathbf{d} = \frac{1}{1+\gamma}\left(\hat{\mathbf{H}}^T\mathbf{g} - \gamma\mathbf{d_0}\right) \tag{22}$$

respectively. These values of $\mathbf{g}$ and $\mathbf{d}$ will give minimum J. Iterative solution of above two equations gives the equalizing filter $\mathbf{g}$ for optimal EIR.

So the algorithm for ROP-MINT can be written as:

1) Set initial $\mathbf{d}$ equal to $\mathbf{d_0}$ (any initial value can be chosen, e.g., $\hat{\mathbf{h}}_\mathbf{p}^\mathbf{d}$.)
2) Calculate $\mathbf{g}$ from the equation (21).
3) Calculate $\mathbf{d}$ from the equation (22) using the value of $\mathbf{g}$ from step 2.
4) Use only first L_s number of coefficient of $\mathbf{d}$ obtained from step 3 normalized by $d(0)$ for the new value of $\mathbf{d}$.

$$\mathbf{d} \leftarrow \frac{1}{d(0)}\,[d(0)\; d(1) \ldots d(L_s-1)\;\; 0 \ldots 0]$$

5) Repeat from step 2 with the value of $\mathbf{d}$ obtained in step 4.

V. Simulation Results

In this section we present simulation results to evaluate the performance of our proposed techniques. Different objective measures of evaluating the quality of speech such as average segmental SNR (segSNR) and perceptual evaluation of speech quality (PESQ) [10] are used to evaluate performance. The higher the values of the segSNR and PESQ are, the better the speech quality is.

For simulation, the room size with dimension of $(5\text{m} \times 4\text{m} \times 3\text{m})$ and a linear array of 8 microphones starting from $(1.0, 1.6, 1.6)$ with 0.1m separation in y direction were used. The RIRs of length $L_s = 1600, 2400, 3200, 4000$ were generated using the well known image model [11] for the reverberation time $T_{60} = 0.2, 0.3, 0.4, 0.5$ ms respectively. To generate estimation errors in the estimated RIRs white zero mean Gaussian noise at $SNR = 20$ dB is added to each RIR.

A. Performance of proposed regularized MINT methods

Table I presents the PESQ values of the dereverberated speech using our proposed methods and original R-MINT method. The experiment was conducted for various reverberation times. In simulation $\delta = 0.001$ was chosen optimally for R-MINT to get the best performance. For clipping method threshold value b was chosen to be 1000. In variable δ parameter method, for the first 20% eigenvalues $\delta = 0.001$ was used while $\delta = .002, .005$ were used for the middle 60% and last 20% eigenvalues. In our root method $\rho = 1.6$ was used to get optimal performance. We see from the Table I that all these methods increase PESQ values of the obtained dereverberated signal. Note that, some PESQ values of dereverberated speech using our methods are even greater

than the dereverberated speech using original R-MINT method. Hence, it is clear from the PESQ values presented in the table that all the proposed methods are almost as effective as the original one.

TABLE I
PESQ OF VARIOUS METHOD OF INCORPORATING REGULARIZATION

T_{60} (s)	Rever-berated	Original R-MINT method	Proposed R-MINT methods		
			Clipping method	Variable δ method	Root method
0.2	2.263	2.851	2.823	2.822	2.856
0.3	2.073	2.486	2.449	2.487	2.483
0.4	1.947	2.301	2.278	2.294	2.326

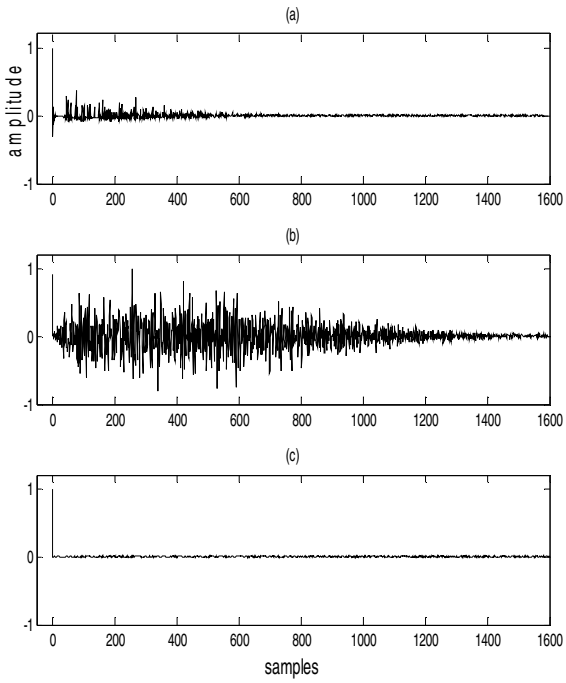

Fig. 2 (a) RIR for first microphone, (b) EIR obtained from MINT, (c) EIR obtained from root method for $\rho = 1.6$

Figure 2 shows the RIR for the first microphone and severely distorted EIR obtained from MINT method. EIR obtained from root method is also shown in the figure. It is clear from the figure that our proposed root method improves the EIR significantly making it almost like impulse function. All other proposed methods also show similar EIR pattern which make MINT more robust.

B. Performance of the proposed ROP-MINT method

Table II presents the PESQ and segSNR values of the dereverberated speech using our proposed ROP-MINT method and the RP-MINT method. The experiment was conducted for various reverberation times. In simulation, we used $\delta = 0.001$ and $L_s = 400$ for RP-MINT to get the best performance. Same values of δ and L_s were used for ROP-MINT while we used $\gamma = 5$ for the new constant. Initial $\mathbf{d}$ was set to $\mathbf{d}_0$. Only 5 iterations were taken for ROP-MINT method.

TABLE II
PERFORMANCE COMPARISON OF ROP-MINT

T_{60} (s)	Reverberated		RP-MINT		ROP-MINT	
	PESQ	seg-SNR	PESQ	seg-SNR	PESQ	seg-SNR
0.3	1.969	-2.181	2.486	-0.459	2.817	5.228
0.4	1.889	-2.688	2.395	-1.205	2.700	4.535
0.5	1.691	-3.029	2.326	-1.494	2.598	3.872

It is clear that in all different cases the PESQ and segSNR values of dereverberated speech using proposed ROP-MINT method are greater than the dereverberated speech using RP-MINT method. So our proposed ROP-MINT is more robust and perceptually advantageous method than the RP-MINT.

VI. CONCLUSION

In this paper, we have investigated the regularization technique and introduced various different ways of incorporating regularization in order to improve the robustness of the MINT method. Simulation results presented here shows that these new methods can dereverb speech signal almost as effectively as the original technique and sometimes even better for specific channels. We have also proposed a new equalization technique which tries to find an optimum EIR. Simulation results presented here shows that the perceptual quality of dereverberated speech obtained by our proposed ROP-MINT method is better than the RP-MINT method.

***Abstract*—Speech dereverberation considering noisy environment as well as speaker's movement is a challenging task. In this paper, we present an utterance-based noise-robust speech dereverberation technique that is suitable for non-stationary speaker. The acoustic impulse responses (AIRs) between the speaker and microphone array are estimated using the spectrally constrained frequency-domain least-mean-squares (LMS) algorithm. The AIRs are then equalized using the iterative multiple-input/output inverse theorem (MINT). It is assumed that the speaker stays still within an utterance, however, the speaker changes his/her position between the utterances. The simulation experiments conducted in various reverberant environment and speaker's position demonstrate that the proposed method can satisfactorily improve the perceptual quality of the noisy reverberated speech.**

***Index Terms*—speech dereverberation, blind multichannel estimation, iterative multichannel equalization, non-stationary speaker, additive noise**

I. Introduction

Dereverberation problem typically deals with extracting the original speech from the (reverberated) microphone signals. Efficient dereverberation can enhance the performance of many speech communication systems such as hands-free telephony, hearing aids and automatic speech recognition [1]. Dereverberation of speech considering practical scenario is a difficult task. First of all, it requires blind techniques in which no training pulses can be sent to estimate the long acoustic impulse responses (AIRs), typically consisting of thousands of coefficients. The degree of complexity of dereverberation problem increases many fold in a noisy environment as the channel vector does not remain collinear with the minimum mean squared error solution [2]. Moreover, the movement of the speaker yields a spatially-varying source-microphone geometry causing the AIRs to be changed from time-to-time. An effective dereverberation technique, therefore, should consider these frequent changes in the AIRs. Although a range of speech dereverberation techniques are available in the literature, the development of practical algorithms that can truly compensate the detrimental effect of reverberation is one of the holy grails for a long time [3].

The effect of reverberation can be reduced in many ways, such as, beamforming, speech enhancement, blind deconvolution, etc. However, the best approach from theoretical point of view would be to obtain the AIRs between the speaker and each microphone and then to cancel out the reverberation by inverse filtering. The pioneer work in this approach was done by Miyoshi and Kaneda in 1988 [4]. They proposed an elegant method commonly known as multiple-input/output inverse theorem (MINT) for multichannel inversion of the room acoustics exploiting the single-input multiple-output (SIMO) structure. But the MINT method has limited application in practice due to its extreme sensitivity to the channel estimation accuracy. Various methods have been proposed to improve the robust-ness of the MINT method. In [5], the authors proposed a so called system-identification-error-robust MINT method, however, it requires knowledge of the error term between true and estimated AIRs. Another approach for robust speech dereverberation, which does not require a priori information about the true AIRs, is to reduce the energy of the equalization filter [6]. A regularized partial MINT method [7] has been proposed capitalizing the same idea of reduced filter energy. The performance of the method is dependent on the appropriate setting of the regularization parameter, which is a computationally intensive task.

Most of the dereverberation techniques available in the literature cannot deal with non-stationary speaker. For example, harmonicity based dereverberation method proposed in [8] requires around 60 minutes of speech data to acquire the inverse filter under the assumption that the system is time-invariant. In fact, the blind identification of the time-varying AIRs are difficult because of the large number of channel coefficients. Therefore, some techniques have been developed to reduce the number of channel coefficients by sacrificing the dereverberation performance. In [9], the authors proposed a speech dereverberation technique considering a moving speaker but a simplified all-pole filter is used to model the time-varying AIRs. Similarly, probabilistic models are used in [10] to reduce the number of time-varying parameters for speech dereverberation.

In this paper, we consider speech dereverberation considering the full-length AIRs. The proposed utterance-based dereverberation technique consists of three stages, namely, the initial channel delay estimation, adaptive channel estimation and iterative channel equalization. The delay estimation stage performs two important tasks: (i) tracking the movement of the speaker in different utterances and (ii) estimating the initial zeros required for the initialization of the adaptive channel estimation algorithm. Then the AIRs are estimated for the given utterance using the noise-robust multichannel LMS algorithm proposed in our previous work [11]. It is to be mentioned here that the speech data from the same utterance is repeatedly feed to the channel estimation algorithm until the steady-state condition is reached. This is how we are able to estimate the AIRs using short-length utterances. Finally, the uttered speech data block is dereverberated using a multichannel equalization filter obtained using iterative MINT method. In order to reduce the noise level of the dereverberated speech, a denoising scheme is applied after the dereverberation

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

stage.

II. RELATION TO PRIOR WORK

The proposed technique incorporates some different ideas that make it suitable for practical reverberant environment as compared to other state-of-the-art methods. First, the channel estimation is performed utterance-by-utterance so that effect of speaker's movement (between the utterances) does not disturb the channel estimation process. In continuous adaptive mode, the channel estimation algorithms cannot track even a 10 cm movement of the speaker [12]. Second, the noise-robust equalization is performed using a multichannel filter obtained from iterative implementation of the MINT method. The proposed method does not require knowledge of the true AIRs (as in [5]) or tedious singular value decomposition of the channel convolution matrix for appropriate setting of the regularization parameter (as in [7]). The formulation of the iterative MINT is conventional [13], but the robustness of this method (without any constraint) to channel estimation error is not reported so far.

III. PROBLEM FORMULATION

Consider a speech signal recorded inside an echoic room using a linear array of microphones. The received signals at the microphones can be modeled as convolutional mixtures of the speech signal and the impulse responses of the acoustic paths between source and microphones. The channel outputs and observed signals are then given by

$$y_i(n) = s(n) * h_i(n) \quad (1)$$

$$x_i(n) = y_i(n) + v_i(n), \quad i = 1, 2, \cdots, M \quad (2)$$

where n represents the time-domain sample index, M is the number of microphones, $s(n)$, $y_i(n)$, $x_i(n)$, $v_i(n)$, and $h_i(n)$ denote, respectively, the clean speech, reverberant speech, the reverberant speech corrupted by background noise, observation noise, and impulse response from the source to the ith microphone. Using vector notation, (1) can be written as

$$y_i(n) = \mathbf{h}_i^T(n)\mathbf{s}(n) \quad (3)$$

where $\mathbf{h}_i(n) = [h_{i,0}(n)\ h_{i,1}(n) \cdots h_{i,L-1}(n)]^T$ represents the channel impulse response vector of length L, the superscript T denotes transpose and $\mathbf{s}(n) = [s(n)\ s(n-1) \cdots s(n-L+1)]^T$. Our objective is to obtain a dereverberated speech signal, $\hat{s}(n)$, from the received noisy signals, $x_i(n)$, $i = 1, 2, \cdots, M$.

IV. PROPOSED UTTERANCE-BASED SPEECH DEREVERBERATION TECHNIQUE

As in [3], we assume that the speakers stay still within an utterance. Therefore, the reverberated speech signal is first partitioned into successive utterances as

$$\mathbf{x}_i = [\underbrace{x_i(0)\ x_i(1)\ \cdots\ x_i(N_1-1)}_{\text{1st utterance}}\ \cdots \underbrace{x_i(N_{k-1})\ x_i(N_{k-1}+1)\ \cdots\ x_i(N_{k-1}+N_k-1)}_{\text{kth utterance}}\ \cdots\ ] \quad (4)$$

where i denote microphone number and N_k represent the length of kth utterance. Since each utterance is processed independently, we can simplify the representation of the utterances as follows

$$\mathbf{c}_i = [c_i(0)\ c_i(1)\ \cdots\ c_i(l)\ \cdots\ c_i(N_k-1)] \quad (5)$$

where, l indicates the sample index within an utterance $\mathbf{c}_i$. In what follows, we present the initial channel delay estimation, adaptive channel identification and equalization stages of our proposed technique.

A. Estimation of initial AIR delays

The delay estimation algorithm does not require the full utterance of speech data to estimate the initial zeros of the AIRs. Therefore, a short-length speech block is formed from $\mathbf{c}_i$ as

$$\mathbf{b}_i = [c_i(0)\ c_i(1)\ \cdots\ c_i(P-1)] \quad (6)$$

where P is the length of the shortened block. Now, the channel delays can be estimated using time-difference-of-arrival (TDOA) estimation algorithms. TDOA estimate, τ_{ij}, between ith and jth channels can be obtained from the cross-correlation function of $\mathbf{b}_i$ and $\mathbf{b}_j$. When the correlation function is evaluated in the frequency-domain, τ_{ij} can be estimated as

$$\tau_{ij} = \arg\max_{\beta} \int_{-\pi}^{\pi} B_i(\omega) B_j^*(\omega) e^{-j\omega\beta} d\omega \quad (7)$$

where $B_i(\omega)$ represents the discrete Fourier transform of $\mathbf{b}_i$ and * denotes complex conjugate. Eq. (7) does not perform well in reverberant environment. A simple technique that is robust to noise and dereverberation is mentioned in [14], which is

$$\tau_{ij} = \arg\max_{\beta} \int_{-\pi}^{\pi} \cos(\angle B_i(\omega) - \angle B_j(\omega) - \omega\beta) d\omega. \quad (8)$$

Eq. (8) is used in this paper to estimate all the relative delays τ_{ij}, where $i = 1, \cdots, M-1$ and $j = i+1, \cdots, M$.

B. Robust channel identification

The AIRs of a multi-microphone system can be blindly estimated by minimizing the cross-relation error [15]

$$e_{ij}(l) = c_i(l) * \widehat{h}_j(l) - c_j(l) * \widehat{h}_i(l) \quad (9)$$

where $\widehat{h}_i(l)$ is the estimate of the ith channel impulse response. Using (9), the multichannel LMS algorithm is formulated as [16]

$$\widehat{\mathbf{h}}(l+1) = \widehat{\mathbf{h}}(l) - \mu_l \nabla J(l) \quad (10)$$

where $\mathbf{h} = [\mathbf{h}_1^T, \cdots, \mathbf{h}_M^T]^T$, $\nabla J(l)$ is the gradient of the cost function comprising of the error terms, $e_{ij}(l)$, and μ_l represents the step size. In order to ensure noise-robust performance, a spectral flatness constraint $\nabla J_p(l)$ is attached to the update equation as [11]

$$\widehat{\mathbf{h}}(l+1) = \widehat{\mathbf{h}}(l) - \mu_l \nabla J(l) + \mu_l \alpha(l) \nabla J_p(l). \quad (11)$$

For implementation details of (11), the readers are referred to [12]. For adaptive estimation, the channel vectors are initialized utilizing the delay estimates τ_{ij} as

$$\widehat{\mathbf{h}}(0) = [\mathbf{0}_{\tau_i \times 1}\ 1\ \mathbf{0}_{(L-\tau_i-1)\times 1}] \quad (12)$$

where τ_i is the relative delay of the ith channel with respect to the minimum delay channel.

C. Multichannel equalization using iterative MINT

The MINT method aims to recover the original speech signal by designing a multichannel filter $\mathbf{g}$ such that

$$\widehat{\mathbf{H}}\mathbf{g} = \mathbf{d} \tag{13}$$

where $\widehat{\mathbf{H}}$ is the channel convolution matrix, and

$$\begin{aligned} \mathbf{g} &= [\mathbf{g}_1^T \ \mathbf{g}_2^T \ \cdots \ \mathbf{g}_m^T]^T \\ \mathbf{d} &= [1 \ 0 \ \cdots \ 0]^T. \end{aligned}$$

For iterative implementation, a cost function can be formulated as

$$J_M(m) = ||\widehat{\mathbf{H}}\mathbf{g}(m) - \mathbf{d}||^2. \tag{14}$$

The gradient of $J_M(m)$ is given by

$$\nabla J_M(m) = \frac{\partial J_M(m)}{\partial \mathbf{g}(m)} = -2\widehat{\mathbf{H}}^T\mathbf{d} + 2\widehat{\mathbf{H}}^T\widehat{\mathbf{H}}\mathbf{g}(m). \tag{15}$$

The update equation of the equalization filter is given by

$$\mathbf{g}(m+1) = \mathbf{g}(m) - \mu_m J_M(m) \tag{16}$$

where μ_m is the step size. Now, the dereverberated speech can be recovered as

$$\hat{s}(k) = \sum_{i=1}^{M} g_i(k) * c_i(k). \tag{17}$$

Finally, we apply a simple spectral subtraction based denoising technique [17] to reduce the noise level of the dereverberated speech. It is to be mentioned here that we need to estimate the AIRs and equalization filter only when the speaker changes his/her position. If the speaker remains stationary, as determined by the delay estimation stage, the equalization filter of the previous utterance segment can be used to obtain the dereverberated signal.

V. Simulation Results

In this section, we present simulation results to evaluate the performance of the proposed utterance-based speech dereverberation technique considering a non-stationary speaker. Different objective measures that are used to evaluate the quality of speech are the log-likelihood ratio (LLR), average segmental SNR (segSNR), weighted spectral slope (WSS) and perceptual evaluation of speech quality (PESQ) [18]. The higher the values of the segSNR and PESQ, and the lower the values of LLR and WSS, the better the speech quality.

For simulation, the dimension of the room size was taken to be $(5 \times 4 \times 3)$m and a linear array consisting of $M = 8$ microphones was used. The first microphone was positioned at $(1.0, 1.6, 1.6)$m and the location of the other microphones can be obtained by successively adding $d = 0.2$m to the y-coordinate of the first microphone. The experiments were conducted for different reverberation times $T_{60} = 0.25, 0.5, 0.7$s. The impulse responses were generated using the well-known image model [19] and the lengths of each AIR corresponding to the above mentioned reverberation times were set to $L = 1600, 3500,$ and 5000 samples, respectively. The additive noise to each microphone signal was white zero-mean Gaussian at SNR=30 dB. The sampling frequency was 8 kHz.

First, we present channel estimation results using (11) of Section IV-B. The accuracy of the channel estimation is indicated by the normalized projection misalignment (NPM) [20]. The lower the value of NPM, the better the channel estimation. Fig. 1 shows the performance of the channel estimation algorithm for various length of the speech segment used to estimate the AIRs. It is seen that a good NPM of the estimated channels can be achieved for speech segments of duration $2T_{60}$s only. Therefore, the minimum utterance lengths that can be considered for speech dereverberation using the proposed technique are $0.5, 1$ and 1.4s for the reverberation times $T_{60} = 0.25, 0.5,$ and 0.7s, respectively. Now, we present the channel equalization performance of the iterative-MINT method utilizing the estimated AIRs. Fig. 2 shows the impulse responses of the equalized channel as well as those of the actual acoustic channel considering different reverberation times. It is seen that both the early and late reflections are substantially mitigated in the equalized channels.

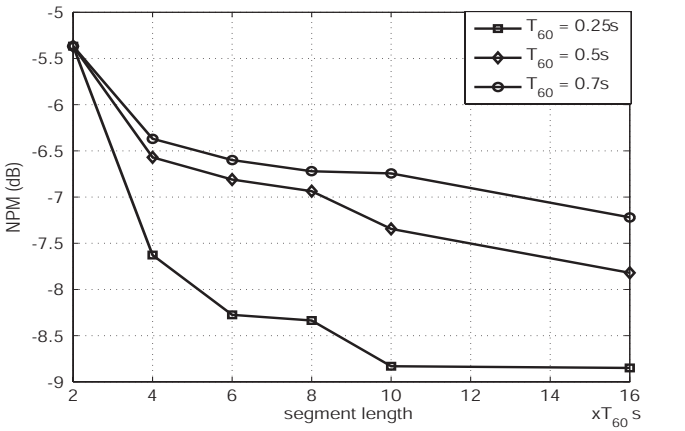

Fig. 1. Channel estimation accuracy in term of NPM for different length of speech segments.

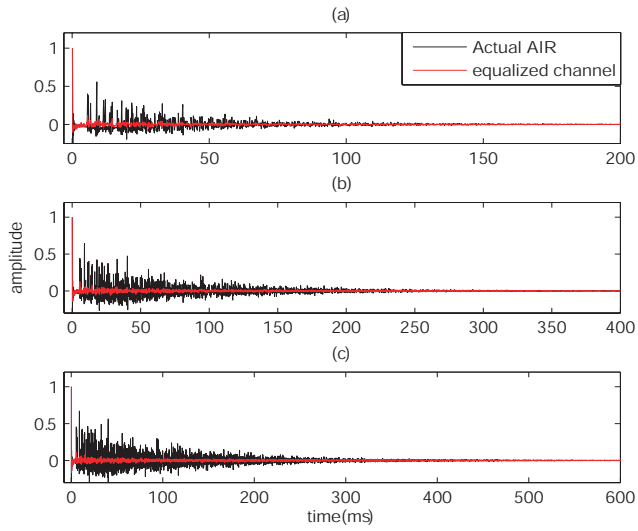

Fig. 2. Impulse response of the actual and equalized acoustic channel: (a) $T_{60} = 0.25$s, (b) $T_{60} = 0.5$s, and (c) $T_{60} = 0.7$s

The perceptual quality of the dereverberated speech using the proposed method in terms of different objective measures is presented in Table I. For comparison, the perceptual quality of the reverberated speech is also presented in the table. In both the cases, we perform spectral subtraction to reduce the noise level of the speech signal. The speaker was initially positioned at $(1.8, 2.0, 1.6)$ m. The speaker's position was successively changed in step-by-step manner at a step of 0.1m

TABLE I
PERFORMANCE OF THE PROPOSED ALGORITHM AT DIFFERENT REVERBERATION TIMES

Reverberation time (s)	NPM (dB)	LLR		segSNR		WSS		PESQ	
T_{60}	(estimated channel)	rev	derev	rev	derev	rev	derev	rev	derev
0.25	-8.028	0.603	0.459	-0.560	5.046	41.823	32.740	2.180	2.831
0.50	-6.618	0.752	0.532	-2.700	2.143	59.848	47.211	1.951	2.499
0.70	-6.269	0.893	0.618	-3.557	0.521	68.216	54.888	1.667	2.183

along x-coordinate. The duration of the uttered speech in each location was around $8T_{60}$s. The LLR, segSNR, WSS and PESQ measures presented in Table I shows the average value obtained for different locations of the speaker. The substantial improvement of the LLR, segSNR, WSS and PESQ measures with respect to the reverberated speech show that the proposed technique is effective for dereverberation for a wide range of reverberation time.

VI. CONCLUSION

We have demonstrated the effectiveness of the blind multichannel identification and equalization technique for utterance-based speech dereverberation. The proposed technique is suitable for noisy environment and non-stationary speaker. The time-varying AIRs are estimated using the spectrally-constrained frequency multichannel LMS algorithm for each utterance. It is shown that the AIRs can be effectively estimated from a speech segment of duration $2T_{60}$s. The AIRs are then equalized using the iterative-MINT method that exhibits robust performance against channel estimation error and additive noise. The quality of the dereverberated speech is substantially improved as compared to that of the received microphone signal which is clearly observed from the LLR, segSNR, WSS, PESQ measures.

Abstract—**In this paper, a new probability based fast inter mode decision algorithm is proposed for H.264/AVC video standard. The main idea is to classify the inter modes into large and small modes category and determine which one is suitable for a macroblock (MB). Depending on this, the probability of each large mode corresponding to the initial Hadamard SAD_{16x16} cost or the probability of each small mode corresponding to the initial Hadamard SAD_{s8x8} cost is determined. Then the best mode can be obtained from their probability characteristics. Thus, it is possible to determine the best inter mode only by calculating the Hadamard Transform (H-SAD) cost instead of rate distortion cost. Moreover, it avails the platform to determine the best mode without comparing the cost of each mode to other modes. As a result, this approach can avoid most of the complex computation processes like quantization, variable length coding, pixel reconstruction etc. The experimental results have shown that the proposed algorithm can reduce 60% to 65% of the total encoding time of H.264/ AVC with negligible distortion.**

Index Terms— **Inter Mode Decision, Macroblock, Hadamard Transform, H.264/ AVC.**

I. INTRODUCTION

H.264/AVC [1], [2] is the latest video standard which has outperformed previous video compression standard like MPEG- 1/2/3 ad H.261/263 in terms of video compression efficiency as well as video quality. It introduces many new techniques which include variable and hierarchical block transform, arithmetic entropy encoding including CABAC and CAVLC, directional spatial prediction for intra frame coding, multiple reference frame motions to outperform the previous standards. Among these features one of the key ones is it uses seven variable blocks sizes for motion estimation and compensation. Among these, large blocks (16×16, 16×8 and 8×16) are generally used for stationary image prediction with high coding efficiency and small blocks (8×8, 8×4, 4×8 and 4×4) are used for complex images for better prediction accuracy. The large blocks requires less computational time and has less accuracy than the small blocks while small blocks require more computational time and have more accuracy than the large blocks. Therefore, a trade of between the computational time and the prediction accuracy which plays a vital role for video quality is needed to decide which partition block size i.e. mode is the best one for motion estimation. This is done by computing rate distortion costs of all available blocks and selecting the best partition block size i.e. mode that can provide relatively the best motion compensation with minimum computational time. This cost calculation is also a highly complex that includes several processes like computation of integer transform, quantization and arithmetic entropy coding and pixel reconstruction process.

That's why this variable block technique involves lots of computational power. As a result, H.264/ AVC have limited applications in real time communication. In [3]-[11] different fast mode algorithms have been proposed applying which it is possible to reduce the computational complexity significantly enabling this video standard for real time application. For examples, in [3], Jing et al proposed mean absolute frame difference of a current frame and mean absolute difference of current MB to determine whether a MB is homogenous or not and decide the best mode among 16×16, 16×8 and 8×16. In [4], Kuo proposes the motion field distribution and correlation method for determining the best modes. In [5], Wei et al, proposes a mode decision algorithm where the mode of a MB is determined using the modes of adjacent MBs. Most of the algorithm proposes methods that skip some unnecessary modes, but need to calculate the rate distortion cost which needs high amount of computational time. In [7], a relative SAD (RSAD) based inter mode decision algorithm is proposed, where it is possible to determine the best mode without calculating rate distortion cost. In [9]-[11], probability based inter mode decision algorithms are proposed. In [9], Chiang proposes a H.264 encoding method based on statistical learning. Here, the best mode is determined using probability and statistic. In this paper, probability based fast new inter mode algorithm is proposed which can decide the best mode without calculating the rate distortion cost maintaining a high rate distortion performance of the H.264/ AVC codec.

Rest of the paper is organized with rate distortion cost functions for H.264/AVC standard in section II. The SKIP mode early termination algorithm is discussed in section III. Then the proposed probability based fast inter mode algorithm is described in section IV. Finally in section V, results and discussion are analysed comparing the standard and proposed algorithm.

II. RATE DISTORTION COST FUNCTION FOR H.264/AVC STANDARD

The objective of using variable block size mode in H.264/AVC standard is to ensure precise motion prediction. When a MB cannot be predicted well enough using a large block, it is suitable to divide it into small blocks and thus ensuring better motion compensation. But if it is possible to predict the MB with a large partition, there is no need for using smaller blocks because it introduces higher complexity calculating processing time. In JVT reference software JM 6.1.d [12], the rate distortion (RD) cost is define as

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

$$J_{SSD}(S, C, Mode|QP) = SSD(S, C, Mode|QP) + \lambda . R(S, C, Mode|QP \quad (1)$$

Where, $\lambda = 0.85 \times 2^{(QP-12)/3}$ is the Lagrangian multiplier and QP is the quantization parameter. The R in (1) can be written as $R = R_{header} + R_{motion} + R_{residual}$, $SSD\ (S.C)$ is the sum of the squared of the difference between the original blocks S and the reconstructed block C and it is defined as:

$$SSD(S, C) = \sum_{i=0}^{N-1} \sum_{j=0}^{N-1} (Sij - Cij)^2 \quad (2)$$

Here, S_{ij} is the (i, j) th element of the current block and C_{ij} is the (i, j) th element of the reconstructed block. N is the image block size and equal to 4 for H.264. In equation (1) best mode is determined from a set of modes mentioned as: $Mode \in \{SKIP, Inter\ 16 \times 16, Inter\ 16 \times 8, Inter\ 8 \times 16, Inter\ 8 \times 8, inter\ 4 \times 4, inter\ 16 \times 16\}$. Here, SKIP mode is an especial mode where no residual bit or motion is encoded. For J_{SAD} cost function, SAD value from the difference between the current MB and predicted MB is calculated. Here, J_{SAD} is defined as

$$J_{SAD} = \begin{cases} SAD(S, P) + \lambda_1 . 4K \\ SAD\ (S, P), \quad otherwise \end{cases} \quad (3)$$

where, $SAD(S, P)$ is the sum of absolute difference of the original block S and the predicted block P and defined as

$$SAD(S, P) = \sum_{i=0}^{N-1} \sum_{j=0}^{N-1} (Sij - Pij) \quad (4)$$

Here, S_{ij} is the (i, j) th element of the current block and P_{ij} is the (i, j) th element of the predicted block. K is equal to 0 for probable mode and 1 for other modes and λ_1 is almost the square of λ and almost the exponential function of quantization parameter QP. This SAD based can save a lot of computation than SSD cost function as it does not need reconstruction or variable length coding like the SSD cost function. But this results a degradation of coding efficiency. To compensate that degradation, sum of absolute transformed differences (SATD) is widely used which uses frequency transform, usually H-SAD of the difference between the original blocks S and the reconstructed block C. It is complex method but takes less computation than SSD based cost function method and also have a better coding efficiency than SAD based cost function. That's why H-SAD cost is considered for the proposed probability based fast inter mode algorithm.

III. PROPOSED PROBABILITY BASED FAST INTER MODE DECISION ALGORITHM

A. Determination of large and small modes

There are seven inter modes of different sizes and shapes as 16×16, 16×8, 8×16, 8×8, 8×4, 4×8 and 4×4 supported by H.264/AVC. There is also a SKIP mode which is employed to encode some static objects and background that remain almost same in adjacent frames. Modes 8×8, 8×4, 4×8 and 4×4 are considered as sub modes and are classified under Inter P 8×8 modes where $Inter\ p\ 8 \times 8 \in \{Inter\ 8 \times 8, Inter\ 8 \times 4, Inter\ 4 \times 8, Inter\ 4 \times 4\}$. Here we have classified these 7 modes into two categories; large modes and Small modes where,

$Large\ modes \in \{Inter\ 16 \times 16, Inter\ 16 \times 8, Inter\ 8 \times 16\}$
$Small\ modes \in \{Inter 8 \times 8, Inter\ 8 \times 4, Inter\ 4 \times 8, Inter\ 4 \times 4\}$.

To find the best mode for a MB, we first calculate the Hadamard $SAD_{16\times16}$ cost. Then, we divide the MB into four 8×8 sub blocks and calculate Hadamard $SAD_{s8\times8}$ cost for each block to find Hadamard $SAD_{P8\times8}$ which is defined as

$$SAD_{P8\times8} = \sum_{i=0}^{3} SAD_{s8\times8} \quad (5)$$

where, i is the ith sub block of the MB. If the cost Hadamard SAD_{16x16} is equal or less than SAD_{P8x8} then we choose the large modes, otherwise we choose the small modes.

B. Finding the best mode from large and small modes

To determine the best mode from large modes we first take the Hadamard $SAD_{16\times16}$ cost of a MB. Then, we find out which mode is the best for that cost for general cases. When a set of the Hadamard $SAD_{16\times16}$ costs are taken and their corresponding best mode is plotted in a curve an interesting characteristic of large modes is found. A characteristic curve for "Foreman" QCIF video sequence is shown in Fig.1.This is a normalized probability curve where it can be seen that a particular mode has a better probability of occurrence at a certain cost. To simplify this thing we divide the data set into small chucks and find out the dominating mode with best probability. The range at which a certain mode dominates is marked with a threshold value. For three large modes (16×16, 16×8 and 8×16) two thresholds are enough to distinguish among them.

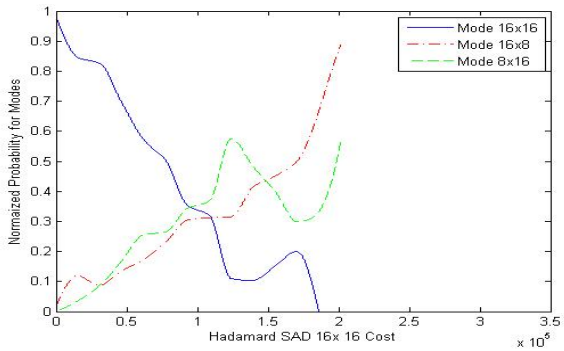

Fig.1 Probability Characteristic Curve of Large Modes

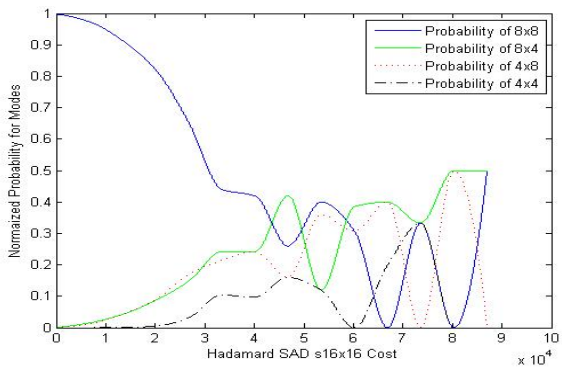

Fig. 2 Probability Characteristic Curve of Small Modes

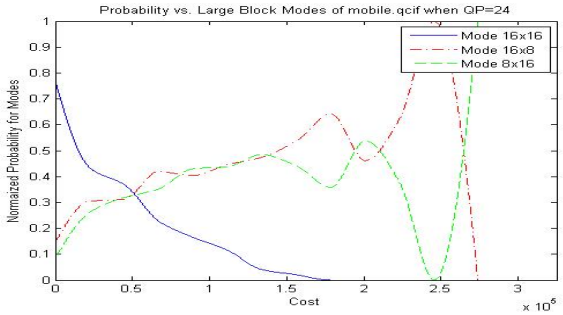
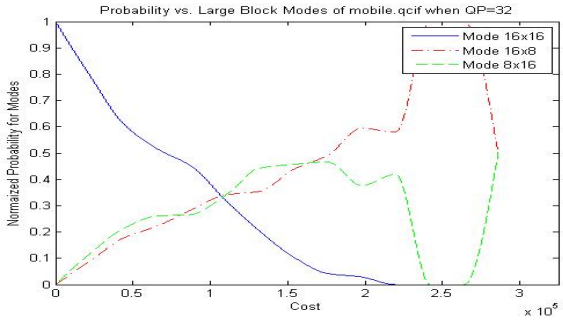
To determine the best mode from the small ones Hadamard $SAD_{s8\times8}$ cost is calculated first for every sub- block and the probability of occurrence of each small mode to the value is found. Similar process can be applied to select the best mode. As there are four modes, three thresholds values are required to distinguish them. Characteristic curve for small modes of "Foreman" QCIF video sequence is shown in Fig. 2. Finally,

this algorithm is combined with SKIP mode early termination process to make it even faster.



(a)



(b)

Fig. 3 Probability characteristic curve of Large modes for News QCIF Sequence at QP = 24, 32

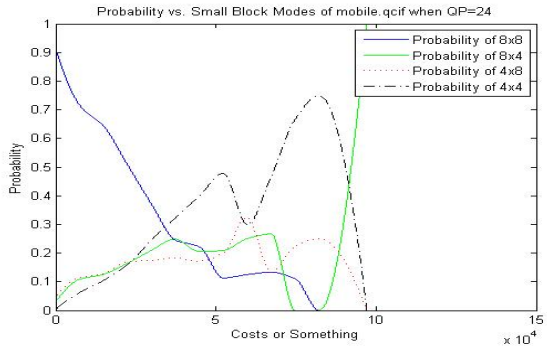
C. *Thresholds determination for each mode*

There are seven inter modes of different sizes and shapes including 16×16, 16×8, 8×16, 8×8, 8×4, 4×8 and 4×4 supported by H.264/AVC. In this paper, these seven block sizes are classified into two categories i.e. Large Blocks (16×16, 16×8, and 8×16) and Small Blocks (8×8, 8×4, 4×8 and 4×4). At first, a MB is taken and its Hadamard $SAD_{16\times16}$ Transform cost calculated. Then the characteristic curve of the probability of large modes vs. Hadamard $SAD_{16\times16}$ Transform cost of that MB is plotted. Finally, the characteristic curve of the probability of small modes vs.

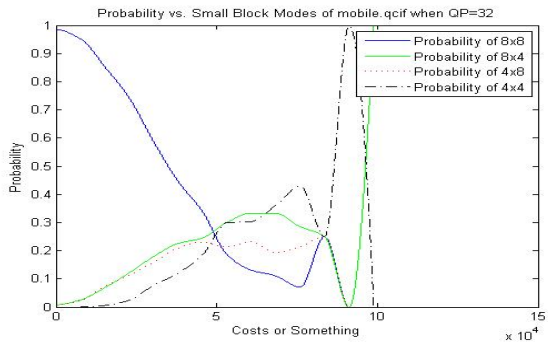
In this research, the probability of modes and vs. the initial MB cost characteristic curves of Mobile.qcif video sequence (100 frames) for different quantization parameter (QP=20, 24, 28, 32, 36, 40) are analyzed. Figure 3 and Figure 4 shows the characteristic changes between Large Modes and Small modes for different quantization parameters. From large modes probability characteristic curve, it has been observed that the range of domination of 16x16 mode increases as the quantization parameter increases. Similar scenarios are found from the small modes characteristic curves. Therefore, it is necessary to determine some thresholds for each mode to determine their range. But as the range for each mode varies with quantization parameter, the thresholds should be adaptive with quantization parameters.

D. *Parameters Selection and Proposed algorithm*

The proposed algorithm first checks whether the large or small modes are suitable for a MB. As there are 3 large blocks, therefore, two thresholds T2 and T3 have been introduced to distinguish them. 16×8 block is considered as the best mode if the initial cost is greater than T2. If the initial cost is greater than T3 then 8×16 mode is selected. Otherwise, 16x16 mode is considered as the best mode. Similarly, as there are four small modes, three thresholds T5, T6, T7 are introduced to distinguish among them. For a greater value than T5, T6, T7 8×4, 4×8 and 4×4 modes are selected as the best one respectively.



(a)



(b)

Fig. 4 Probability Characteristic Curve of Small Modes for News QCIF Sequence at QP = 24, 32

Otherwise, 8x8 mode is selected as the best sub-mode. The threshold for each mode is taken very carefully for different quantization parameters. Table 1 shows the thresholds for different video sequences for different QP obtained by observing and analyzing the mode vs. cost characteristic curves. To find optimum thresholds, polynomial curvature fitting theorem has been applied. Thus, optimized thresholds values of Foreman, News and Mobile video sequence for different QP's are obtained which are shown in Table 2. Therefore, it is possible to use the data from Table 2 to get the thresholds values for determining the best inter mode. Therefore, probability based fast inter mode algorithm can be represented with following steps:

Step 1: Initialize the thresholds T2, T3, T5, T6 and T7 for a specific QP value.

Step 2: Select a macroblock and determine its Hadamard $SAD_{16\times16}$ cost.

Step 3: Check if the MB is suitable for SKIP mode, if not go to Step 4, if yes select skip mode as the best mode.

Step 4: Divide the macroblock into 4 8×8 sub blocks and determine Hadamard $SAD_{s8\times8}$ cost for each block and calculate them to find Hadamard $SAD_{p8\times8}$ cost.

Step 5: If Hadamard $SAD_{16\times16}$ cost is less or equal to Hadamard $SAD_{p8\times8}$ cost choose large modes category, otherwise small modes category.

Step 6: If Large mode category is chosen, compare the Hadamard $SAD_{16\times16}$ cost with the T2 and T3 to determine the best Large mode (16×16, 16 ×8 and 8×16).

Step 7: If small mode category is chosen, compare the $SAD_{s8\times8}$ of a sub block with the T5, T6 and T7 to determine the best small mode (8×8, 8×4, 4×8 and 4×4).

Based on this algorithm it is possible to determine the best inter mode without calculating the rate distortion cost function.

IV. RESULTS AND DISCUSSION

Proposed algorithm was tested using the first 100 frames of different video sequences of QCIF format. Due to page limitation among them the results of "Foreman" that has medium motion changes with dominant luminance changes, "News" that has a low spatial details and changes in motion and "Mobile" that has a complex horizontal and vertical motion with slow zooming and panning are shown. The experiment is carried out in the JM 18.2 [12] encoder and the parameters selected as CABAC enabled; GOP structure is IPPPP; Maximum search range for motion estimation is 32; QP values are 20, 24, 28, 32, 36 and 40.

The thresholds determined by the experiment varied very slightly for different video sequences. Compared to the original H.264/ AVC video encoder, proposed algorithm has reduced the computational time significantly by around 60% to 65% for different QP values which are shown in Table 3. Though the bit rate increases and PSNR has reduced slightly, but the degradation of video quality for is very low and considered almost negligible. Therefore, the proposed algorithm is applicable for real time applications where reducing computational time is preferable compensating the video quality with negligible distortion.

Abstract - **Load flow solution is an inevitable tool for power system planning and operation. Among various methods of load flow solution techniques Newton Raphson (N-R) and its derivatives are the most popular and widely used ones. In Newton Raphson method one of the generator buses is treated as slack bus which is kept out of calculation during iterations. This is because of the fact that the slack bus is to carry entire loss of the system and total loss cannot be calculated before the end of iterations. The exclusion of slack bus from the load flow iteration restricts many analyses to make. Consideration of distributed slack bus, load flow for Microgrids, study on minimization of system losses etc. cannot be performed when the slack bus is excluded from the iterations. This paper reports the development of a method of including slack bus into the Jacobians for N-R load flow study. The method involves formulating the loss equation and then devising the formula for the terms to be included with the elements of the Jacobian matrix. The modified N-R method is applied to all of the buses and the losses are calculated in each iteration and included with the slack bus. The results obtained using the modified method are compared with those using conventional method. The agreement of the results confirms the accuracy of the developments.**

Index terms: **Inclusion of Slack bus, Jacobian modification, Microgrid load flow**

I. INTRODUCTION

The buses of a power system are divided into three categories in a load flow study. They are PV-, PQ- and Slack-bus [6]. Slack bus is also called infinite bus because theoretically the generation capacity at this bus is very large. It is treated as reference bus and with respect to it, all phase angle of the other bus voltages are calculated. In practice, in power flow solution, the slack bus is kept out of the iterative solution process and its power is calculated at the end of convergence of the iteration. Thus all losses of the network are burdened on this slack bus.

The new tools for planning and operating distribution systems have become essential with the increase of distributed generators (DGs) installed within power network called Microgrid network. Application of conventional power flow solution techniques in microgids using one slack bus is not possible [1]. This is because of the fact that the generating units are of small in capacity having comparable sizes and no one can be treated as slack generator of infinite capacity. So, the slack bus should be treated as normal PV bus. In other words slack bus should be included in the iterative process of load flow solution. Mohapatra [2] devised a method of eliminating burden of slack bus while maintaining the equal incremental loss criteria for optimum generation scheduling. Again, because of special characteristics of distribution systems, such as high R/X ratios and network imbalance, consideration of distributed slack bus is more realistic than a single slack bus [3, 4]. The previous work done for transmission system [5] cannot be applied directly in distribution system. Similar to the cases described, the consideration of keeping the slack bus outside the load flow study creates restrictions in different other studies.

This paper analyzes the system loss equation and it is found to be a function of bus voltage magnitudes and their angles. Since the elements of Jacobian in N-R method are the derivatives of real and reactive power with respect to voltage magnitudes and angles, hence with the inclusion of loss, it is necessary to modify the elements by adding terms involving the rate of change of loss with respect to the two variables. This paper devises a formulation for such inclusion. The method has been applied to solve the load flow considering slack bus to carry all losses and the results obtained from the new method are compared with those obtained using conventional method. The new method is also applied for the case of distributed losses.

II. MATHEMETICAL FORMULATION

For given loads in a system, the scheduled generations in the generator buses except the slack bus are known beforehand. The conventional load flow solution provides us the power to be maintained at the slack bus. In the developed method, at the beginning of iteration the generation power at the slack bus is assumed to be equal to total loads minus total generations in all other generating buses. It means that, at start, the losses are assumed to be zero and the generators are sufficient to supply the loads only. After each iteration, the total loss is calculated and included with the scheduled power of the slack bus. Simultaneously the rates of change of losses are included into the Jacobians in the iterative process.

A. The Power Equations

The apparent power injected at a bus *i*, is given by

$$S_i = P_i + jQ_i = V_i I_i^* = V_i \sum_{k=1}^{n} V_k^* Y_{bus_{ik}}^* \tag{1}$$

So, the real and reactive power is expressed as,

$$P_i = \mathrm{Re}\left[V_i^* \sum_{k=1}^{n} V_k Y_{bus_{ik}} \right] \tag{2}$$

$$Q_i = -\mathrm{Im}\left[V_i^* \sum_{k=1}^{n} V_k Y_{bus_{ik}} \right] \tag{3}$$

Since, we have considered that the slack bus will take the total loss of the system, so the loss calculated after each iteration is added with original scheduled power considered at

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

the beginning of the iteration. The modified scheduled real power should be equated with the injected real power, P_1 (assuming bus #1 as slack bus) obtained from equation (2). In other words, the original scheduled real power at slack bus can be equated with the injected power obtained from equation (2) minus the losses calculated after each iteration. The modified injected power may be termed as modified injected power at the slack bus. The modified injected power at bus #1 is given by,

$$P_1^{'} = P_1 - loss \tag{4}$$

By combining equations (2) and (4) we obtain,

$$P_1^{'} = \mathrm{Re}\left[V_1^{*} \sum_{ik=1}^{n} V_k Y_{bus_{ik}} \right] - loss \tag{5}$$

The total loss is summation of losses of all branches of the system. It is a function of voltages of the buses.

B. The Loss Equation

The total loss can be expressed as,

$$loss = \sum_{i=1}^{n-1} \sum_{k=i+1}^{n} \left| (V_i - V_k)^2 Y_{bus_{ik}}^2 \ \mathrm{Re}\left[\frac{-1}{Y_{bus_{ik}}} \right] \right|$$

$$= \sum_{i=1}^{n-1} \sum_{k=i+1}^{n} \left| (V_i - V_k)^2 C_{ik} \right| \tag{6}$$

$$where, C_{ik} = Y_{bus_{ik}}^2 \ \mathrm{Re}\left[\frac{-1}{Y_{bus_{ik}}} \right] \tag{7}$$

C. The Modification in Jacobian

Now in the Newton-Raphson method [2], the elements of the Jacobian corresponding to ΔP_1 is given by,

$$\frac{\partial P_1}{\partial \delta_1} = \frac{\partial}{\partial \delta_1} \left\{ \mathrm{Re}\left[V_1^{*} \sum_{k=1}^{n} V_k Y_{bus_{ik}} \right] \right\} - \frac{\partial loss}{\partial \delta_1} \tag{8}$$

$$\frac{\partial P_1}{\partial |V|_1} = \frac{\partial}{\partial |V|_1} \left\{ \mathrm{Re}\left[V_1^{*} \sum_{k=1}^{n} V_k Y_{bus_{ik}} \right] \right\} - \frac{\partial loss}{\partial |V|_1} \tag{9}$$

< Conventional term > < new term >

The derivation of the conventional terms can be found in ref. [7].

The new terms in equations (8) and (9) can be obtained by differentiating equation (6) with respect to δ_1 and $|V|_1$ respectively. They are,

$$\frac{\partial loss}{\partial \delta_1} = 2 \sum_{\substack{k=1 \\ k \neq i}}^{n} C_{1k} (V_1 - V_k) j V_1 \tag{10}$$

$$\frac{\partial loss}{\partial |V|_1} = 2 \sum_{\substack{k=1 \\ k \neq i}}^{n} C_{1k} (V_1 - V_k) e^{j\delta_1} \tag{11}$$

Therefore, the elements of the Jacobian [J] given by equation (8) and (9) are updated by including the new terms from equations (10) and (11).

D. Shifting of Reference

Since all busses are included in the iteration process, so the angles of all buses, including the slack bus, are subjected to change. Therefore after each iteration, all bus voltage is rotated in the opposite direction with the angle of bus #1 so that it always remains as reference. This is done by multiplying each voltage vector by $e^{-j\delta_1}$.

III. THE TEST SYSTEMS

A 6-bus system [8] is selected for the validation of the new method. Single line diagram of the system is shown in Figure 1. It consists of three generators and three loads. Apart from the 6-bus system, The developed method has also been applied to a 30-bus and a 57-bus IEEE test systems [9]. Salient information on the three systems is exhibited in Table I. The line parameters and other system data of the three systems are available in [8,9].

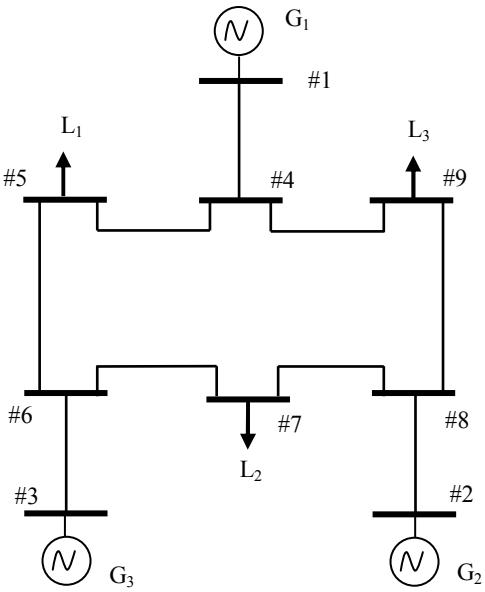

Fig. 1: 6-bus test system

TABLE I
DATA ON SYSTEMS STUDIED

Items	6-bus	30-bus	57-bus
Scheduled Gen. at Slack bus (at the beginning of iteration), MW	100	23.53	450.8
Scheduled generation at other gen. buses, MW	110	165.67	800.0
Total load, MW	210	189.3	1250.8
No. of genenrator bus	3	6	4
Total no. of bus	6	30	57

IV. RESULTS

Matpower [10], an open source MATLAB program for load flow studies, have been modified to implement the method developed and described in Section II. The original program implements conventional Newton-Raphson method for load flow solutions.

The validity of the formulation is established by applying the proposed method and the conventional N-R method for the load flow solutions of the test systems mentioned in section III and comparing results. While applying the proposed formulation two different case has been considered, (i) losses included in the slack bus generation only and (ii) losses distributed among all the generator buses.

A. Validation of the Developed Method

In the modified program the slack bus is included into the Jacobian and the program is run for the 6-bus system. It

converged after three iterations. The conventional N-R program is then run for the 6-bus system having the same slack bus. The conventional method also took three iterations to converge. The slack bus power after convergence is found to be 107.88 MW. It is found that the losses are exactly the same for both the methods. Also, voltage magnitudes and angles obtained by the two methods matched exactly.

In the modified program, the losses were calculated in each iteration and subtracted from the injected power to compare with the scheduled power of the slack bus. The losses obtained in different iterations are tabulated in Table II.

TABLE II
CONVERGENCE OF LOSS FOR 6-BUS SYSTEM

Iteration count	Losses, MW	Net Power at bus 1, MW
1	7.55	107.55
2	7.87	107.87
3	7.88	107.88

Similar studies have been carried out for the 30-bus and the 57-bus IEEE systems. The convergences of losses are shown in Table III and Table IV respectively. In both cases the numbers of iterations were also found to be the same for the conventional and the modified methods.

For all systems, it is observed that loss figures when calculated during iterative process converge earlier than the convergence of real and reactive powers. It indicates that the inclusion of loss and its effect on Jacobian is correct.

TABLE III
CONVERGENCE OF LOSS FOR 30-BUS SYSTEM

Iteration count	Losses, MW	Modified Scheduled Power at bus 1, MW
1	4.67	28.20
2	5.52	29.05
3	5.53	29.06
4	5.53	29.06

TABLE IV
CONVERGENCE OF LOSS FOR 57-BUS SYSTEM

Iteration count	Losses, MW	Modified Scheduled Power at bus 1, MW
1	27.84	478.64
2	27.86	478.66
3	27.86	478.66

B. Loss Distributed Over All Generator Buses

The capacities of the generators in microgrid are comparable and hence it may not be possible to impose all losses on a single generator. The developed method has been applied in 57-bus system and the total losses have been distributed over four generator buses in proportion to their capacities. The result is presented in Table V. The table compares losses for the two case, i.e. losses included in the slack bus generation only and losses distributed to all generator buses. It is seen from the result that the loss is reduced when it is distributed over different generation buses. This is a more accurate result. This type of study is now possible with the developed method.

TABLE V
COMPARISON BETWEEN NON-DISTRIBUTED AND DISTRIBUTED LOSS

Gen. Bus	Losses applied to slack bus		Losses distributed among gen. buses	
	Losses, MW	Gen. power, MW	Loss, MW	Gen. power, MW
1	27.86	478.36	9.64	459.64
3	0.0	40.0	0.86	40.86
8	0.0	450.0	9.63	459.63
12	0.0	310.0	6.63	316.63
Total	27.86	1278.36	26.76	1277.26

V. CONCLUSION

A method of including the slack bus during iterative process of Newton Raphson method has been presented. It is based on inclusion of line losses at every iteration. The effect of inclusion of loss has an impact on Jacobian elements. The mathematical formulation of this impact has been analyzed and the expressions of the variation of loss with voltage magnitudes and their angles have been presented in the paper. The validity of the formulation has been applied in three test systems. The agreement between the results of the new method with the conventional one proved the accuracy of the development. The new technique is also applied to a case of loss distributed among different generator buses. The ease of new method has opened up a new avenue to explore numerous studies which are not possible by the conventional method.

ACKNOWLEDGEMENT

Author[1] likes to express his thanks to Bangladesh University of Engineering and Technology for approving sabbatical leave during which the research was carried out. Thanks also to BRAC University for allowing the use of their facility in order to carry out the research.

***Abstract*—The simultaneous ac-dc power transmission system can increase the load carrying capability of a long transmission line. A mathematical model is developed in this paper for simultaneous ac-dc power transmission system to analyze the behavior of a composite system in comparison with the original ac system. The load carrying capability of an ac-dc composite system is compared with that of original ac system through numerical solution in this paper.**

***Index Terms*— AC-DC composite system, loadability, zigzag transformer, thermal limit.**

NOMENCLATURE

P_l	Steady state power flow through unconverted ac line in p.u
E_g	Internal generated voltage of the generator in p.u
E_r	Receiving end voltage in p.u
X	Transfer reactance of unconverted ac system in p.u
I_l	Current through unconverted ac line in p.u
I_{th}	Thermal limit of the conductor
I_L	Steady state current of unconverted line
δ	Load angle of the generator for unconverted system
V_{acon}	Per phase ac voltage of converted line
V_{dc}	DC voltage component in each phase.
P_{comb}	Combined steady state ac-dc power flow
P_{ac}	Steady state ac power in ac-dc composite system
P_{dc}	Steady state dc power in ac-dc composite system
I_{dc}	DC component of composite system line current
I_{AC}	AC component of composite system line current

I. INTRODUCTION

A long EHV ac transmission line has an upper limit of loading dictated by stability consideration and this line is not loaded to its thermal limit to keep sufficient margin for transient stability. Flexible AC Transmission System (FACTS) is used in existing ac transmission line to improve load carrying capability along with the overall system performance [1-2]. Series compensation with mechanical switch can be other option for increasing the loadability of existing transmission line [3]. Now a days, for power flow and stability improvement HVDC line is operating in parallel with HVAC line [4].

Simultaneous ac-dc transmission is a new approach for the increase of power flow through the existing line proposed by H.Rahman and B.H.Khan [5]. The simultaneous ac-dc power flow derives the benefit of parallel HVDC line without constructing it. In this system of power transmission existing ac line conductors are used to carry ac power along with dc power simultaneously. The proponents of this new approach conducted the numerical analysis considering only transmission line, disregarding the whole system from generator to infinite bus. A feasibility study is performed for small power tapping from simultaneous ac-dc transmission line in [6]. Simulation results of this paper clearly indicate that the tapping of a small amount of ac power from the composite ac–dc transmission line has a negligible impact on the normal functioning of the composite ac–dc power transmission system. To date, all the works those have been done on simultaneous ac-dc power transmission are based on numerical solution. From the numerical result it is difficult to formulate a generalized comment. However, to investigate the behavior of a system comprehensively an appropriate mathematical model is a necessity. Moreover, the change of which parameter of the system impact how much on its performance by using the mathematical model someone can evaluate easily.

In this paper, a comprehensive analysis is presented on simultaneous ac-dc system by developing an appropriate mathematical model. The model is used to investigate the load carrying capability of an existing long ac transmission line in case of simultaneous ac-dc power flow. A numerical analysis also performed for the validation of developed mathematical model.

II. Simultaneous AC-DC Power Flow

In simultaneous ac-dc power transmission system same conductor is used to transmit ac power along with dc power, the schematic diagram of simultaneous ac-dc flow is shown in fig.1. The main concern of this paper is to convert existing long EHV ac line into ac-dc composite line. According to the figure, a remote generating unit is feeding to an infinite bus through a long transmission line. A portion of ac power, taking from the generator bus, converted into dc and feeding to the existing ac transmission line through the neutral point of zigzag transformer.

At the receiving end, dc portion of power is taking away from the neutral point of zigzag transformer and converted into ac before feeding to the infinite bus. Zigzag connection is used at both ends of the transmission line to avoid magnetic saturation in the transformer core due to dc current.

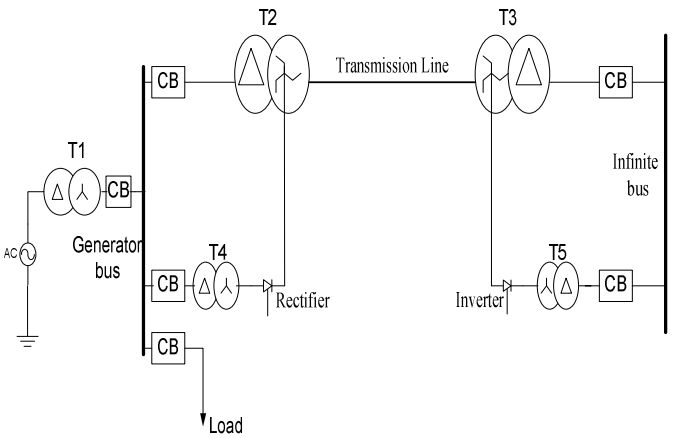

Fig. 1 AC-DC composite power transmission system

In converting ac line into ac-dc composite line the insulator remain unchanged and thus the maximum value of the phase voltages must be kept same. The output dc current of rectifier is equally divided among all the three phases and each conductor carries ac-dc modulated current wave. A communication link is needed between rectifier and inverter for better control of dc power flow.

III. Loadability Model

A simple ac transmission system is presented in fig. 2. In case of ac transmission line the power flow equation is given as follows.

$$P_l = \frac{E_g E_r}{X} sin\delta \quad (1)$$

$$I_l = \frac{E_g\angle\delta - E_r\angle 0}{jX} \quad (2)$$

$$X = X_{te} + X_{Tr} \quad (3)$$

Here,

X_{te} = Reactance that includes the reactance of generator and transformer in p.u.

X_{Tr} = Reactance of the transmission line in p.u.

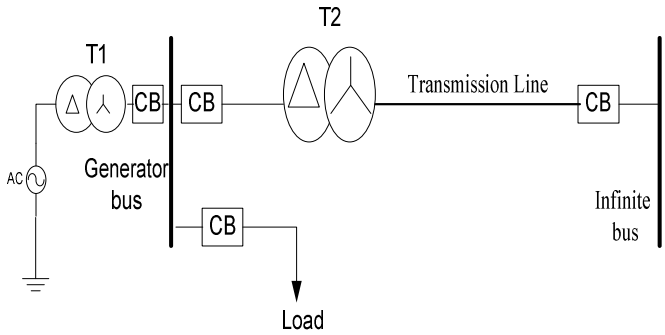

Fig. 2 A.C power transmission system

For a long ac transmission line minimum steady state stability margin is recommended as 30% and steady state power transfer angle would be 40^0 – 44^0 [7]. Although the thermal limit is qualified as line design and it depends on conductor selection but according to the loadability characteristics of a long transmission line the thermal limit is much higher than the steady state stability limit.

Let α is the ratio between steady state current and thermal limit of the conductor.

$$I_L = \alpha\, I_{Th} \quad (4)$$

As the mechanical infrastructure (i.e. insulating material, clearing distance and creepage distance) of composite line remain unchanged the maximum value of the phase voltage in converted line is to keep same as unconverted line. The sum of the dc voltage and per phase maximum ac voltage is equal to the maximum value of the unconverted line phase voltage but in this case maximum value of ac voltage must be greater than or at least equal to the dc voltage so that electric field changes its direction in each cycle, as the line insulators are not changing. Let k is a factor that quantifies the ac voltage level and 1-k quantifies dc voltage level. The value of k varies between 1 and 0.5 i.e.$0.5 \le k < 1$.

$$V_{\emptyset m} = \frac{\sqrt{2}}{\sqrt{3}} V_L \quad (5)$$

$$V_{acon} = \frac{1}{\sqrt{2}} k V_{\emptyset m} \quad (6)$$

$$V_{dc} = (1-k) V_{\emptyset m} \quad (7)$$

Here,

$V_{\emptyset m}$ = maximum phase voltage for unconverted ac system

V_L = Line voltage for unconverted ac system

V_{acon} = AC phase voltage for composite system

V_{dc} = DC voltage in each phase for composite system

Combined power flow is the summation of ac power and dc power in composite system.

$$P_{comb} = P_{ac} + P_{dc} \quad (8)$$

$$P_{ac} = P_{acmax} \sin\delta_{ac} = \frac{E_g E_r}{X'} \sin\delta_{ac} \quad (9)$$

δ_{ac} is the transmission angle and X' is the transfer reactance from generator to the infinite bus for ac power transmission in composite line.

Let β is the ratio between composite line ac current I_{AC} and unconverted line ac current I_L, where the expression of β can be found as

$$\beta = \frac{X}{kX'} \left| \frac{E_g\angle\delta_{ac} - E_r\angle 0}{E_g\angle\delta - E_r\angle 0} \right| \quad (10)$$

The expression of β can further be simplified by using the approximated current expression presented in [5].

$$\beta = \frac{X}{kX'} \left(\frac{\sin\delta_{ac}}{\sin\delta} \right) \quad (11)$$

Now the ac power flow equation (9) can be expressed in a simple form in terms of unconverted ac power.

$$P_{ac} = k\beta \frac{E_g E_r \sin\delta}{X}$$
$$= k\beta P_l \quad (12)$$

In case of ac-dc system the line can be loaded up to the thermal limit and it is assume that the line voltage at the sending and receiving end would be the same, so the dc current and power at this loading are given as ,

$$I_{dc} = \sqrt{I_{Th}^2 - I_{AC}^2} \quad (13)$$

$$I_{dc} = I_L \sqrt{\frac{1-\alpha^2\beta^2}{\alpha^2}}$$
$$= I_L\,\gamma \quad (14)$$

Here, $\gamma = \sqrt{\frac{1-\alpha^2\beta^2}{\alpha^2}}$

$$P_{dc} = 3V_{dc}I_{dc}$$
$$= \frac{3\sqrt{2}}{\sqrt{3}}(1-k)V_L\,I_L\,\gamma$$
$$= \frac{3\sqrt{2}}{\sqrt{3}\sqrt{3}}(1-k)\gamma\left(\frac{E_g E_r \sin\delta}{X}\right)$$
$$= \sqrt{2}\,(1-k)\gamma P_l \quad (15)$$

Now the combined power in terms of unconverted ac power is given by (16)

$$P_{comb} = [k\beta + \sqrt{2}(1-k)\gamma]P_l \quad (16)$$

The equation (16) clearly reveals that the combined ac-dc power depends on the values *k,* β and γ respectively. The value of *k* has huge impact on transfer reactance of converted ac system that is shown below.

$$X' = X_{te} + X'_{Tr}$$
$$= X_{te} + \frac{X_{Tr}}{k^2}$$
$$= X_{te} + mX_{Tr} \quad (17)$$

where, $m = \frac{1}{k^2}$

In case of long transmission line $X_{Tr} >> X_{te}$. Therefore, in case of ac-dc composite system with very much lower value of *k* the equivalent terminal system reactance would be negligibly small compare to the converted line equivalent reactance and considering the equation (3) and (17) the following approximation can be made.

$$X' \approx mX \quad (18)$$

The combined power flow equation (16) can be expressed in a simple form as follows

$$P_{comb} = AP_l \quad (19)$$

Here, $A = k\beta + \sqrt{2}(1-k)\gamma$

To get the combined power flow higher than the unconverted ac power the value of *A* must be greater than 1. i.e. $A > 1$.

For example, if the value of *k* is 0.5 that gives 50% ac voltage and 50% dc voltage mix and if the value of α is considered 0.5 the value of *A* would be 1.62 which means 62% improvement in combined power flow is obtained. In this case, same power transfer angle is considered for ac power transmission in composite ac-dc system and unconverted ac system which is 44^0 [7]. Considering some reasonable values of *k* and *α* the Loadability Improvement(LI) is presented in Table I.

TABLE I
LOADABILITY IMPROVEMENT FOR DIFFERENT AC AND DC VOLTAGE MIX

k	$\alpha = \frac{I_L}{I_{th}}$	P_{ac}	P_{dc}	P_{comb}	LI (%)
0.5	0.50	$0.25P_l$	$1.37P_l$	$1.62\ P_l$	62
	0.45	$0.25P_l$	$1.53P_l$	$1.78\ P_l$	78
	0.40	$0.25\ P_l$	$1.73\ P_l$	$1.98\ P_l$	98
0.52	0.50	$0.27P_l$	$1.31\ P_l$	$1.58\ P_l$	58
	0.45	$0.27P_l$	$1.47\ P_l$	$1.74\ P_l$	74
	0.40	$0.27\ P_l$	$1.66\ P_l$	$1.93\ P_l$	93
0.54	0.50	$0.29\ P_l$	$1.25\ P_l$	$1.54\ P_l$	54
	0.45	$0.29\ P_l$	$1.40\ P_l$	$1.69\ P_l$	69
	0.40	$0.29\ P_l$	$1.59\ P_l$	$1.88\ P_l$	88
0.56	0.50	$0.31P_l$	$1.19P_l$	$1.50\ P_l$	50
	0.45	$0.31P_l$	$1.39P_l$	$1.70P_l$	70
	0.40	$0.31\ P_l$	$1.51\ P_l$	$1.82\ P_l$	82
0.58	0.50	$0.33P_l$	$1.13\ P_l$	$1.46\ P_l$	46
	0.45	$0..33P_l$	$1.27\ P_l$	$1.60\ P_l$	60
	0.40	$0..33P_l$	$1.44\ P_l$	$1.77\ P_l$	77

Table I clearly shows that for a particular value of *α* if the value of *k* is increased the load carrying capability of the composite system will decrease. The increase in *k* represents increase in ac voltage mix and decrease in dc voltage mix. The value of α also has a significant impact on LI. For a particular value of *k* smaller decrease in α cause greater increase in LI.

IV. NUMERICAL ANALYSIS WITH SIMULATION RESULT

For the numerical simulation a power system is considered which presented in appendix. In case of unconverted ac line, considering 30% steady state stability margin [7], following results are found after simulation.

Steady state loading = 436MW
Steady state power transmission angle = 44.44^0
Line current = 0.7574kA
Value of α = 0.4208

Now, ac-dc composite system is analyzed through developed mathematical model and the results are compared with those obtained from the numerical simulation using MATLAB. The improvement in load carrying capability, shown in Table II, obtained using developed mathematical model is very much close to those observed from the numerical simulation. A small percentage of error is observed in loadability improvement with the developed model. This small percentage of error is due to some logical assumptions that are considered to make the model simple.

TABLE II
COMPARISON OF LOADABILITY IMPROVEMENT BETWEEN DEVELOPED MODEL AND NUMERICAL SIMULATION

$\alpha = \frac{I_L}{I_{th}}$	k	Loadability Improvement (LI)		% of error
		With developed model (%)	With numerical simulation(%)	
0.4208	0.50	95.37	101.49	6.03
	0.52	90.96	96.82	6.05
	0.54	86.62	92.21	6.06
	0.56	82.36	87.69	6.07
	0.58	78.17	83.25	6.10
	0.60	74.05	78.88	6.12

Again the ac-dc composite system is analysed, using developed mathematical model, to investigate the impact of different dc voltage mix on loadability improvement. The change of dc voltage in composite system has huge impact on steady state loading that shown in fig. 3

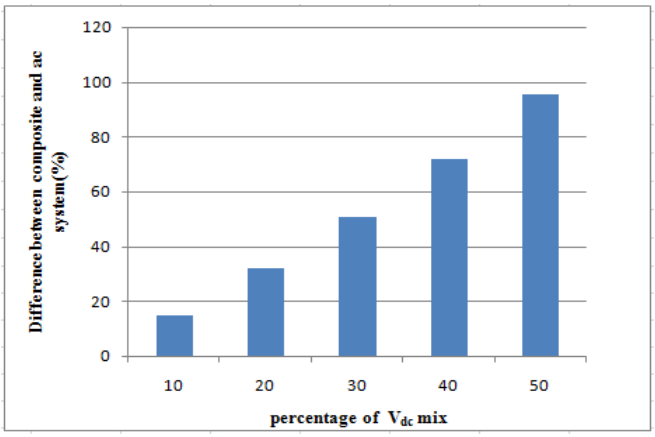

Fig. 3 Loadability improvement in ac-dc composite system

It is clearly observed from the figure that the loadability improvement increases with the increase in the value of dc voltage mix and obtained improvements for this system varies from 14.9% to 95.6% with the dc voltage mix variation from 10% to 50% respectively.

V. CONCLUSION

Conversion of a long EHV transmission line into simultaneous ac-dc composite system can give an improvement in load carrying capability of the line. Moreover, ac-dc composite power transfer system provides the benefit of ac-dc parallel transmission system without constructing separate line. The mathematical model developed in this paper for simultaneous ac-dc power flow through the existing line clearly shows, without numerical simulation, that the loadability of existing line increase with the increase of dc mix.

APPENDIX

A sample power system is considered for the simulation study with numerical data

A. *Unconverted AC line configuration*

Base power=550MVA

Line voltages are 24kV, 132kV, 345kV for the generator, generator bus and transmission line respectively.

Ratings of different components are as follows:

Two identical generators each has the following rating 550MVA, 24kV, 50Hz, H=3.5sec, 30% transient reactance.

Transformer T_1&T_2(Between generator and generator bus) each of 550MVA, 24/132 kV, 50Hz, 10% reactance.

Transformer T_3 : 1100MVA,132/345 kV,50Hz, 8% reactance.(At the sending end of the line)

Transformer T_4 : 1100MVA,345/132 kV,50Hz, 8% reactance.(At the receiving end of the line)

Transmission line: ACSR(Moose; commercial name) twin bundle conductor, 345kV, 50Hz, 400km single circuit line has following parameters

X_{Tr} = 0.33086 Ω/km/phase, R = 0.03252 Ω/km/phase

$Y = 3.33797*10^{-6}$ S/km/phase

current carrying capacity of each sub conductor is 0.9kA.

I_{th}(thermal limit)=1.8kA,

B. *Composite AC-DC configuration*

Transformer T_3 = 550MVA, 132/172.5kV, 50Hz, 8% reactance.

Transformer T_4 = 550MVA,172.5/132kV, 50Hz,8% reactance.

A Study On Low Grid Voltage Problem Near Rooppur Nuclear Power Plant

A. Hasib Chowdhury, Md. Khurram Monir Rabby*
Dept. of EEE, Bangladesh University of Engineering and Technology
Dhaka-1205, Bangladesh
*khurram.rabby@gmail.com

Abstract— **Faced with the need of achieving the highest possible efficiency in the utilization of primary resources, nuclear power plants (NPPs) are considered as a viable alternative or addition. In case of transmission system voltage interruption, especially low voltage, NPPs have historically been susceptible to stations trip. Because of low voltage problem, the resulting loss in real and reactive power support can embitter transmission events. In this paper, the possibility of low bus voltage in the Western grid of the Bangladesh power system network, where the planned Rooppur NPP will be sited, is calculated and reported. It has been observed that even with small load factor, buses around the Rooppur NPP experience low voltage. A detailed investigation to study the problem and possible solutions is thus recommended.**

Index Terms—**Nuclear power plant, low voltage, loading factor, Bangladesh power system network**

I. Introduction

There are two basic characteristics of power system for identifying quality of supply and having great influence on operability of safety related electrical equipment. Those two characteristics are system voltage and system frequency [1].Problems of operating a NPP within an electric grid of limited capacity or of low voltage have long been a serious concern because the grid has direct bearing on the starting and running of the NPP [1]. To avoid the low voltage problem the design of the power system should be according to the NRC [2]. Similar requirements can be found in IAEA [3]. Moreover NRC's design criteria ensure that any mode of plant operation shall not degrade the performance of any safety system load below an acceptable level [4]. According to [5], emergency power supply (EPS) has the ability to detect and disconnect from its power source in event of degradation (over- and under-voltage, over- and under-frequency), and have possibility to connect directly to the alternative source. Limitation regarding degradation of voltage in power system depending issues are described in [6-10]. In [11], voltage stability, power transfer limits, reactive reserves, methods of improving voltage stability, load conservation procedures and effects of deregulation on nuclear power generating stations have been described. For the voltage case consideration, the phenomenon of voltage sag on the safety bus due to various transients as electrical operating modes is simulated and analyzed in [12-15].

The permitted deviations of NPP in standardized design may differ from one supplier to another and must be carefully verified by the prospective owner of the NPP with regard to the currently prevailing conditions of the grid. Typical IEEE approved supplier-guaranteed limits for correct operation at start-up conditions may include: high-voltage motors: down to 75% of nominal voltage, low-voltage motors: down to 70% of nominal voltage and valve drives: down to 80% of nominal voltage. Short-time voltage drops can be tolerated if high-capacity motors are started. For bus-bars of diesel back-up generators, a drop of 15-20% is generally IEEE acceptable. However, continuous operation of large-capacity fully loaded motors at such levels is not recommended. Off-nominal voltage conditions of prolonged duration can be compensated by on-load tap changers; usually, these compensate for the following deviations from nominal values:± 10% for normal transformers and ±15% for stand by grid transformers.

This paper presents a continuous power flow based approach to predict the most probable low voltage buses close to the Rooppur nuclear power plant buses in Western grid of the Bangladesh power system network.

II. Cases of Low Voltage

Off-nominal voltage conditions at various points of the grid are mainly due to the inability of the grid protection system to quickly clear transmission line faults, long transmission lines without intermediate power stations, lack of voltage control equipment, such as synchronous condenser and static capacitors, absence of on-load tap-changing transformers and insufficient capacity of the transmission lines to carry the peak load. The other types of low voltage reasons are described below.

A. Sharp Drop In Voltage

A rapid drop in voltage (voltage dip) is mainly due to an electric fault on a transmission line. The extent of the dip depends upon the proximity and nature of the fault, and upon the sensitivity of the automatic voltage regulator (AVR) equipment of the generators connected in the grid. The duration of the dip depends on the speed of the protective relays and their co-ordination as well as on the circuit breaker characteristics and their speed of operation. During sharp voltage dip conditions, all connected motors will be retarded. The magnitude of the retardation is determined by the voltage dip and its duration, the characteristics of the load, and the mass moment of inertia of the motor-pump assembly.

B. Inadequacy Of Voltage Control Equipment

When the voltage control equipment is inadequate, it may not be possible to maintain the same voltage at different points of the grid at all times, and poor voltage conditions may develop and persist over extended periods. Prolonged low voltage on the grid may create problems in starting and running large-capacity motors of the NPP. Some motors are provided with flywheels and have a relatively long start-up time.

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

C. Voltage Constraints

It is normal for grid voltage to sway, as grid voltage is dependent of total system production and consumption of reactive power, and in the case of absence of the feeding transformer tap changer voltage present at the safety busbars will also change. There are two distinctive voltage events that can occur with different causes and effects, and are therefore separately considered.

D. Undervoltage/Degraded Voltage

Undervoltage state at safety busbars can be result of following events:

Degradation of high voltage (grid voltage) - Either imbalance of production/consumption of reactive power within system or loss of one or more phases can cause voltage to decrease significantly and have negative impact on the electrical safety related equipment of a NPP.

Consequences of degraded voltage condition are loss of multiple electrical components, trip of motors due to thermal protection actuation (Thermal overload) and inability of electrical (such as auxiliary relays) components to actuate or stay actuated, thus limiting the ability of the safety (and non-safety) related equipment to operate and perform its intended function.

III. System Description and Modelling

Bangladesh power system network (BPSN) is mainly divided into five operational regions. They are Dhaka, Central, Southern, Northern and Western region. Dhaka region has the largest bulk of generation. It exports power to the western part. The Eastern Grid is formed by Dhaka, Central and Southern regions, and Northern (Rajshahi-Rangpur) and Western (Khulna- Barisal) region form the Western Grid.

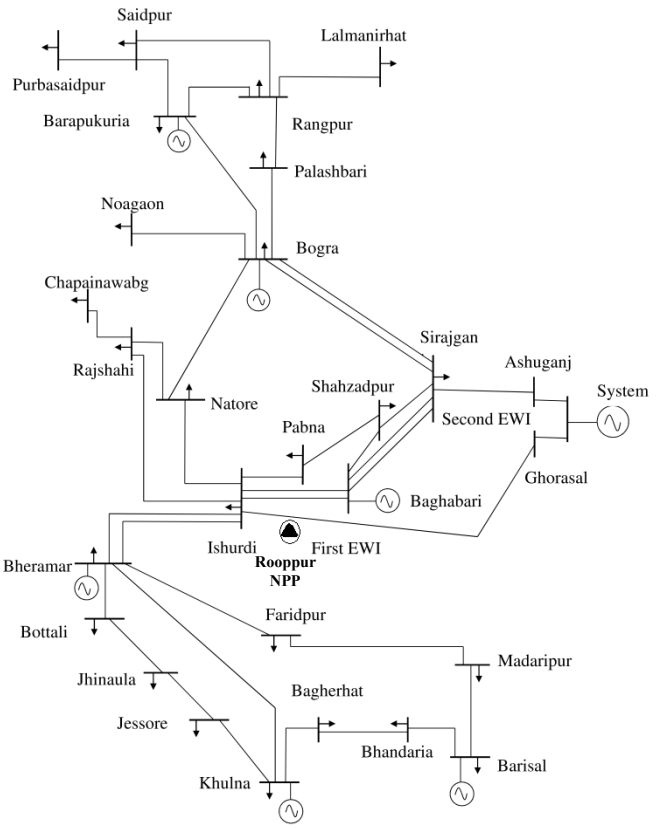

Fig. 1 Reduced EWIS of BPSN with proposed Rooppur NPP

The network model used in this study is fully based on the detailed transmission system of the BPSN, as available from Power Grid Company of Bangladesh (PGCB) website. Figure 1 shows the east-west interconnected system (EWIS) that has been created for representing BPSN in this work. Two 230 kV tie-lines interconnect the greater Eastern and Western Grid, which are considered as the first EWI and second EWI respectively, that are geographically divided by the combined flow of rivers Jamuna, Padma and Meghna [16].

Bulk power is generated in the eastern grid of Bangladesh power system network (BPSN). This power is transmitted to the western grid by means of two tie lines that are Ghorasal to Ishurdi (1st EWI) and Ashuganj to Sirajganj (2nd EWI). The newly proposed Rooppur NPP is indicated in the above figure. This topology has been derived from the actual network condition of BPSN.

Taking into account widely varied characteristics of the constituent load types, such as, resistive loads and mixed resistive-inductive loads, rotating inductive loads, thermostatic loads, extinction lighting loads etc., modeling of power system loads is a complex task [16]. Typical loads are represented as static voltage dependent load models where active and reactive powers are expressed as a function of bus voltages [16]. There is an exponential representation that represents the voltage dependency of the loads by varying the value of exponent, as shown in equation (1a) and (1b):

$$P = P_0 \left(\frac{V}{V_0}\right)^a \tag{1a}$$

$$Q = Q_0 \left(\frac{V}{V_0}\right)^b \tag{1b}$$

Where P_0 and Q_0 are the active and reactive power consumed at a bus at reference voltage V_0. If a=b=2, the resulting load model is constant impedance type where power varies with square of voltage magnitude. If a=b=1, it represents constant current load model, where power varies directly with voltage magnitude. Assuming a=b=0, i.e., ignoring voltage dependency, results in constant active and reactive power load model, which exerts maximum stress on the system [16].Constant P-Q static load model has been considered in this study due to unavailability of any reported study on load modelling for BPSN. System load data has been obtained from operational records of PGCB.

IV. Analytical Technique

Low voltage profile can be determined by bifurcation analysis. Bifurcation analysis is an effective tool for analysing nonlinear system stability. Only the saddle node and Hopf bifurcation are of interest. All type of bifurcation analysis is carried out by changing parameters of the system until bifurcation patterns immerge in system behaviour. In case of power system, the change in eigen value of the system due to changes in load bus power as a bifurcation parameter is studied. To locate the bifurcation, system parameter is presented with suitable mathematical equation [17]. The dynamic behaviour of the system can be presented by the following mathematical formulation [17,18],

$$\dot{x} = f(x, y, \lambda, p) \tag{2a}$$

$$o = g(x, y, \lambda, p) \tag{2b}$$

Where, $x \in R^n$ represents the system state variables, dynamic state of generators, loads and other time varying elements in the system, such as static VAR compensator controllers, exciter governor of the machine

etc.; $y \epsilon R^n$ corresponds to the algebraic variables, usually related to the transmission system and steady-state element models such as some generating sources and loads in the network; $\lambda \epsilon R^m$ corresponds to set of variables that are not controllable, varies continuously, typically loading factor is one of the parameters which varies as system load changes, and leads the system into bifurcation; $p \epsilon R^k$ stands for some directly controllable parameters such as degree of series shunt compensation; $f(.)$ and $g(.)$ represents vector function of algebraic equation and system constrains function, respectively [17]. From the bifurcation analysis PV diagram can be obtained. Using this PV diagram, low voltage profile can be predicted with LF analysis.

Another method of determining system stability is continuation power flow (CPF) technique. CPF technique consists of three steps: predictor, corrector and parameterization [17].

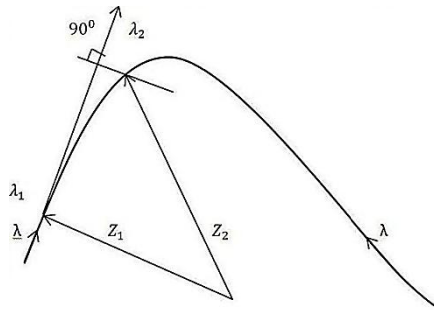

Figure 2 Continuation geometry analyses in state space and load parameter space

Predictor step involves arbitrary steps for λ and state variable to predict a new equilibrium point from the previously known equilibrium point. Corrector step is used to find intersection between the perpendicular plane to the tangent vector at the preceding equilibrium and branch as shown in Fig. 2. Step size is reduced if the process does not converge. As the system closes to the solution of power flow equation by varying loading parameter, system Jacobian becomes ill-conditioned. Then parameterization involves switching loading parameter to the new variables of the system that presents highest changes and guarantees the Jacobian of the power flow solution is non-singular at the saddle node bifurcation point [17].

V. RESULTS

The proposed Rooppur NPP is connected to the Ishurdi bus. So if Ishurdi and the buses directly connected to it in the Western grid (Bheramara, Rajshahi, Pabna, Baghabari and Natore) have low voltage effect, the NPP must have to bear the low system voltage impact.

The bus voltage and associated line length of Rooppur NPP are presented in Table I.

TABLE I
LINE VOLTAGE ANDLINE LENGTH CLOSE TO ROOPPUR NPP

Lines between buses	Voltage (kV)	Length (km)	
		Route	Ckt
Ghorasal-Ishurdi	230	178	356
Ishurdi-Baghabari	230	55	110
Ishurdi-Baghabari-Shahjadpur	132	57	57
Ishurdi - Pabna - Shahjadpur	132	56	56
Rajshahi - Natore	132	40	40

In Fig. 3, the PV diagram shows that for the system without compensation EWIS experiences low voltage for increasing loading factor (LF).

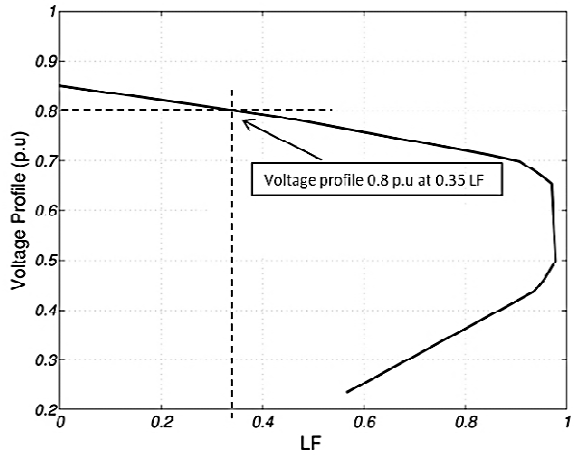

Fig. 3 Low voltage PV diagram

From the steady state analysis, it can be seen that with increasing LF, the voltage profile (p.u) of the above mentioned buses decreases. According to IEEE approval, around 0.8 voltage profile is considered as low voltage profile bus. From the Fig. 3, it is observed that at 0.35 LF voltage reaches 0.8p.u. After crossing the 0.35 LF, if the loading factor is further increased, the voltage profile (p.u) of the above buses falls so drastically that it does not able to meet the system voltage requirement.

The continuation power flow analysis using UWPFLOW has been performed for the overall system low voltage analysis. The result is presented in Table II, where the low voltage threshold is set at 0.80 p.u.

TABLE II
EWIS LOW VOLTAGE ANALYSIS

Bus Name	Corresponding Near Buses	LF (0.8 voltage p.u)	Actual minimum voltage (pu) (March-June, 14)
Barisal	Bhandaria, Madaripur	0.07	0.82
Bhandaria	Barisal, Bagherhat*	0.32	0.79
Faridpur	Madaripur, Bheramara*	0.07	0.86
Madaripur	Faridpur, Barisal	0.40	0.83
Saidpur	Purbasaidpur, Rangpur*	0.30	0.82
Purbasaidpur	Saidpur, Barapukuria Region*	0.20	0.83
ChapaiN'ganj	Rajshahi*	0.20	0.78

** means less affected buses*

If any buses of the power system experience low voltage then corresponding nearby buses also experience adverse effect due to it. As a result, not only the load buses but also the corresponding adjacent buses experience low voltage.

From above table it has been observed that actual minimum voltage (p.u) of Barisal, Faridpur, Madaripur, Saidpur and Purbasaidpur is more than 0.8p.u. Because loading of those buses is less. So voltage is comparatively high. But with the additional LF makes those buses voltage down to 0.8p.u. On the other hand, actual minimum voltage (p.u) of Bhandaria and ChapaiN'ganj is less than 0.8p.u. Because loading of

those buses is high. That's why voltage profile is low. So the above table shows their actual LF at 0.8 voltage profile (p.u).

From the above analysis, it has been observed that the buses around Rooppur NPP have the possibility to face the low voltage problem. In the system analysis for safety purpose in NPP criteria it is decided for 0.8 p.u voltage profile. Normally, after the 0.8 p.u voltage, with increasing LF the bus voltage decreases so drastically that system doesn't get enough time to recover its safe state.

VI. Conclusions

The deployment of NPPs to supply a portion of the electricity on a power grid brings with it a number of requirements on the grid design that is unique to it. The requirements must be considered by power grid planners and system operators. Unlike conventional power sources NPPs have long term shutdown cooling requirements that consume power and have stringent voltage and frequency limitations (imposed to assure the operability of critical emergency cooling systems). The operation process of electric grids must recognize the performance characteristics which are assumed by an NPP. All components and equipment within NPP electrical distribution system have their own protection and it is considered that the under voltage event can be only caused by events initiated outside the safety related electrical system. Degraded voltage condition is considered to be special type of under voltage event where voltage has lowered enough to cause equipment failure and/or damage if this state is present long enough. Under voltage event is the most likely event to occur among considered events.

In this paper a continuous power flow based approach to predict the most probable low voltage buses close to the Rooppur nuclear power plant buses in Western grid of the Bangladesh power system network has been presented. It has been observed that even with small load factor, buses around the Rooppur NPP experience low voltage which does tally with the actual situation. A detailed investigation to study the problem and possible solutions is thus recommended.

***Abstract*—Among many great scientific achievements, discovery of electricity stands out in an unparalleled manner. The twentieth century has made use of electricity so extensively that it has almost changed the face of the earth. With this exponential rise in demand, power shortage has become a global phenomenon. South Asian countries alone are facing an average shortage of 15%-30% in electricity. In order to cope up with the increasing demand, short-term measure like oil based generation system has been introduced which has hiked up the cost of electricity. In a developing country like Bangladesh, cost of energy must be kept at bay to ensure minimum standard of life. That's where the term "affordable cost" comes into action. From the point of view of Bangladesh, where natural resource is scarce, nuclear based electricity generation is a suitable way to sustain increasing demand in an affordable manner. In this paper, fundamental concentration is given on both affordability and nuclear energy.**

***Index Terms*—Nuclear energy, affordable cost, reserve, tariff, consumption rate.**

I. Introduction

South Asia is an under-developed and energy resource deficient region that houses 1.65 billion people at present, which makes one-fifth [1] of the total population of the world. This region contains the highest number of people without access to electricity (658 Million) [2]. And most of the countries, including Bangladesh have a very low energy consumption rate. Key reasons behind this are low per capita income, high cost of energy, insufficient natural resources etc.

Affordable cost is an amount that a consumer feels comfortable to pay for energy and it doesn't lower his living standard by any means. It can be measured by considering net income, present tariff and consumption rate of energy. Scenario for the last 15 years in Bangladesh [3] is shown in Fig. 1.

It shows that, consumption rate and tariff have increased quite rapidly. In addition to that, Fig. 2 shows that electricity production cost is increasing day by day. However, in case of Bangladesh, maximum generation is much less than installed generation capacity which is shown in Fig. 3. To meet both affordable cost and high demand; we have to design a generation system versatile enough in both ends. Nuclear based generation system is an worthy candidate for that.

II. Affordable Cost Analysis

Affordable cost is a term dependent on numerous factors, most of them related to economics. Electricity has become one of the fundamental rights of the people. So, ensuring this right in a tranquil way is an imperative aspect for the country.

To determine affordable cost in the perspective of Bangladesh, a comparison is studied in Table I amongst the countries having the same economic standards as Bangladesh,

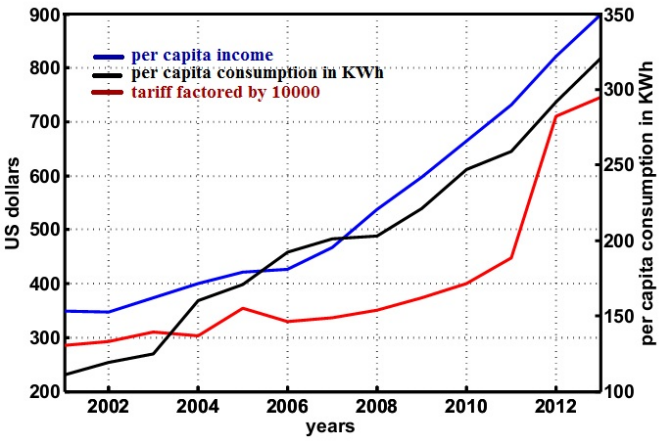

Fig. 1. Year-Wise Per Capita Income, Consumption Rate and Tariff in Bangladesh

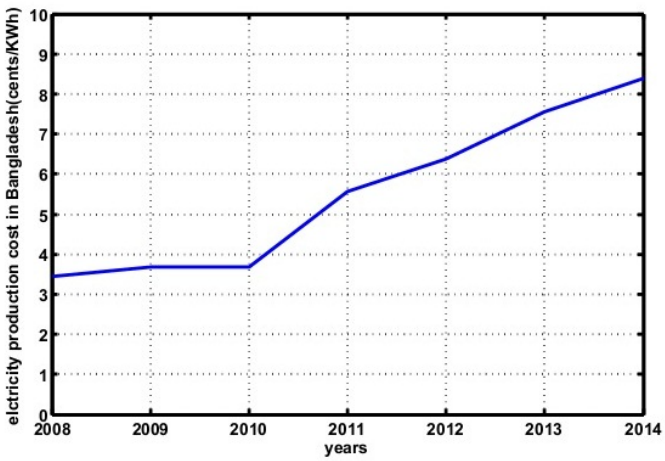

Fig. 2. Year-Wise Electricity Production Cost in Bangladesh

like Pakistan, India, Nepal, Sri lanka on the topics of per capita annual income, present tariff, per capita consumption, energy expense as a percentage of income etc. [3].

Here it is seen that, for most of the countries, energy expense as a percentage of income remains almost in the same range. This is the sign of a same level economic zone.

By observing year-wise energy expense as a percentage of income in these countries in Fig. 4, it can be deduced that except for Bangladesh, all other countries almost have a steady rate. In case of Bangladesh [4], it's evident that expense rate is getting steeper day by day. So conclusion can be made that, cost of energy in Bangladesh isn't affordable in general.

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

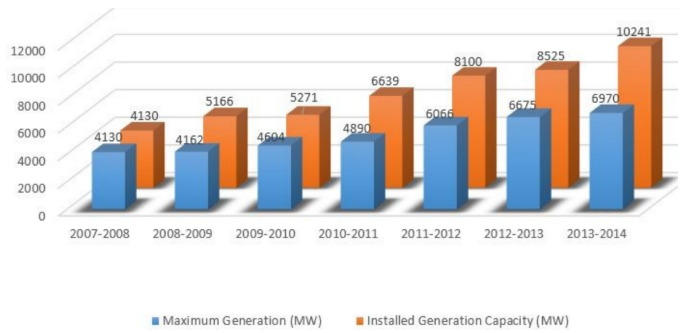

Fig. 3. Installed Generation Capacity vs Maximum Generation

TABLE I
COMPARISON OF ECONOMIC PARAMETERS AMONG SOUTH-ASIAN COUNTRIES IN 2013

Country name	Per Capita Annual Income ($)	Electric-ity Tariff (cents)	Per Capita Consumption (kWh/year)	Energy Expense as % Income
Bangladesh	903	5.833	321	2.0735
India	1504	9.48	787.3	4.9625
Pakistan	1307	10.92	431	3.601
Sri Lanka	3161	13	572	2.3524
Nepal	692	7.56	112	1.2236

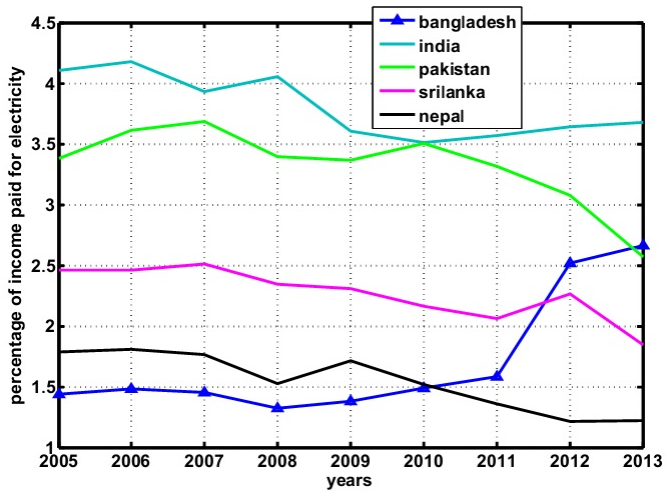

Fig. 4. Energy Expense As a Percentage of Income in Different South-Asian Countries

In order to obtain an affordable cost of energy, a seven step method is devised here which is shown in Fig. 5. Per capita annual income of Bangladesh in 2014 is around $ 1190. As it is seen that, in previous years, when the cost of energy was affordable, energy expense as a percentage of income was around 1.5% [4]. A highest limit of affordability can also be set and assumed that it is 2.0% of the income. From this point of view, a safe range of affordable cost can be ascertained which is, energy expense must remain within 1.5%-2.0% of the income. Comparing with the annual per capita income, annual cost of energy per capita should ranges from $ 17.85 to $ 23.8. Annual consumption rate per capita in Bangladesh is 321 kWh in 2014. So, affordable tariff of electricity should ranges from BDT 4.32 to BDT 5.76 per kWh.

Tariff consists of production cost alongside transmission cost, maintenance cost etc. So, affordable production would be a bit less than that derived tariff and can be assumed as

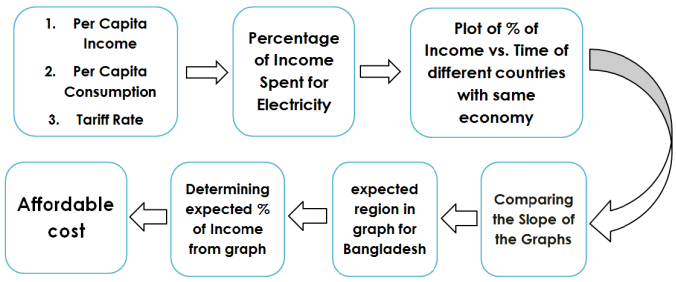

Fig. 5. Block Diagram of The Methodology of Determination of Affordable Cost

TABLE II
GAS AND COAL RESERVE OF BANGLADESH IN 2013

Gas Reserve		Coal Reserve	
Description	status	Location (exploration year)	Actual reserve (MMT)
Total no. of gas fields	23	Boropukuria (1985)	390
No. of gas fields in production	17	Khalashpir (1995)	143 (GSB), 685 (Hosaf)
Total reserve of extractable gas (proven & probable)	20.605 TCF	Fulbaria (1997)	572
Total reserve remaining after usage	11.174 TCF	Jamalganj (1965)	1050
Daily extraction	2035 MCF	Dighipara (1995)	200 (partial evaluation)
Daily demand	2500+ MCF		
Daily supply shortage	500+ MCF		

BDT 4.00 to BDT 5.00 per kWh. Bangladesh Government provides a huge subsidy in energy sector. In this production cost range, Government will not need to provide subsidy that much.

The production cost or tariff derived here is an average one and reflects the overall affordability of the whole population. No discrimination is done on the aspect of residential, industrial or commercial loads. Moreover, this range is for the whole consumption as no slab system is introduced here.

III. APPROACH TO AFFORDABILITY

There are some options regarding choice of fuel for electricity generation in our country. Natural gas, being the fundamental fuel for some time, has now reached its limit, whereas coal has a low production rate in Bangladesh. Feasibility of these fuels for future production is studied below:

A. Natural Gas

At present, around 80% of the produced electricity comes from natural gas. Being the fundamental fuel for electricity generation, natural gas is losing its reserve. At current rate of use in Bangladesh (1000 mmcfd), the estimated proven reserves would last 45 years [5]. If present rate of use increases at 10% per year, these reserves would last about 17 years. Another problem regarding this fuel is its fluctuation in supply, often the power plants do not get the necessary gas which halts the smooth generation system. Natural Gas reserve along with coal is shown in Table II.

TABLE III
RATE OF TAX ON COAL IN 2013 AND 2014

Solid Fuel	Rate of Tax at 1 May 2013 (US dollar per ton)	Rate of Tax at 1 May 2014 (US dollar per ton)
Coal	26.33	52.67
Peat:		
Peat briquettes	18.33	36.67
Milled peat	8.99	17.99
Other peat	13.62	27.25

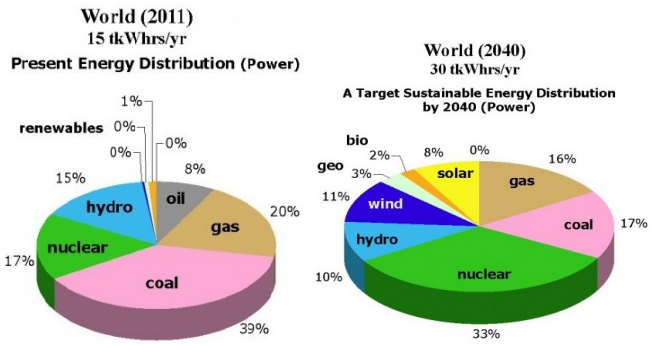

Fig. 6. Present and Proposed Future Energy Distribution of the World

B. Coal

Coal is another source which is getting low in reserve also and adding to that, coal of Bangladesh has low heat producing capacity. Coal reserves of five fields in Bangladesh are estimated at 3.0 billion tons equivalent to 67 tcf of gas, which can conveniently serve the energy needs of Bangladesh for 50 years [6]. Moreover, to tackle the environmental hazard, tax on coal has almost been doubled which is mandatory to be paid by the developing countries also. Short history on coal Tax is shown in Table III.

C. Hydro

Around 4% of total electricity generation comes from hydro power plant in Bangladesh. Though it has the advantage of almost zero fuel cost and longevity, hydro energy falls behind for its dependency on weather, extra-long setup time and extremely high capital cost.

D. Diesel and furnace oil

It has the advantage as short term solution but can't be used in the long term generation because of its extreme expense. Mainly to supplement the emergency crisis, oil based generation system can be used.

E. LNG

Liquefied natural gas (LNG) is natural gas (predominantly methane, CH_4) that has been converted to liquid form for ease of storage or transport. It might be used for very small scale generation but has a high risk of pressure related accident.

F. Nuclear

Nuclear fuel is increasing in percentage of the total fuel mix in the whole world. Because of low reserve, coal and gas sectors are shrinking and giving space to nuclear energy. Per kWh cost for overall generation in nuclear energy is quite low comparing to other sources.

TABLE IV
PRESENT AND TARGET SCENARIO OF ENERGY DISTRIBUION IN BANGLADESH

Fuel type	Installed Capacity in April 2012		Derated Capacity in April 2012		Target in 2021	
	MW	%	MW	%	MW	%
Gas	5086	76	4651	76.74	5651	30
Furnace Oil	110	1.64	85	1.4	65	0.3
Diesel	1017	15.2	905	14.9	500	2.97
Coal	250	3.74	200	3.3	9984	53
Hydro	230	3.44	220	3.63	188	1
Nuclear	0	0	0	0	1884	10
Renewable	0	0	0	0	565	3

Present and future fuel mix for electricity is shown in Fig. 6. In the perspective of Bangladesh, she doesn't have a single resource rich enough to produce majority share of the electricity. So, with the gas gone, she needs another long term generation system alongside coal. Nuclear based system fits right into the category. Proposed target for 2021 supports this fact as well [7] which is shown in Table IV.

IV. HISTORY OF NUCLEAR ENERGY AND FUTURE PLAN OF BANGLADESH

In 2011 nuclear power provided 10% of the world's electricity. In 2007, the International Atomic Energy Agency (IAEA) reported that there were 439 nuclear power reactors in operation in the world, operating in 31 countries. However, many have now ceased operation in the wake of the Fukushima nuclear disaster while they are assessed for safety. In 2011, worldwide nuclear output fell by 4.3%, the largest decline on record, on the back of sharp declines in Japan (-44.3%) and Germany (-23.2%).

The United States uses the highest nuclear energy, with nuclear power providing 19% of the total electricity it consumes, while France produces the highest percentage of its electrical energy from nuclear reactors that is 80% as of 2006. In the European Union as a whole, nuclear energy provides 30% of the electricity. Nuclear energy policy differs among European Union countries, and some countries such as Austria, Estonia, Ireland and Italy, have no active nuclear power station. In comparison, France has a large number of these plants, with 16 multi-unit stations in current use. In United States, while the coal and gas electricity industry is projected to be worth $85 billion by 2013, nuclear power generators are forecast to be worth $18 billion.

Bangladesh first considered building a nuclear power plant in 1961. Since then, several feasibility studies have been carried out, affirming the feasibility of the project. In 1963, Rooppur site was selected. In 2001, Bangladesh adopted a national Nuclear Power Action Plan. On 24 June, 2007 government of Bangladesh announced plans to build a nuclear power plant to quench electricity shortages. In May, 2010 Bangladesh signed a civilian nuclear agreement with the Russian Federation [8]. Bangladesh also has framework agreement for peaceful nuclear energy applications with the US, France and China. Although the Ministry of Science and ICT, the Ministry of Energy and Mineral Resources and Bangladesh Power Development Board (BPDB) are working on the electric grid system integration, the demographics and circumstances

TABLE V
EVALUATION OF ECONOMIC COEFFICIENT OF DETERMINATION FOR BANGLADESH VS NEIGHBORING COUNTRIES

Bangladesh vs	Per Capita Income	GDP	Tariff	Energy Consumption	Country Average
India	0.86	0.11	0.01	0.98	0.49
Pakistan	0.94	0.09	0.28	0.32	0.41

present do raise the question if indeed Bangladesh can produce energy from nuclear sources [9].

In February 2011, Bangladesh reached an agreement with Russia to build the 2,000 megawatt (MW) Rooppur Nuclear Power Plant with two reactors, each of which will generate 1,200 MW of power. The Perspective Plan of the Planning Commission of the government of Bangladesh for the period 2010-2021 has recommended an energy mix to achieve the generation of 20,000 MW by 2021. Targets of electricity production by 2013 and 2015 are 7,000 MW and 8000 MW, respectively [10].

V. SCRUTINIZING THE AFFORDABILITY OF NUCLEAR ENERGY IN BANGLADESH

As generation is yet to start in Bangladesh, there is no sample data to compare with the affordable rate which has been derived. So, study will be done with the data of the countries having almost same level of economy. India and Pakistan have been using nuclear energy for some time. First, economic co-relation will be calculated between India, Pakistan and Bangladesh, then respective co-relation factors will be multiplied with nuclear energy cost of these countries and that will be checked if it falls in the affordable cost region. If not, an alternative way will have to be fashioned to generate nuclear energy within desired affordable cost.

The co-relation [11] between x and y is expressed as,

$$R_{xy} = \frac{\sum_{i=1}^{n}(x_i - \overline{x})(y_i - \overline{y})}{\sqrt{\sum_{i=1}^{n}(x_i - \overline{x})^2 \sum_{i=1}^{n}(y_i - \overline{y})^2}} \quad (1)$$

In equation 1, $(x_i - \overline{x})$ is each x-value minus the mean of x and $(y_i - \overline{y})$ is each y-value minus the mean of y.

In statistics, the coefficient of determination, denoted R^2 and pronounced R squared, indicates how well data points fit a statistical model, sometimes simply a line or curve. It is a statistic used in the context of statistical models whose main purpose is either the prediction of future outcomes or the testing of hypotheses, on the basis of other related information. It provides a measure of how well observed outcomes are replicated by the model, as the proportion of total variation of outcomes explained by the model.

Obtained data by using this formula is shown in Table V. Average production cost of nuclear energy in Pakistan is 9.59 pakistani rupee/kWh [12], which is equivalent to BDT 7.58/kWh and average production cost of nuclear energy in India is 4.00 indian rupee/kWh [13], which is equivalent to BDT 5.16/kWh. These data are multiplied with the respective economic coefficients of determination between Bangladesh and both Pakistan, India which are 0.41 and 0.49. So, in comparison with Pakistan, average production cost of nuclear energy in Bangladesh should be around BDT 3.11/kWh and in comparison with India, average production cost of nuclear energy in Bangladesh should be around BDT 2.53/kWh. So, it can be said that, the range of average production cost of nuclear based electricity generation system in Bangladesh would be around BDT 2.53 to 3.11/kWh.

This range of cost is of course experimental and in comparison with the data received from neighboring countries. So, actual data may deviate from the findings.

VI. CONCLUSION

Asia is the main global region where electricity generating capacity and specifically nuclear power is growing significantly. In East and South Asia there are 119 operable nuclear power reactors, 49 under construction and there are plans to build a further 100 [14]. Many more are proposed. There may be some concerns regarding the safety of a nuclear power plant, but with the passage of time, safe modern technology like generation 3 and generation 4 reactors are ushering nuclear energy into a new era of possibility. Countries like France and Russia are acting as pioneers in nuclear energy sector. Bangladesh should tag along in this booming operation and ensure affordable electricity for her citizen.

***Abstract*—In this paper, the focus is on the dispatching strategy of microgrids with minimization in costs and emissions. The novelty of this paper is in proposing a new approach toward combined heat and power generation in a grid with renewable energy resources, such as wind turbines, photovoltaic cells which reduces the overall costs considerably. In this research, for simulating the optimal dispatch of DG units and other power generation resources, GAMS software is applied to the problem, which results in a lower calculation time.**

***Keywords*— Microgrid; Power Systems Operation; Distributed Generation; Optimization; Cost Minimization**

I. INTRODUCTION

Nowadays, local control and minimized cost are the most important factors in the field of generation and saving the energy at distribution level. To improve system performance, the Distributed Generation (DG) resources are widely used. They are applicable in ranges of a few kilowatts to tens of megawatts such as micro-turbines, fuel cells, photovoltaic systems, wind turbine systems, diesel motors, and gas turbines are examples of DG units [1]. Few works have analyzed the technical/economic benefits and potential issues of aggregated microgrid islands on the network comprehensively. There exist several algorithms to address this issue and find a method for an islanded-network online monitoring. In [2], the authors have studied the effects of switching from power factor to voltage control mode for distributed resources in case of transferring from grid-connected to islanded mode. Six main parameters are defined based on generators' terminal measurements of voltage and current to control the system in these two scenarios (grid-connected and islanded). Permutations of these parameters will provide 64 operating modes; the objective is to find the most appropriate mode for each scenario. Other similar research works, like those mentioned in [3-6] mostly discuss the reliability aspects of aggregation of several DGs either in grid-connected or islanded mode.

Also, due to the fact that the existence of distributed units decreases efficiency of conventional overcurrent protection methods which use same rate of current relays to the whole network [3], it is believed that new methods should be investigated. References [7-9] have proposed several novel algorithms regarding this matter; e.g. applying knowledge-based methods such as genetic algorithm to redesign the relay schemes with higher current limits.

The superior of CHP units compared to other distributed resources can be justified by the obtained efficiency, where the power loss and service reliability in the network increase because of usage of output heat in several applications [10-11]. A project has been conducted for supplying a limited area with electrical and thermal demands in New York City, and it has been shown that the efficiency of generation has roughly increased to 60% [12]. The process of demand response including CHP units is also performed in [13], and has been shown by adding CHP units to the network, total costs for households has been reduced by 1–4%.

In this paper, a novel approach for economic dispatch of a grid including distributed units (either in grid-connected or islanded mode) has been proposed. Solar power, photovoltaic cells, wind turbines, and CHPs are implemented in the system along with diesel generators, micro turbines, and fuel cells to be able to study the associated electrical and environmental issues comprehensively.

II. MODELLING OPTIMIZED OPERATION OF MICROGRIDS

In this part, distributed generation units have been modelled.

A. Diesel Generator

Diesel generator's fuel cost is mathematically formulated in polynomial form and depends on output power.

$$F_{DG,i} = \sum_{i=1}^{N} a_i + b_i P_{DG,i} + c_i P_{DG,i}^2 \quad (1)$$

N = Number of generators.

$P_{DG,i}$ = Output power and generator i

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

a_i, b_i, c_i = Generator's coefficients

From information of diesel generator's manufacturer, Caterpillar, Table I for parameters of (1) for a 6 kW, 50 Hz generator is resulted [14]:

TABLE I. PARAMETERS OF DIESEL GEMERATOR

Parameter	a_i	b_i	c_i
Value	0.4086	0.2419	0.0063

B. Micro Turbine

Efficiency of micro turbine is in a linear relationship with input power. In other words, the overall and electrical efficiencies are given by the following equations:

$$\eta_{tot} = \frac{P_J + Q_{dh}}{Q_{fuel}} \tag{2}$$

$$\eta_J = \frac{P_J}{Q_{fuel}} \tag{3}$$

where P_J is the electrical generated power, Q_{dh} is the output heat, and Q_{fuel} is fuel produced energy. With respect to (2), the cost for micro turbine's fuel is calculated as following:

$$C_{MT} = C_{nl} \sum_J \frac{P_J}{\eta_J} \tag{4}$$

In this equation, P_J is the output power generated in time period J, and C_{nl} is the price per unit of natural gas for supplying to micro turbine.

C. Wind Turbine

In design of wind turbines, there are two important factors that should be considered; one is accessibility to wind sources, and next is the output power characteristic of the turbine. Here, it is assumed that accessibility to wind sources is equal for all locations in the system; so for modelling of the performance of a wind turbine, the output power is analysed.

Based on information from wind turbine manufacturer-model AIR403, in wind speeds more than 18 m/s, the output of turbine is 130 W [15].

D. Photovoltaic Cell

Photovoltaic cells convert sun's heat energy to electricity. In this modelling, the information of manufacturer for model Solarex MSX-83 in standard situation (1000 W/m^2, and 25 □C) has been used [16]. The output power P_{PV} based on environment temperature is calculated as follow:

$$P_{PV} = P_{STC} \frac{G_{ING}}{G_{STC}} (1 + k(T_C - T_r)) \tag{7}$$

In (7), P_{STC} is the maximum module in standard situation, G_{ING} is the object radiation, G_{STC} is radiation in standard situation, k is heating coefficient of power, T_C is the cell temperature, T_r is the reference temperature.

The output characteristics for photovoltaic cell Solarex MSX-83 are the following: peak power equals to 83 W, voltage in peak power is 17.1 V, current in peak power 4.84 A, short circuit current 5.27 A, and open circuit voltage is 21.2 V [17].

E. Main Objective

The main objective includes cost function and air pollution released from each resource and is written as one polynomial. This objective should satisfy the following constraints:

1) Minimizing Operation Costs

The total operational costs, $CF(P)$, of the microgrid is defined as:

$$CF(P) = \sum_{i=1}^{N} (C_i \times F_i(P_i) + OM_i(P_i)) \tag{8}$$

$F_i(P_i)$ is the cost of fuel, $OM_i(P_i)$ is the cost for service of units.

The service cost is in relationship with generated power, and is shown as bellow. In (9), K_{OM_i} is coefficient of service cost.

$$OM_i = \sum_{i=1}^{N} K_{OM_i} P_i \tag{9}$$

In Table II, K_{OM_i} for each unit is presented:

TABLE II. K_{OM} VALUES FOR EACH UNIT

Name of Generator	Diesel Generator	Micro Turbine	Wind Turbine
Value of Coef.	0.01258	0.00587	0.00684

2) Minimizing Pollution

The air pollution usually includes gases such as SO_2, CO_2, etc. It is possible to model each of these polluting factors separately. In this problem, only CO_2 is modelled and considered in the objective problem. The final emission level of this polluter is given by:

$$E_P = \sum_{i=1}^{N} 10^{-2}(\alpha_i + \beta_i P_i + \gamma_i P_i) \quad (10)$$

In the above equation, α_i , β , γ_i are non-negative coefficients derived from micro turbine's and diesel generator's output characteristics. The values of these variables are presented in the Table III:

TABLE III. MICRO TURBINE AND DIESEL GENERATOR COEFFICIENTS IN EQUATION (12)

	α_i	β_i	γ_i
Micro Turbine	0.06490	0.05554	0.06490
Diesel Generator	-0.06131	0.05555	0.05151

3) Demand Response Constraints

For stability analysis of electric power system, the following constraints should be satisfied:

$$\sum_{i=1}^{N} P_i = P_L - P_{PV} - P_{WT} \quad (11)$$

As the first constraint suggests, in the above equation, $\sum_{i=1}^{N} P_i$ is total power generated by micro turbine and diesel generator, P_L is the total demand, P_{PV} is the output power of photovoltaic cell, and P_{WT} is the output of wind turbine in terms of kW.

The other constraint is supplying the heat demand. In this constraint, the output heat should exceed the input heat.

$$P_{L^{th}} - P_{MT^{th}} - P_{Heater} \geq 0 \quad (12)$$

In the above equation, $P_{MT^{th}}$ is the micro turbine's output heat, $P_{L^{th}}$ is the input heat, and P_{Heater} is the generated power by heater.

In order to prevent excess heat generation, penalty is considered dependent on the above variables.

$$Penalty = \left(\frac{P_{MT^{th}} + P_{Heater} - P_{L^{th}}}{40}\right) \quad (13)$$

In the (13), 40 is an arbitrary coefficient that will give an average reasonable penalty and is derived based on public surveys presented in [18].

For achieving a stable operation, the maximum and minimum output generated power for each unit should be kept in a range of minimum and maximum value.

$$P_i^{\min} \leq P_i \leq P_i^{\max}, \forall_i = 1, \ldots, N \quad (14)$$

F. Combined and Non-Combined Generation of Power and Heat Scenarios

The objective function is studied in two scenarios of combined and non-combined generation of heat and power in a network that is either grid-connected or islanded.

In the CHP mode, in addition to using heaters, the output heat of micro turbines is utilized. Conversely, in the non-CHP generation scenario, for responding to electrical demands, wind turbines, photovoltaic cells, diesel generators, and micro turbines are considered. Regarding the constraint for supplying thermal load, $P_{MT^{th}}$ is replaced with zero in this scenario.

III. SIMULATION RESULTS

Due to the fact that the problem has multi objectives to be satisfied and a nonlinear nature, it is not possible to use the conventional gradient solution for microgrid operation optimization. Therefore, a new mathematical approach has been proposed which is formulated in the previous section and is modelled in this section. This model follows a non-linear mathematical (polynomial) representation that includes several environmental and electrical constraints. Also, heat generation is included based on information derived from manufacturers' catalogues, and the effects of microgrids' islanding in CHP mode is studied as well.

In this paper, the calculations are done using GAMS software package. In this software, several algorithms are applied and examined to find the optimum solution for linear, non-linear, mixed integer, mixed integer non-linear, mixed integer complementarity problems.

A. Simulation Results

In this problem, operation costs, demand, and pollution level are considered for 24 hours. Figure 1 and 2 show the procedure of demand response between microgrid's generating units, in case that micro turbine is being operated in CHP mode, and $\omega = 0.7$. According to this information, with increase in demand at peak times, micro turbine and diesel generator's output will increase. Heater is turned on in the initial four hours that micro turbine's heat output is not adequate, and will be turned off in other hours. Photovoltaic cells and wind turbines provide the base demand and do not possess a large share of total generation.

Figure 1. Diesel Generator Daily Output in Different Weighted Coefficient

Figure 2. Micro Turbine Daily Output in Different Weighted Coefficient

Table IV shows total cost and pollution emmision level in three scenarios: in the first and second scenarios, optimization is done based on one single objective, and the third one will be based on a multi-objective problem. As it can be seen, in the first scenario, the level of emission is minimized, while in second one, operation cost is minimized, and finally in third scenario, both the emmision and operation costs are considered for optimization with $\omega = 0.7$. It can be seen that minimum cost for generation considering the level of pollution is about 22.21×10^3 USD for one day.

TABLE IV. TOTAL COST AND POLLUTION IN SCENARIOS

Scenario	Total Cost (USD×10^3 /day)	Total Pollution(Kg /day)
Single Objective (Pollution)	28.63	10.348
Single Objective (Cost)	21.22	14.307
Multi-Objective ($\omega = 0.7$)	22.21	13.171

In the Table V, the difference between these the cases could be clearly observed. In the case of CHP availability with $\omega = 0.7$ as in our case study, the overall cost is lower 12×10^3 USD averagely.

TABLE V. TOTAL COST IN CHP AND NON-CHP IN VARIOUS WEIGHTED COEFFICIENTS

Weighted Coefficient ω	1	0.9	0.8	0.7	0.6	0.5	0.4	0.3	0.2
Total Cost (CHP) (10^3×USD)	21.22	21.226	21.226	21.226	21.226	22.21	23.78	25.27	26.67
Total Cost (non-CHP) (10^3×USD)	33.47	33.47	33.47	33.47	33.47	34.52	35.99	37.56	39.09

IV. CONCLUSION

This paper proposes an optimal operation scheme for microgrids. For implementing such a network, the whole area should be investigated for all availabilities; in areas with adequate sun power, it is possible to use photovoltaic cells, and similarly wind turbines, diesel generators, and so forth. The important issue in such a network is the way of dispatching the sources, so the two main objectives, pollution level and operational costs, would be minimized. The main purpose of this research is to propose a new nonlinear analytical representation for optimal dispatch of these sources in a microgrid.

It was seen that because renewable sources that mostly provide base load, rely on environmental factors, their output is constant in all values of ω. For non-renewable sources such as diesel generators and micro turbines, for ω close to 1, micro turbine had the main responsibility for providing output power because of inexpensive generation cost, and vice-versa in ω near to 0 the major generation is from diesel generator because of low polluting factors. In addition, it was observed because the output heat of micro generation units can be recycled, considering CHP mode in micro turbines, total costs decrease dramatically.

***Abstract*—Efforts have been underway to estimate the life remaining of the paper insulation used in power transformers, and thus estimate the remaining life of the whole unit. However, one problem encountered when estimating remaining life is that the current state of the paper is not often exactly known. One method to determine the condition of paper is to measure the furan content of the oil to estimate the degree of polymerization of the paper. However, one problem with this technique is that paper does not age uniformly within a transformer. In particular, paper usually degrades fastest at the top of the winding where the temperature is highest.**

We therefore set out to determine whether a correlation exists between the condition of the paper at the top of the winding and that inferred by the furan content of the oil. Samples of paper from sixteen decommissioned transformers were used to investigate the rates at which paper degrades at the top of the winding. These results imply that the rate of ageing of paper in this location did not exceed double that calculated from using oil furan content.

***Index Terms*—Power transformers; Paper products; Dielectric breakdown; Oil insulation**

I. Introduction

The life of a power transformer is ultimately dependent on the condition of its solid electrical insulation, which is usually of cellulosic paper and pressboard. This insulation paper is wrapped around the, usually copper, windings of the transformer. Over time chemical reactions occurring with the paper insulation cause it to become brittle [1], where it may eventually detach from the windings. These chemical reactions involve atmospheric oxygen, water and mineral acids [2 – 6]. These acids are generated from oxidation of the mineral oil [6]. Water can be generated from the oxidation of either paper or oil, or ingress from the atmosphere.

Models are being investigated to estimate the life remaining of paper insulation based on the water content of this insulation and the oxygen concentration of the oil in addition to temperature [5]. The problem with applying these models to an operating transformer is that the condition of its paper is not always known especially if no monitoring has been used. One technique frequently used to determine the state of paper is the furan measurement, in particular 2FAL [1]. This furan molecule is generated from the degradation of paper, and dissolves into the oil where its concentration can be measured by High performance Liquid Chromatography (HPLC). The condition of the paper has been found to be related by an empirical function of this concentration.

A problem with this technique is that paper does not degrade uniformly within a transformer. Paper often degrades fastest towards the top of the winding where the temperature is highest [7].

Given that insulation will fail on its weakest link, it is important to be able to estimate the condition of the brittlest paper within the transformer from a 2FAL measurement. In this study insulation paper extracted from decommissioned power transformers was studied, to investigate the difference between the condition of the paper at the top of the winding, and that inferred from the concentration of furans dissolved in the oil. Our strategy was to determine the average rate of ageing of paper derived from 2FAL and then investigate how it varies for paper located around a transformer winding.

II. Structure of Cellulosic Paper, its Ageing, and Furan Generation

A cellulose macromolecule is a very long chain formed of repeating glucose molecules. For the Kraft paper inside a newly manufactured transformer the average number of glucose rings per molecule, its degree of polymerization (DP), is about 1,000 to 1,200 [8]. Water, oxygen and oil acids steadily react with the cellulose breaking down the number of rings per molecule [9]. As the degree of polymerization falls the paper becomes more brittle. A DP of 200-250 is usually taken as being the end of life because the tensile strength of the paper has fallen to around a quarter of its original value [10, 11]. The key reaction modes affecting cellulose are [3]:

- Oxidation, involving atmospheric oxygen
- Hydrolysis, involving water which has either been sourced from the atmosphere or generated from chemical reactions
- Pyrolysis, involving only temperature

Oxidation changes the chemical composition of oil creating a large number of different compounds [12 - 13]. These compounds can then continue to react with the cellulose. For instance, mineral acids generated by the oxidation of the oil will react in combination with water promoting hydrolysis [6, 14 - 17].

In a previous paper, [5], two populations of transformers were analysed. One population was sealed while the other was free breathing. Despite these transformers having very similar levels of water dissolved in their insulation oil, furan levels indicated that the condition of the paper of the free breathing transformer population was worst.

As paper degrades furans are produced [1]. Furans are not generated by insulating oil, and so are indicative of the ageing of the paper [18]. The concentration of furan 2-

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

furfural (2FAL) dissolved in the oil has been shown to correlate with the DP of the paper by various researchers, including Chendong, Hill et al, De Pablo, Burton and Vuarchex [18].

However, problems have been noted such as the partitioning of the furan between the oil and paper is related to temperature, i.e. the concentration of furan can spike during periods of increased loading of the transformer [18]. Furans degrade over time, reacting chemically with the water and oxygen dissolved in the oil [18]. Consequently, determining a definitive mathematical relationship between the furan concentration and paper DP is challenging, as many factors must be taken into account. A higher precision in the relationship between DP and 2FAL levels would be possible with a large database by segregating the transformer classes of generation, transmission and distribution [18].

III. Modelling Degradation of Paper [17]

The reduction in DP of paper can be modelled using (1), where k is the rate of ageing, DP_0 and DP_t are the degree of polymerisation of the paper at the start (≈1,000) and after time t. Rate k is related to the temperature and conditions of ageing (i.e. water and oxygen content of system) given in (2), where A is a function of the water and oxygen content, E is the activation energy of the reaction (≈111 kJ/mol), R is the ideal gas constant (8.314 $JK^{-1}mol^{-1}$) and T is the temperature in Kelvin. Within normal transformer operating temperatures the A value is considered to be independent of the temperature, i.e. it does not change with temperature.

For approximately every 6-8 °C increase in temperature rate k is doubled [1], which is also evident in (2). However, in a transformer as the temperature increases there is a general tendency for cellulose to desorb water, slowing down rate k. This desorbed water can be adsorbed by cooler areas of the transformer's cellulosic materials.

$$\frac{1}{DP_t} - \frac{1}{DP_0} = kt \tag{1}$$

$$k = Ae^{-E/RT} \tag{2}$$

Online condition monitoring equipment is available which can measure the water content and temperature within a transformer, allowing these equations to be applied. For a new transformer the DP of the paper is known, being around 1000-1200 [1]. However, a challenge encountered when attempting to apply this model to an aged transformer is that the DP of the paper is not accurately known. It is also not a single value because the paper does not degrade uniformly; there is both a temperature and water concentration gradient along the winding.

As paper degrades furans are released. The De Pablo model suggests that each time three cellulose chains are broken, one 2FAL molecule is generated [18].

Chendong et al. found a linear relationship between the furfural concentration in logarithmic scale and the degree of polymerisation [19]. This was represented by (3), where F is the 2FAL concentration in mg/L. Stebbins et al [20] modified (3) to (4) where F is the 2FAL concentration in ppb.

$$Log\ F = 1.51 - 0.0035 \times DP \tag{3}$$

$$DP = \frac{\log(0.88 \times F) - 4.51}{-0.0035} \tag{4}$$

De Pablo published a comprehensive report on furanic compound analysis [21], reporting a similar log-linear relationship between the furans and DP. He has reported five different relationships based on experiments conducted at different conditions.

In [22] De Pablo reported a relation between furfural and DP as shown in (5) below, where 2FAL is the furan concentration expressed as mg/kg of oil.

$$DP = 7100/(8.88 + 2FAL) \tag{5}$$

Pahlavanpour [23] modified the formula based on transformer conditions, and an assumption that 20% of winding paper and the inner paper layer degrades twice as fast as the rest of the paper. The revised formula is (6).

$$DP = 800/[(0.186 \times 2FAL) + 1] \tag{6}$$

IV. Tested Transformers

Five Australian utilities provided data on power transformers which had been scrapped, and subsequently had had samples of paper removed for analysis and comparison with a furan measurement. To be of use for this study the paper had to have been noted as being extracted from the top of one of the windings, often paper had been taken yet the utility had not recorded where it had been extracted from. Data from 16 power transformers was sufficiently complete for this study. The DP estimated using the Chendong equation was compared with the DP of the paper from the top of the winding. The year when these transformers were manufactured was known, and therefore two average rates of ageing were calculated for both DP measures, and then they were compared. This data is given in Table I.

A. Transformer #1

This was a 110/33 kV 48/60/80 MVA transformer manufactured in 1978 and decommissioned in 2011. Paper was removed from the top, middle and bottom of different windings. The DP of these samples of paper was mostly less than that estimated using 2FAL (Fig 1). This is a concern since there was less life left in the paper than that estimated using furan.

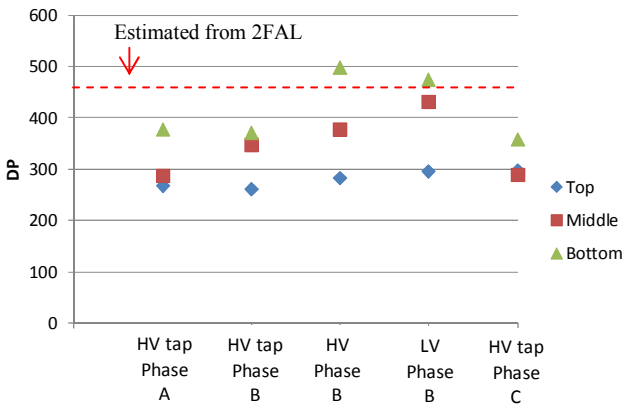

Fig. 1. Degree of polymerisation of paper from different sections of transformer #1.

B. Transformer #2

A scrapped 132/33/11 kV 45 MVA had several samples of paper removed from one winding. This unit was manufactured in 1963 and decommissioned in 2013. The DP

along one winding is shown in Fig 2. The 2FAL content was 987 ppb, providing a calculation for DP of 449. The values shown in the figure below are very close to calculated DP. As this transformer was used in the transmission network, it probably ran fairly cool with a minimal temperature gradient.

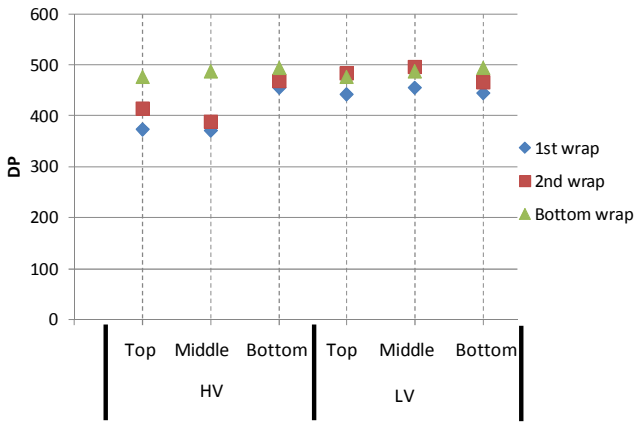

Fig. 2. Degree of polymerisation of paper from different sections of transformer #2.

C. Transformer #3

Samples of paper were removed from a failed 47 year old 20/27 MVA transformer [7], Fig 3. The DP of the paper from the top of the windings was nearly always lower than at the bottom of the same winding (only the paper on the HV tap of phase A did not show this relationship). The 2FAL concentration was used to estimate DP using (4). A value of 350 was calculated for this transformer from a 2FAL concentration of 2.2 ppm, which is around the average value of the measurements. However, the minimal DP shows that the paper at the top of the winding had very nearly reached the end-of-life criterion set by IEC 60076/7.

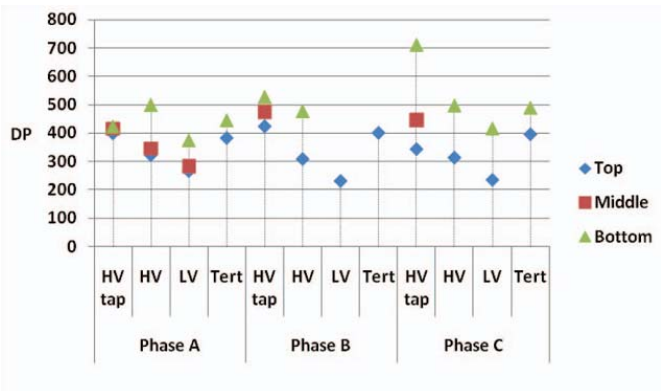

Fig. 3. Degree of polymerisation of paper from different sections of transformer #3.

D. Transformers #4 and #5

These transformers were operated by the same utility. Their DP measurements are shown in Fig 4. Transformer 4 (132/69 kV 30/45 MVA) was installed in 1981 and was 32 years old when decommissioned. Transformer 5 (unknown rating) was installed in 1961 and scrapped in 2012. Both their paper is more degraded than suggested by furan level, which is 600 and 440 respectively for the two units.

E. Transformers #6 to #16

A utility habitually collects at least one paper sample from each decommissioned transformer, however, does not have a policy on where the paper should be taken from. They supplied a database of results, which was filtered to only contain DP of paper knowingly taken from the top of the winding. These results are given in Table I.

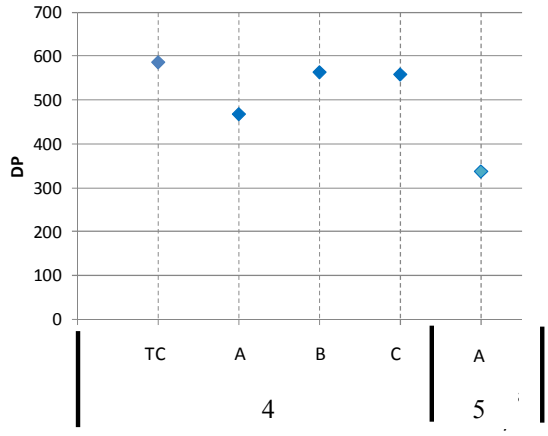

Fig. 4. Degree of polymerisation of paper from different sections of transformers #4 and #5.

V. Analysis

The rates of ageing obtained from using both the DP calculated from furan level, k_{DP-F} , and from the DP measurement on the paper removed from the top of the winding, k_{DP-TW}, are shown in Table I. The ratio of k_{DP-TW} to k_{DP-F} is also given in the table as k_R. For most of these transformers k_R was between 1.4 and 2.7, with an average of 1.9. The precise location of the tested paper was not always known, in reality there are likely to be temperature gradients between LV, HV and tertiary windings, which was not explored in this article.

The 2FAL level clearly did not match the DP expected for the paper from five transformers, numbers 8, 11, 13, 15 and 16 do not agree very well. For the first four transformers the furan concentration is less than expected this may infer that furans were removed from the oil, for instance if the oil has been dried during the life of the transformer [7, 18]. During an online dryout of a transformer furans were removed by the sieves used to extract water. For the fifth transformer the 2FAL level is higher than that expected. One possibility is that this transformer was running at a higher load than normal, which forced more 2FAL into the oil.

There does seem to be general trend that the paper at the top of a winding ages at a rate up to 3 times faster than the rate obtained from furan. However, one 2FAL measurement may not be sufficient for this calculation because in about a third of these cases it did not adequately reflect the condition of the paper. Furthermore, there does not appear to be an effective technique to indicate that there is a problem with the 2FAL level. The utility should therefore make regular, periodic, measurements and track trends.

For the transformer investigated in [7] the furan levels were adjusted after they had been removed by the online dryout system. The furan concentration was measured directly after the oil was processed, and then any increase was added to the original level. However, most of the furans stay absorbed in the paper, rather than dissolving into the oil [18]. It is likely that some of the increase in oil furan concentration would have been caused by furans moving from the paper into the oil.

TABLE I
AGEING RATES OF PAPER

	YOM	Age on Test (years)	2 Furfural (ppm)	Paper DP Determined from (4)	Rate of Ageing $\frac{1}{DP_t} - \frac{1}{DP_0}$ (h^{-1})	Paper DP value	Rate of Ageing	Ratio k_R

VI. CONCLUSIONS

Furan analysis is an effective method to estimate the condition of paper. However, it has several drawbacks such as furans degrade over time, furans exist in partition between the oil and paper where temperature affects this partition, and furans are removed during oil conditioning. A utility should therefore track furan level over time so they can detect these drawbacks. The paper within a transformer ages at different rates, thus one value of DP does not adequately describe the condition of the weakest paper. The remaining life of the overall transformer is dependent on this weakest paper.

In these sixteen analysed power transformers, the insulation paper at the top of the windings clearly degraded at a faster rate than that implied using the furan content of the oil. In most cases the rate of ageing for this paper was no more than twice the rate of ageing determined from furans. This is useful because when determining the life remaining of paper insulation this method can help indicate the condition of the most degraded paper within the transformer.

When a utility samples paper from a decommissioned transformer the location of the paper must be noted, and which layer. The sample should be taken from the top of a winding where the paper is likely to degrade fastest. As per [18], there may be better correlation between DP and furans when the class of transformer is known.

Abstract—**Passing clouds can create unacceptable rapid voltage variations in weak distribution networks with a significant solar PV penetration. This paper investigates the benefit of a PV inverter ramp-rate control strategy using battery energy storage for the mitigation of rapid voltage variations. By controlling the discharging/charging operation of the energy storage appropriately, not only the inverter ramp-rate can be maintained at a desired level, but also the voltage variations can be controlled within acceptable limits. Results, from simulation using a real Australian distribution feeder with real load demand and PV output profile, show that with a high penetration of PV, the voltage variations can increase beyond the allowable limit stipulated by the IEC 61000-2-2 standards. However, with the proposed ramp-rate control, the variation can be maintained well below the limits.**

***Index Terms*—Solar PV, Rapid voltage variation, Ramp-rate control, Energy storage.**

I. Introduction

The impact of the fluctuation of the solar photovoltaic (PV) output due to cloud passing on electric utility operation has been reported in previous literature [1]. Voltage fluctuation caused by steep variations in PV output is particularly significant for low voltage (LV) distribution systems as the LV feeders are normally located far away from the main sub-station and often feature low strength or fault level [2]. Further, the LV distribution feeders with a high R/X ratio are highly vulnerable to the threat of unacceptable rapid voltage variations due to the active power variations of PV inverters. IEC standard 61000-2-2 [3] suggests that a rapid voltage variation over 3% of the nominal value is not acceptable for LV distribution systems. In a weak distribution feeder with a high penetration of PV systems, there is a possibility that this limit will be violated. Rapid voltage changes in distribution networks can cause unacceptable flickers in illumination devices, spurious tripping of relays and sensitive electronic equipment, stalling of induction motors [4], and may also create hunting of voltage regulating devices in the upstream networks [5]. Therefore, a solution for smoothing the sudden variations in PV output is necessary.

Previously reported research works have addressed the PV output smoothing problem using various methods including the use of electric double-layer capacitor [6], battery energy storage [7], or a combination of both [8, 9]. Although moving average control of energy storage was performed in some earlier works e.g. [6, 10] for PV inverter ramp-rate control, the authors of this paper pointed out a drawback of the traditional moving average method to achieve an accurate control of the inverter ramp-rate and to achieve this, the authors proposed a new strategy for ramp-rate control in [11]. While this approach mitigates the effect of the PV output fluctuation, it can also smooth out the rapid variations of voltage by injecting or consuming the appropriate amount of power using the energy storage device integrated with the PV system. The benefit of ramp-rate control in voltage fluctuation mitigation was not clearly identified in [11], as the paper mainly proposed the new approach and investigated its general application as a ramp-rate control algorithm. However, such an approach could have the value added benefit of mitigating the rapid voltage variations in distribution networks, especially in the LV feeders with sensitive installations where the limits of rapid voltage variation should be strictly adhered to.

This paper investigates the rapid voltage variations caused by cloud passing induced PV output fluctuations and explores the potential of the inverter ramp-rate control using energy storage for smoothing out the voltage fluctuations. A real PV output profile is imposed on the PV inverters connected to an Australian LV distribution feeder featuring the characteristics of a weak grid to analyze the true nature of the rapid voltage variations. Finally, energy storage devices integrated with rooftop PV systems are intelligently controlled using the proposed ramp-rate control strategy and its effect on the voltage smoothing, particularly its ability to maintain the allowable rapid variation limit, is assessed. Results presented in this paper are obtained from simulations using steady-state and dynamic analysis.

II. Analysis of Voltage Fluctuations Caused by Cloud Induced Fluctuations in PV Output

A PV system connected to a distribution network, as shown in Fig. 1, is considered for analyzing the voltage variation caused by steep changes in PV inverter output. For the discussions in this section, it is assumed that the energy storage is not yet integrated with the PV system.

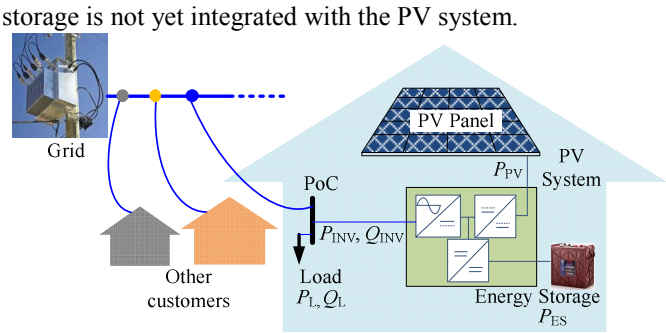

Fig. 1 A PV system connected with the grid.

The change in voltage magnitude ($\Delta|V|$) at the point of connection (PoC) of a PV inverter system is a function of the change in net change of active (ΔP) and reactive power (ΔQ) at the PoC as given in (1).

$$\Delta|V| = \frac{\Delta P\sigma_{Q\delta} - \Delta Q\sigma_{P\delta}}{\sigma_{P|V|}\sigma_{Q\delta} - \sigma_{P\delta}\sigma_{Q|V|}} \quad (1)$$

where, $\sigma_{P\delta}, \sigma_{Q\delta}, \sigma_{P|V|}, \sigma_{Q|V|}$ are the sensitivities of active and reactive power with the magnitude and angle of voltage, respectively, obtained from the Jacobian of the classical Newton-Raphson approach.

For a given equilibrium condition of the network, the variation in PoC voltage will mainly depend of the variation in load demand (ΔP_L, ΔQ_L) and PV inverter output (ΔP_{INV}, ΔQ_{INV}) as given below.

$$\Delta|V| = \frac{(\Delta P_L - \Delta P_{INV})\sigma_{Q\delta} - (\Delta Q_L - \Delta Q_{INV})\sigma_{P\delta}}{\sigma_{P|V|}\sigma_{Q\delta} - \sigma_{P\delta}\sigma_{Q|V|}} \quad (2)$$

As the PV inverters at LV feeders mainly operate at unity power factor and the load demand does not change as abruptly as the change in PV output caused by passing clouds, the rapid change in PoC voltage caused by cloud passing can be attributed mainly to ΔP_{INV} as given below.

$$\Delta|V| = \frac{-\Delta P_{INV}\sigma_{Q\delta}}{\sigma_{P|V|}\sigma_{Q\delta} - \sigma_{P\delta}\sigma_{Q|V|}} \quad (3)$$

To quantify the rapid changes in voltage in a PV integrated network caused by passing clouds, a performance index termed as Rapid Voltage Change Index (RVCI) is defined as given below.

$$\text{RVCI} = \frac{\Delta|V(k)|}{V_{Nom}} = \frac{|V(k)| - |V(k-1)|}{V_{Nom}} \quad (4)$$

where, $\Delta V(k)$ is the voltage change at PoC at any given k-th instant, determined from the change in voltage between two consecutive instants and V_{nom} is the nominal voltage. RVCI will be expressed in percentage to compare with applicable standards; a value of RVCI beyond 3% will result in violation of the IEC standard 61000-2-2 [3].

III. Ramp-rate Control of PV Inverter for Voltage Fluctuation Mitigation

This section develops an approach for smoothing out the sudden changes in PV output by controlling an energy storage unit integrated with the PV system. The smoothing out of the PV output will result in the mitigation of the rapid changes in PV output.

A. The Ramp-rate Control Algorithm

The ramp-rate control of the PV output is essentially the action of limiting the value of ΔP_{INV} in (3) to a desired value. This can be realized by integrating an energy storage device with the PV system, as shown in Fig. 1. The energy storage device will need to be controlled in such a manner that it delivers (discharges) or consumes (charges) an appropriate amount of power, P_{ES} so that ΔP_{INV} can be controlled at a desired value. The necessary change in storage power ΔP_{ES} at a given k-th instant for controlling the ramp-rate of P_{INV} to a desired value ($\Delta P_{INV\text{-}des}$) can be determined using the expression below [11].

$$\Delta P_{ES}(k) = \frac{\Delta P_{INV\text{-}des}(k)}{\eta_{INV}} - \Delta P_{PV}(k) \quad (5)$$

where, η_{INV} is the inverter efficiency. This change in P_{ES} will, in effect, contribute to mitigate the sudden voltage fluctuation at the k-th instant as evidenced in (6).

$$\Delta|V(k)| = \frac{-[\Delta P_{PV}(k) \pm \Delta P_{ES}(k)] \times \sigma_{Q\delta}}{\sigma_{P|V|}\sigma_{Q\delta} - \sigma_{P\delta}\sigma_{Q|V|}} \quad (6)$$

The ± sign in (6) indicates that either charging or discharging operation of the storage device needs to be performed for voltage fluctuation mitigation. If PV output is suddenly reduced due to cloud shadow, the storage device will discharge ΔP_{ES} amount of power which will be added to the PV power for minimizing a sharp decrease in voltage. If the PV output increases suddenly due to the removal of cloud shadow, then the storage device will charge the storage device with ΔP_{ES} amount of power which will be subtracted from the PV output to mitigate a sharp increase in voltage. The ramp-rate control algorithm given in (4) is illustrated in Fig. 2 using a fictitious PV output P_{PV} continuing for 4 consecutive time instants from (k-1)th to (k+2)th.

During the first time instant denoted by (k-1)th, P_{INV} is equal to P_{PV} (assuming η_{INV} is 100% for simplicity of the description). At the k-th instant, P_{PV} decreases sharply due to cloud shadow by such an amount that exceeds the desired ramp-rate, $\Delta P_{INV\text{-}des}$. To control the ramp-rate at the desired value, the storage power P_{ES} is changed by $+\Delta P_{ES}(k)$, determined using (5). At the (k+1)-th instant, P_{PV} increases sharply as the cloud passing period ends. To limit the change of P_{INV} at the desired value, P_{ES} is changed by $-\Delta P_{ES}(k+1)$, determined using (4). At the (k+2)-th instant, P_{PV} does not change; however, P_{ES} is changed by $\Delta P_{ES}(k+2)$ to increase P_{INV} for attaining the level of $P_{PV}(k+2)$. This change is performed in such a way that the ramp-rate of P_{INV} does not exceed $\Delta P_{INV\text{-}des}$. This brings an important consideration for developing a ramp-rate control strategy. The value of $\Delta P_{INV\text{-}des}$ during the in-ramp and post ramp events of a fluctuation needs to be selected in such a way that controlling of PES itself do not create any fluctuation. Interested readers are referred to [11] where a detailed methodology for the selection of appropriate values of $\Delta P_{INV\text{-}des}$ for PV inverter ramp-rate control has been proposed.

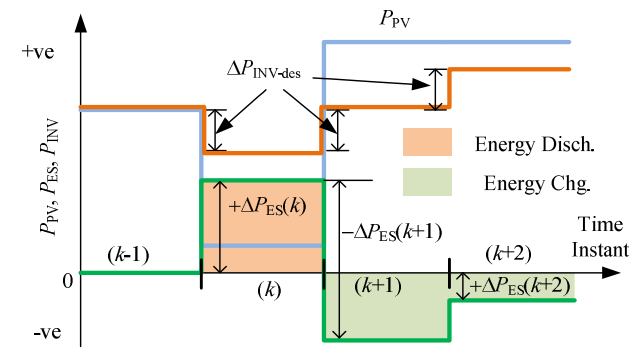

Fig. 2 An illustration of the ramp-rate control algorithm.

B. Control Flowchart

A flowchart of the ramp-rate control approach is given in Fig. 3. The PV panel output PPV is continuously monitored to detect any step change higher than the $\Delta P_{INV\text{-}des}$ for the given instant. If such a step change is detected, the controller determines the appropriate $\Delta P_{INV\text{-}des}$ depending on the event and then the required change in P_{ES} is obtained using (5).If the determined value of P_{ES} at the given k-th instant is positive, then SoC is checked to determine if it is higher than SoC_{min}. If "Yes", then discharge operation is performed; if "No", then the controller transits to the next time instant. On the other

hand, if P_{ES} is negative, the SoC is checked to determine if it is lower than SoC_{max}. Charging operation is performed if the result of the SoC status-check is "Yes", or transition to the next instant is initiated if the result is "No".

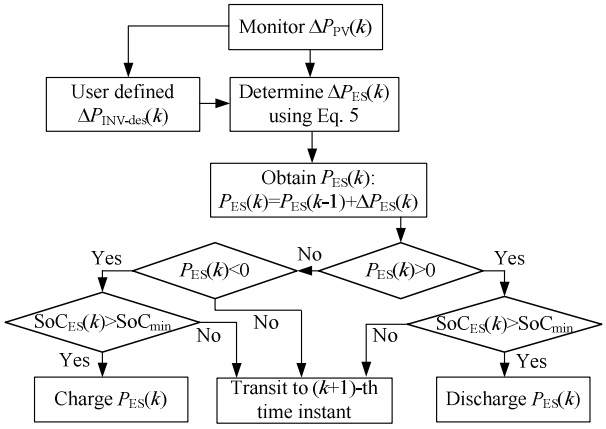

Fig. 3 Ramp-rate control flowchart.

C. Dynamic Model of the PV-Storage System

Power electronic systems and battery energy storage devices have time lags as any other physical devices. The smoothing operation of the ramp-rate control algorithm will be influenced by the associated time delays and controller characteristics. A dynamic model of the PV-storage integrated system is therefore necessary for investigating the transient response of voltage as a result of performing the ramp-rate control of the PV inverter. A dynamic model incorporating the time delays associated with the PV inverter and the energy storage device is developed for this purpose, as shown in Fig. 4 [11]. Details of the dynamic model including the state-equations and the method used for tuning the PI controller can be found in [11].

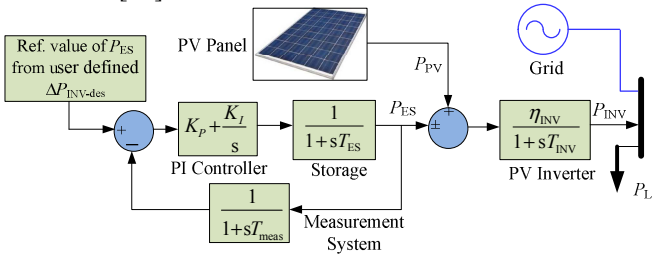

Fig. 4 A dynamic model of the PV-storage integrated system.

IV. Example of Voltage Fluctuation Mitigation in a Real Distribution Network

The benefit of PV inverter ramp-rate control in mitigating voltage fluctuation is investigated in this section using an Australian LV distribution feeder shown in Fig. 5. This LV feeder characterizes the features of a weak radial system located far from the main substation, as typically observed in rural Australian regions.

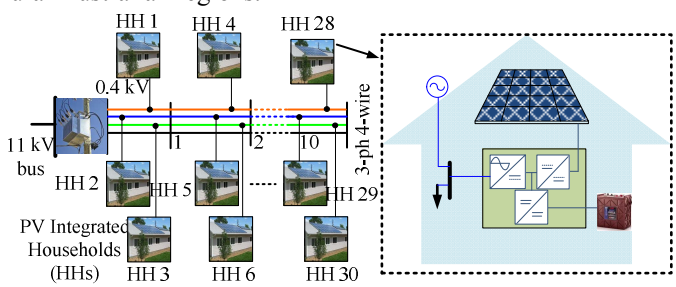

Fig. 5 Test distribution feeder.

All the households connected to the feeder are assumed to have rooftop PV systems with integrated battery storage devices. Valve Regulated Lead Acid batteries rated at 12 kWh is used for the investigations in this paper; SoC_{min} and SoC_{max} values are set to 40% and 100% respectively. The modelling of the storage devices incorporate the non-linear voltage versus SoC characteristics and the effect of internal resistance, as described in [12].

The results shown in this paper correspond to the household no. 28 (HH 28) connected to phase *a,* bus 10 of the feeder. The load demand profile is derived from the data captured by an Australian distribution utility and the PV output data correspond to the irradiance profile of 20th of March, 2010, captured by National Renewable Energy Laboratory's irradiance monitoring facility in the Oahu Island, Hawaii [13]. The normalized values of the PV output profile (P_{PV}) logged in 1-second resolution is shown in Fig. 6(a) that indicates severe power fluctuations occurred between 09:00 hours to 14:00 hours. The ramp-rate of PPV during this interval is shown in Fig. 6(b) where the highest negative ramp-rate caused by passing cloud is found to be -30%/second. A 5-minute interval around the highest negative ramp-rate event is considered for analyzing the effect of the ramp-rate control on voltage fluctuation.

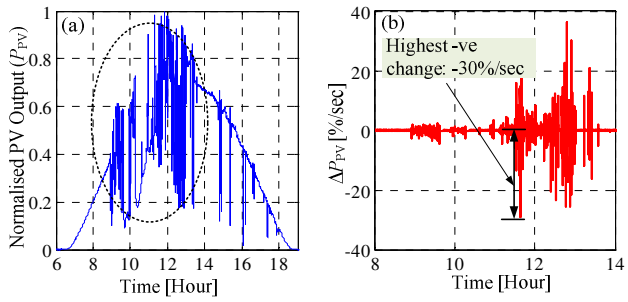

Fig. 6 Fluctuations in a real PV output profile. (a) Normalized P_{PV}. (b) Ramp-rate of PV output.

For illustration, the desired ramp-rate of the PV inverter ($\Delta P_{INV\text{-}des}$) is controlled at two values: 50 W/sec and 10 W/sec. The effects of the ramp-rate control are observable from Fig. 7. The P_{INV} profiles with and without ramp-rate control is shown in Fig. 7(a). Smoothing of the PV output fluctuation is clearly visible in Fig. 7(a), where the degree of smoothness increases with the decrease of the set value of $\Delta P_{INV\text{-}des}$ (from 50 W/sec to 10 W/sec).

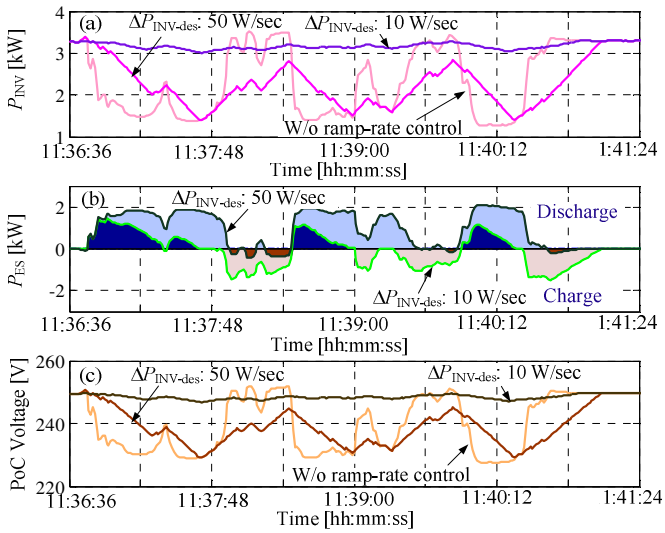

Fig. 7 Effect of the ramp-rate control on PV inverter output and PoC voltage. (a) Inverter power P_{INV}. (b) Storage power P_{ES}. (c) PoC voltage.

The storage power (P_{ES}) profiles that provide this smoothing effect are shown in Fig. 7(b) where the discharging

(+ve P_{ES}) and charging (-ve P_{ES}) operations required for ramp-rate control are identified. Finally, the mitigation of voltage fluctuation is shown in Fig. 7(c). Without the ramp-rate control, the voltage follows the similar trend of fluctuations as the PV output, and likewise, the voltage profile is smoothened with the application of the ramp-rate control.

As this paper focuses on the benefit of PV inverter ramp-rate control on voltage fluctuation mitigation, further investigations are performed on the results in Fig. 7(c). The rapid changes in the voltage profiles in Fig. 7(c) are plotted in Fig. 8(a) in terms of RCVI defined in (4). It is observed that without any ramp-rate control, RCVI can exceed the allowable limit of 3%. With the ramp-rate control, the value of RCVI is significantly reduced. A closer view of the highest negative ramp-rate event is provided in Fig. 8(b) where the decrease of RCVI from -4.7% to -0.2 % (for 50 W/sec) and to -0.05% (for 10 W/sec) is shown.

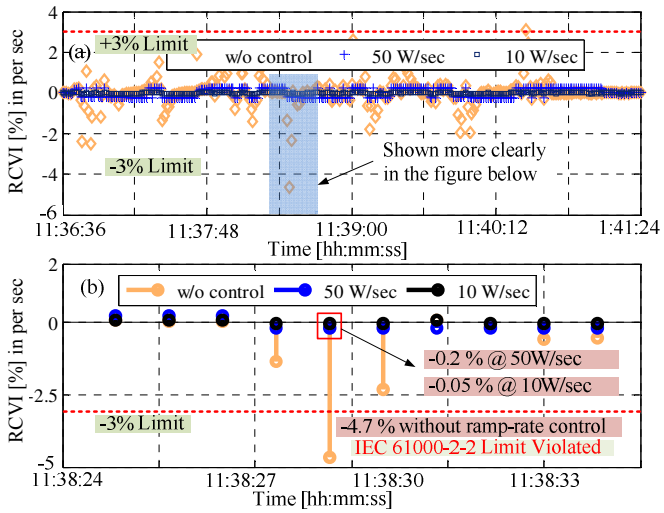

Fig. 8 Quantification of rapid voltage change with and without ramp-rate control. (a) RCVI over 5-min interval. (b) RCVI at the highest negative ramp-rate.

The dynamic performance of the ramp-rate control strategy in voltage fluctuation mitigation is investigated in Fig. 9. A 500 millisecond snapshot around the highest negative ramp-rate event of the PV output profile is used for this investigation. The dynamic model parameters (corresponding to Fig. 4) are given in Fig. 9(a).

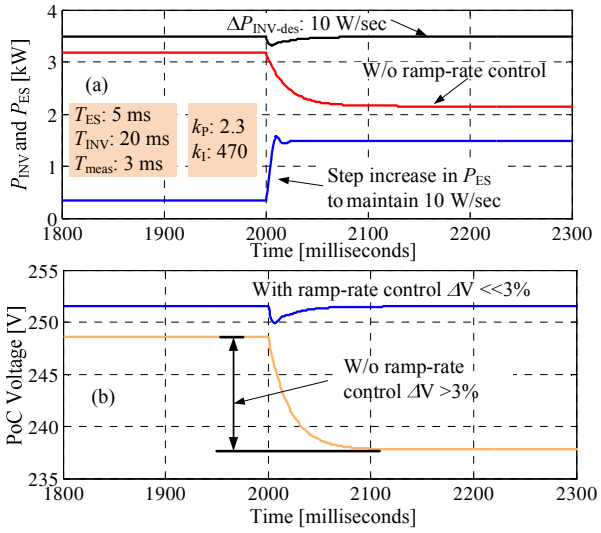

Fig. 9 Dynamic performance of the ramp-rate control. (a) Transient response of P_{INV} and P_{ES}. (b) Transient response of PoC voltage.

The transient response of P_{INV} with and without the ramp-rate control is shown in Fig. 9(a) that shows how P_{INV} maintains the desired value with the appropriate amount of power discharged by the battery storage. The transient response of P_{ES} resulting from the step change command by the storage controller is also observable in Fig. 9(a). The transient response of the PoC voltage a given in Fig. 9(b) that shows how the rapid voltage change is minimized with the help of the ramp-rate control of the storage device.

V. Conclusions

This paper has investigated the added benefit of the PV inverter ramp-rate control using an integrated battery energy storage system for the mitigation of unacceptable rapid voltage variations in distribution networks due to passing clouds. The amount of power delivered or stored by the energy storage device is appropriately controlled at each instant of time to maintain the inverter ramp-rate at a desired level. This results in mitigating the steep voltage variations at the inverter connection point. An analysis performed on a typical weak distribution feeder in Australia using captured PV outputs and measured load demands revealed that, without any support, the voltage variation can increase beyond the international standard limit. However, with a proper ramp-rate control, the variation can be maintained well below the limits.

Abstract—**More than one in five homes in South Australia have a rooftop solar photovoltaic (PV) system and this number is expected to continually increase in the future. This paper investigates the possibility of storing the solar power generated during daytime and strategically releasing it during peak period to relieve stress on the national power grid. A small scale experimental setup with a battery storage is designed and developed for this purpose. The experimental results found are systematically described. The peak demand problem for South Australia power network and the challenges of reshaping the load curve through storing and releasing solar power are also discussed.**

***Index Terms*-Energy storage, load management, reshaping load curve, solar PV systems.**

I. Introduction

Adverse effects of greenhouse gases on environment have motivated the world towards reducing the use fossil fuels and increasing the utilization of renewable energy sources. Solar and wind are the fastest growing renewable energy technologies in the world. Both solar and wind are emission free renewable energy sources and are abundant in many parts of the world.

In South Australia (SA), the weather conditions are favourable for solar photovoltaic (PV) systems. With generous government subsidy, the installed capacity of rooftop solar PV systems onto residential houses in SA has increased exponentially over the past few years as can be seen in Fig. 1 [1, 2]. The total installed capacity of rooftop PV panels in SA reached 400 MW (as June 2013) and that contributes about 3.7% of the state's electrical energy demand [1]. It is expected that the capacity of rooftop PV system may exceed 1000 MW by 2023 [1].

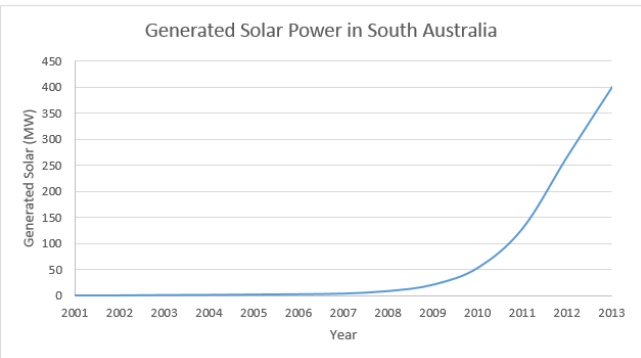

Fig. 1. Installed rooftop PV capacity in SA from 2001-2013.

The ratio of peak demand to average demand in SA is relatively high and this requires significant generation capacity and transmission/distribution facilities to meet the peak demand. However, with existing solar PV systems, an opportunity exists to reduce the peak demand by storing solar energy during daytime and strategically releasing the energy during peak period which usually occurs in early evening.

There are various forms of energy storage such as batteries, fly-wheels, super capacitors, compressed air, pumped hydro, etc. However, with present technologies, battery energy storage is possibly the most effective and efficient for small scale applications. Lead-acid batteries are commonly used in off-grid energy storage with solar PV systems and are also used in this study.

Numerous studies have been conducted on energy storage system. Giraud and Salameh [3] considered a 44-kWh of battery storage for a 2.5-kW solar PV and a 1.5-kW wind turbine system to power a grid-connected residential load during peak demand period. It is suggested that a hybrid system consisting of solar PV and wind generators is more reliable than a purely solar or wind system. Tina and Pappalardo [4] used a 200-Ah, 48-V battery storage system for a 2-kW solar PV system to power a grid-connected residential load. It is claimed that the system can control the amount of energy drawn from or injected into the grid and that allows the plant owner to save electricity cost by exploiting the time of use tariff. In addition, the system can assists to reduce system demand during peak periods. Siddique et al. [5] studied a rooftop hybrid system that stores solar and wind energy to use during peak period. It is encouraged to install solar and wind hybrid system to minimize the problems associated with peak demand. The system implemented was a 440-W solar PV system and 2x400-W wind turbines combined with 2x360-Ah, 12-V battery storage system. The above three systems have the capability of discharging the storage energy during peak demand period.

This paper analyses the peak demand problem of South Australia region and discusses the opportunity of exploiting the state's existing rooftop solar PV systems to reduce the peak demand. An experimental setup is build-up for this purpose and the results found are carefully analysed and discussed. The cost benefit analysis of the experimental setup is also outlined.

II. Minimizing Peak Demand

In an ideal electrical power system, the demand should remain more or less constant for better utilization of system assets. However, the electricity demand for most of the systems or regions is not constant but varies widely. In general, a system has low demand in the early morning hours and peak demand in the early evening hours. In order to cater the peak demand, the system should have adequate generation

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

capacity as well as transmission and distribution facilities and that contribute significantly to overall cost of electricity.

In SA, the peak demand usually occurs around 7pm, when most household appliances are in use. The peak demand occurs after sunset, when the solar panels cannot generate electricity. Thus, the entire demand is transferred to the traditional power plants of the national grid. Fig. 2 shows the average demand in 2008 (blue) and 2012 (red) in SA. The data of the figure is obtained from Australian Energy Market Operator (AEMO) website [6]. It can be noticed in the figure that during the day hours (8am to 6pm), the demand in 2012 is significantly lower than that in 2008. This is due to sudden start of installing rooftop solar PV systems at the beginning of 2008 and increasing exponentially each year (see Fig. 1) due to attractive financial incentive in the form feed-in tariffs and rebates [1]. Since the amount of installed solar PV system in 2008 was negligible compared to 2012 (as can be seen in Fig. 1), the area between the two curves (2008 and 2012) can be considered as the average daily energy supplied by solar PV systems in 2012 and was calculated as 1239 MWh. Note that load growth in SA between 2008 and 2012 was not significant.

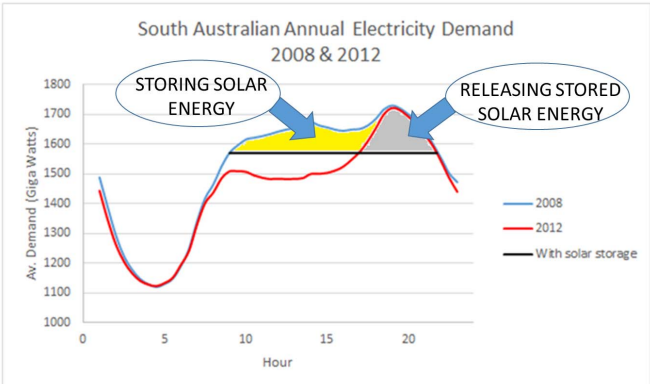

Fig. 2 Electricity demand in SA for years 2008 and 2012.

The objective of this study is to store some of the energy generated by solar PV systems during the daytime and strategically releasing it during the peak period to reduce the system stress and consequently flattening the peak demand. A simple calculation indicated that the state requires about 800 MWh of battery storage (represented by yellow area in Fig. 2) to flatten the peak demand. In practice, once the batteries are fully charged during the day, the PV systems can either supply power to the homes or feed into the grid, depending on the owner's preference and the configuration of the control circuitry. There are potential benefits for both the PV system owners and the power utilities.

The PV system owners would be benefited most if the anticipated smart metering system is introduced. The owners can manage their energy consumption and exploit the benefit of time-of-use tariff. In general, the cost of electricity is high during peak period. With sufficient PV energy storage systems, the owners may not need to pay such a high price and thus the system may eventually payoff itself or even save money. In addition, taking up of solar energy storage systems by a large number of customers would reduce the peak demand significantly and thus the utilities may not require the same level of generation capacity and transmission/ distribution facilities. This potentially means that the costs of electricity for the consumers may decrease or at least will not continue to increase at the same rate as in the recent years.

The main challenge for a solar PV energy storage is to develop a system that is cost effective with a relatively short payback period. The PV panels are becoming more cost effective each year as manufacturing techniques improve both the quality and efficiency of the panels. Energy storage is an emerging technology and does not yet have the same competitive price as the solar PV panels. However, with increased research and development programs in energy storages, it is anticipated that the energy storage system would follow a similar economic trend as the solar PV panels have seen. In fact, industry professionals are predicting that solar storage will be the new solar boom [7].

III. Experimental Setup and Results

In this study, a small-scale rooftop solar PV storage system is designed and developed to efficiently store solar energy during the daylight hours and release the energy during the peak hours. Fig. 3 shows a schematic diagram of the system with main components such as PV panel, battery storage, maximum power point tracker (MPPT), inverter, loads, and measuring instruments. A photograph of a part of the system is shown in Fig. 4.

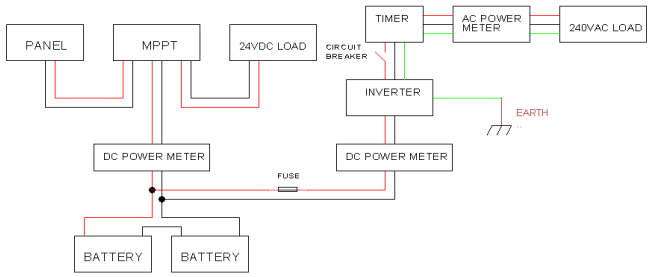

Fig. 3. Schematic diagram of the experimental setup.

Fig. 4. A photograph of the exerimental setup (excluding the PV panel).

One Karra-250 solar PV panel was used in the experimental setup. The panel has a rated output power of 250-W under standard test condition (STC) of irradiance 1000 W/m^2, solar spectrum of AM 1.5, and module temperature of 25°C. The panel was installed facing towards North at an optimal tilt angle of 30° for the site (Adelaide, South Australia, 34°55' 44.4'S 138°36'3.6'E) during experimental period. At the rated power, the output voltage and current of the panel are specified as 30.89 V and 8.10 A, respectively.

The solar irradiance of Adelaide, South Australia was downloaded from Bureau of Meteorology website [8]. The monthly average solar exposure of Adelaide is shown in Fig. 5 and it indicates that the average daily solar exposure in 2012 was 17.9 MJ/m^2 which corresponds to 4.97 kWh/m^2. That is the average peak sun hour (PSH) of the site is 4.97 hours/day.

The average daily energy yield for the panel (E_{PV}) can be obtained as

$$E_{PV} = P_{STC} \times \eta_m \times \eta_{dirt} \times H_{PSH} \quad (1)$$

Here P_{STC} is the PV panel output power under STC, η_m is the manufacture's specified output efficiency, η_{dirt} is the efficiency factor for dirt/dust on panel, and H_{PSH} is the average peak sun hour. For $\eta_m = \eta_{dirt} = 0.95$, the daily average output energy of the 250-W panel is found as 1.12 kWh/day. The temperature de-rating factor is not considered as it is assumed that the average annual day temperature of the site is around the standard test temperature of 25^0C.

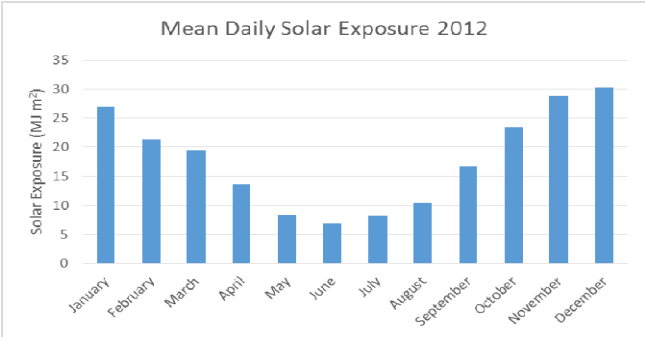

Fig. 5. The average daily solar exposure in 2012.

The efficiency of the panel (η_{PV}) can be defined as

$$\eta_{PV} = \frac{E_{PV}}{1000 A_{PV} H_{PSH}} \times 100\% \qquad (2)$$

Here A_{PV} is the area of the PV panel in m^2. The manufacturer's specified area of the panel is $1.73m^2$ and that provides an efficiency of the panel as 13.03%.

The size of the battery depends on the average daily energy generated by the PV panel and depth of discharge (DoD) of the battery. The DoD is directly related to lifespan of the battery. In this study, the battery size is determined based on 80% DoD (shorter lifespan and smaller capacity) as well as 50% DoD (longer lifespan and larger capacity). For a 24-V system, the minimum battery size of the system is found as 58.33 Ah for 80% DoD and 93.33 Ah for 50% DoD.

In this study, two 12-V, 38-Ah gel cell deep-cycle lead acid batteries are used. The batteries are connected in series to configure as 24-V to make compatible with the solar PV panel and the battery charger. Due to budget limitations, lower battery capacity was used compared to the calculated values of 58.33 Ah for 80% DoD, and 93.33 Ah for 50% DoD. The battery bank is housed in a wooden box and is sheltered from weather with appropriate ventilation. Since the charging voltage changes with temperature, the batteries have a temperature sensor attached so that the MPPT charger can continuously adjust the charge voltage according to the battery temperature to increase the battery life.

A microprocessor controlled MPPT battery charger with a current rating of 30 A is used. The charger is suitable for both 12V dc and 24V dc systems. The battery charge level determines the charging procedure is to be followed. The various charging procedures are bulk charging, absorption charging, and float charging which are performed automatically. The MPPT battery charger also has a deep discharge protection feature which protects the batteries and assists to increase the battery lifetime.

To convert the dc stored energy into ac energy (at 240 V), a modified sine wave inverter is used. The inverter is rated at 400-W for continuous load and 1200-W for surge load. The inverter has protection circuits such as a battery low voltage alarm and a thermal shut down with an alarm.

A total 400-W, 240-V incandescent light globes were used as the base load for this study. The load was limited by the inverter rating. Different loads such as fluorescent lights, water pump and water filter were also used to investigate the discharge times.

The system was monitored by a number of meters. DC meters were used in conjunction with a data logger to record the necessary data such as power, voltage, and current over time on the dc side. A 240 V ac meter was also used to monitor the quantities on the ac side of the system.

The experimental setup successfully stored the solar energy during the daytime hours and released it during the peak hours. With the measured data at various points, the efficiency of the battery storage and the dc/ac inverter was found as 79.69% and 90.11%, respectively. For a sunny day the system provided more than 725 Wh of energy, and for an overcast day the system provided less than 490 Wh of energy.

The inbuilt low voltage cut-off function in the dc/ac inverter is designed to protect the batteries against deep discharging (more than 44%). However, to further discharge the batteries, a 24V dc load was directly connected to the batteries, which in a real application could represent a 24V dc lighting circuit or something similar.

The undersized capacity of the deep-cycle batteries meant that the batteries would be fully charged before the end of the day's sunlight. To overcome this issue and get the maximum benefit, different operating modes of the system were considered which are discussed in the following.

Fig. 6 shows the power output from the MPPT battery charger during the daylight hours for a sunny day. Since the battery capacity is undersized, the batteries are fully charged by middle of the day and after that the MPPT battery charger is not extracting the maximum power from the panel. It is simply extracting enough power to float charge the batteries. Fig. 7 shows the power output form the MPPT battery charger during the daylight hours for a sunny day when the battery is allowed to discharge during the day. Unlike Fig. 6, the MPPT continues to extract the maximum power from the solar PV panel for the entire daylight hours as the batteries are fully charged only at the end of the day.

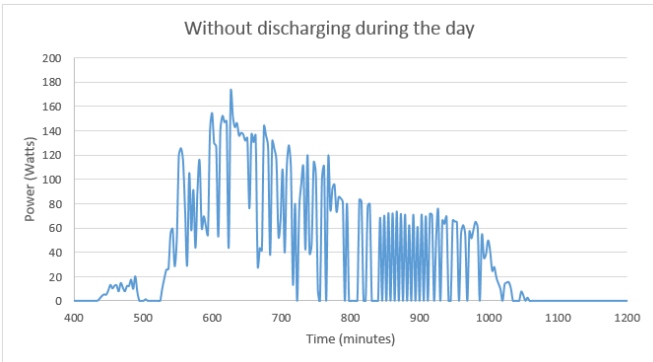

Fig. 6. Output power of MPPT without discharging the batteries.

To overcome the undersized battery issue, three operating modes of the system are defined. (a) For a low solar radiance day, the system can operate as charging the batteries during the daylight hours and discharging it during the peak hours, (b) For a high solar radiance day, the system can operate as both charging and discharging modes during the daylight hours and ensuring that there is enough stored energy to discharge during the peak hours, (c) For a high solar radiance day, the

system can operate as charging the batteries and powering a 24-V dc load during the daylight hours, and discharging the batteries during the peak hours.

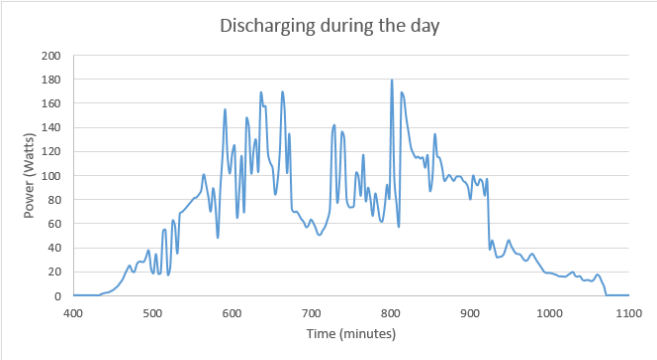

Fig. 7. Output power of MPPT when discharging the batteries.

IV. Cost Benefit Analysis

The experimental setup was a part of an undergraduate final year project and was designed as a small scale because of budget limitations. The system can deliver a power of 270 W during the peak demand for a period of 108 minutes (or 1.8 hours). With an electricity price of 30c/kWh, the system can save 14.6c/day. The cost of the components (excluding metering equipment) was A$865 and that translates to a simple payback period of 16.23 years which is longer than the life expectancy of the batteries. However, it is expected that the return would be better for a typical installation of about 3-kW size PV system. The indirect benefit of battery storage system is the reduction of system peak demand and hence utility installed capacity including transmission and distribution facilities.

The average Australian home consumes about 10-15 kWh of energy per day and the average South Australian 3-kW solar PV system produces about 12.6 kWh of energy per day [9]. Table-I summarizes the energy consumption of a typical Australian household during peak period (5pm to 8pm) [9].

TABLE 1
Typical Australian household load during peak period

Appliance	Power (W)	Hr. usage during peak (hrs)	Energy used during peak (Wh)
Kitchen Appliances			
Refrigerator/freezer	300	1.5	450
Oven	750	0.5	375
Stove	2000	0.5	1000
Microwave	1200	0.25	300
General Household			
Light – CFL (7 @ 12W)	84	3	252
LCD television	200	3	600
Laptop computer	30	2	60
Assorted electronics(10 @ 3 W)	30	3	90
Cloths washer	250	0.75	187.5
Air conditioning (2kW split)	2000	1.5	3000
Miscellaneous (10% of load)	---	---	631
	Total		6945.5

Considering the inverter efficiency of 85% and the deep-cycle lead acid battery efficiency of 80%, the minimum size of the energy storage system (ESS_{min}) required to deliver the energy during peak period can be calculated as

$$ESS_{\min} = \frac{E_{peak}}{\eta_{inv} \times \eta_{batt} \times DoD} \qquad (3)$$

Here E_{peak} is the energy consumption during peak period, η_{inv} is the inverter efficiency, η_{batt} is the battery efficiency, and DoD is depth-of-discharge of the battery. Using (3), the minimum energy storage system EES_{min} per household is found as 12.77 kWh. For a 24-V battery system, the size of the battery required is 532 Ah.

A typical 3-kW fully installed rooftop solar PV system with a 25 year warranty costs about A$4,500. A 15-kWh battery bank costs about A$6,000 (at a rate of A$400/kWh). Assuming the installation cost of the battery storage system to integrate it with the rooftop solar PV system is A$1,500, thus the total cost for the rooftop solar PV storage system becomes A$10,000. The average daily energy production of a 3-kW system in SA is 12.6 kWh and with the battery storage efficiency of 80%, the system can deliver 10.08 kWh of energy. With the current electricity price of abut 30c/kWh, the simple pay-back period of the system is 9.06 years. This is around the expected life time of the battery bank and presently does not seem to be overly cost effective. However, as solar storage technology develops, the above prices will come down and the payback period will become increasingly more attractive to perspective buyers.

V. Conclusions

More than 20% of Australian homes have rooftop solar PV systems. This paper investigates the possibility of storing solar PV energy during daytime and strategically releasing it during peak period to reduce system stress during peak demand. A small scale experimental set has been built as a final year project to demonstrate some of the experimental results. With declining trend of the cost of battery energy storage, the system may become more attractive in future. The addition benefit of the system is the reduction of peak demand and consequently reduction of system generation capacity as well as transmission and distribution facilities.

Abstract— **Charge controller is the heart of a Solar Home System (SHS) which controls the charging and discharging of battery from photovoltaic (PV) module. This paper analyzes test results of fifteen charge controllers available in Bangladesh according to the specification of Infrastructure Development Company Limited (IDCOL). The different parameters are battery high voltage disconnect (HVD), low voltage disconnect (LVD)/ reconnect, short circuit protection etc. It is found that eight charge controllers meet the technical specifications of IDCOL. There is also a study of different features of the charge controllers. Finally a brief discussion on further improvement of charge controller is presented.**

Index Terms— **Solar Photovoltaic, Solar home system, Charge controllers, Testing, IDCOL.**

I. Introduction

A solar charge controller is needed in virtually all solar PV systems that utilize batteries. The job of the solar charge controller is to regulate the power going from the solar panels to the batteries. The most basic function of a charge controller is to prevent battery overcharging. If battery is allowed to routinely overcharge, their life expectancy will be dramatically reduced [1]. A charge controller will sense the battery voltage, and reduce or stop the charging current when the voltage gets high enough. This is especially important with sealed lead acid battery where we cannot replace the water that is lost during overcharging [2]. There are some other functions that a charge controller performs such that preventing battery over-discharge, protecting from electrical overload, and maximum power tracking etc.

To fulfil the basic electricity requirement in the rural areas of Bangladesh, IDCOL has introduced solar program. With support from International Development Association (IDA) and Global Environment Facility (GEF), IDCOL provides both grant and refinancing to solar energy projects in rural areas. IDCOL provides grants to lower costs of solar home system (SHS) and also offers soft loans to the partner organizations. To coordinate the program, Technical Standard Committee (TSC) has been formed with members from Bangladesh University of Engineering and Technology (BUET), Rural Electrification Board (REB), Local Government Engineering Department (LGED) and IDCOL. TSC determine the technical standards for the equipments such as solar panel; charge controller, battery etc. of solar home system. The equipment that is not approved by TSC is ineligible for IDCOL grants and refinance. In local market all available charge controller are not approved by IDCOL. Collected charge controllers are tested according to the standards given by IDCOL.

II. Charge Controller Tests And Analysis

For a solar system, the controller must comply with the technical standards provided by TSC of IDCOL in Bangladesh. The sample charge controllers are taken from Partner Organizations (PO) of IDCOL. Some foreign manufactured charge controllers are also collected for testing purpose. Performances of these sample charge controllers are measured to inspect the conformity to the specifications provided by the IDCOL [3]. Low voltage disconnect /reconnect(LVD), Battery high voltage disconnect, current handling capacity, self current consumption, short circuit protection, over current protection etc. were measured.

A. Low Voltage Disconnect (LVD)

If deep discharge occurs, it will cause some battery damage. Every time this happens, both the capacity and the life of the battery will be reduced by a small amount. If the battery sits in this over discharged state for days or weeks at a time, it can be ruined quickly. So, LVD is necessary to protect the battery.

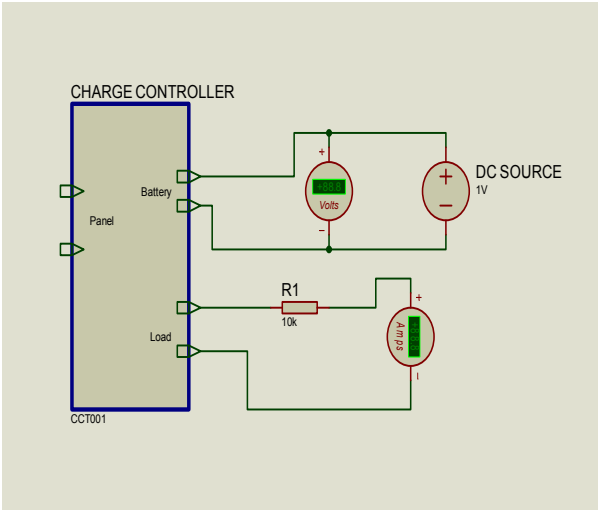

Fig. 1 Circuit connection for LVD disconnect/reconnect test

For measurement of LVD disconnect/reconnect voltage circuit was connected as Figure 1.

1) *Disconnect Voltage*: When the state of charge of battery is reduced below the specified level then charge controller disconnects load from battery. Test result of different samples is shown graphically in Figure 2.

According to the IDCOL standard, LVD disconnect voltage is 11.6±0.1 V. So the sample no.04, sample no.09 and sample no.12 did not comply with the specification.

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

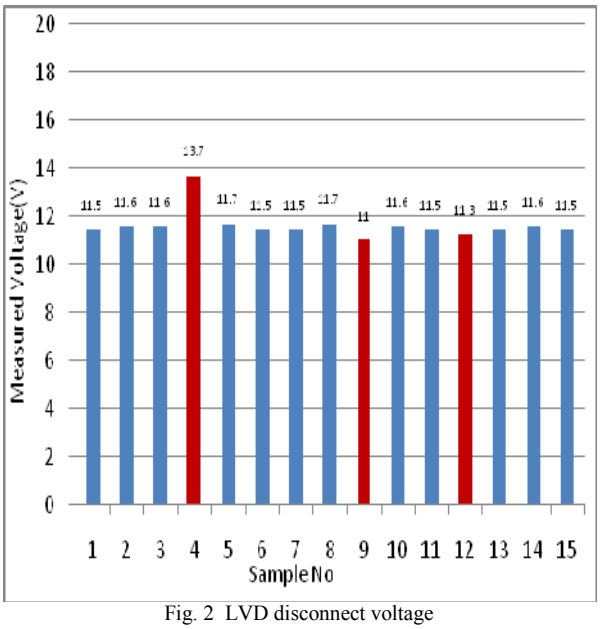

Fig. 2 LVD disconnect voltage

2) *Reconnect Voltage*: When battery voltage rises up to a specified level then charge controller automatically reconnect the load with battery. Reconnect voltage for different samples is shown in Figure 3.

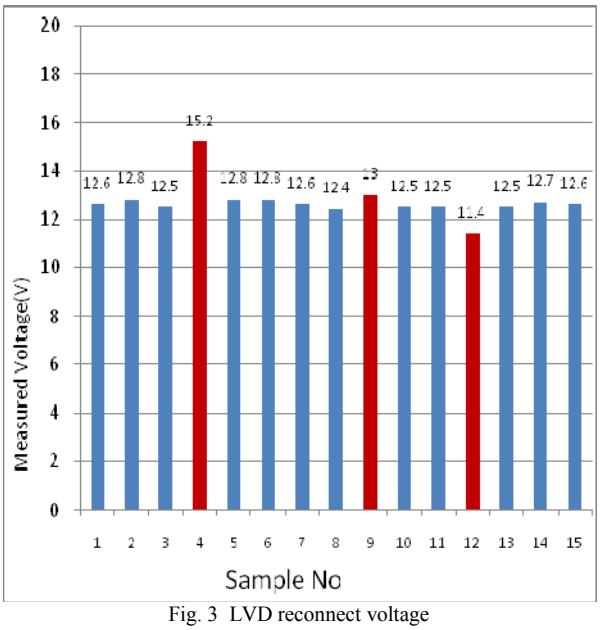

Fig. 3 LVD reconnect voltage

According to IDCOL standard, LVD reconnect voltage is 12.6±0.2 V. So the sample no.04, sample no.09 and sample no.12 did not comply the specification.

B. High Voltage Disconnect (HVD)

When a battery reaches full charge, it can no longer store incoming energy. If energy continues to be applied at the full rate, the battery voltage gets too high. There is excessive loss of water, and a chance that the gasses can ignite and cause a small explosion. The battery will also degrade rapidly and may possibly overheat. Preventing overcharge is simply a matter of reducing the flow of energy to the battery. That is why at a specified battery voltage the battery is disconnected from solar panel to stop current flow for charging.

The circuit was connected as Figure 4. The DC source voltage was higher than the battery and supplying sufficient current. When the current reading of Ammeter was 0Amp, reading of the Voltmeter was taken.

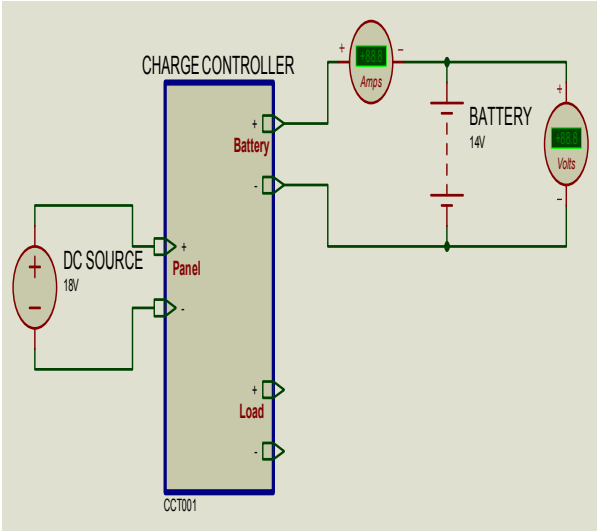

Fig. 4 Circuit connection for HVD test

Measured battery high voltage disconnect voltages are shown in Figure 5.

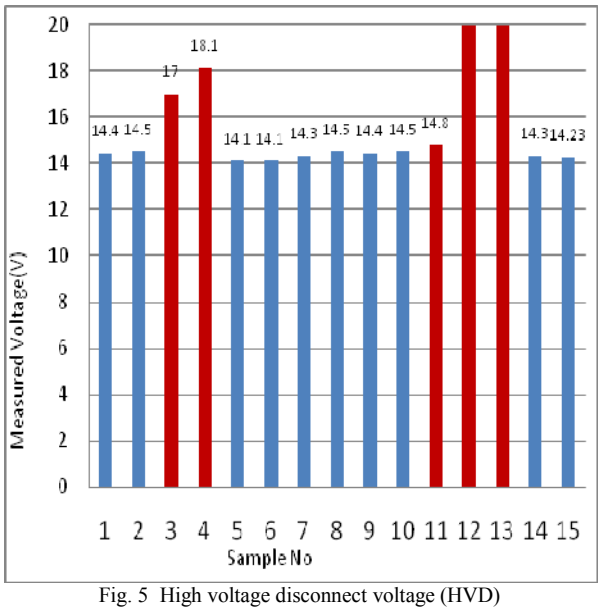

Fig. 5 High voltage disconnect voltage (HVD)

According to the IDCOL specification, HVD is 14.3±0.2 V. From graphical representation it is seen that sample no.03, sample no.04, sample no.11, sample no.12 and sample no.13 didn't comply this. Although sample no.03, sample no.04 and sample no.11 did not comply with the specification they have high voltage disconnect. But sample no.12 and sample no.13 did not have HVD feature.

C. LVD Maximum Current Handling Capability

According to IDCOL standard, The LVD must be capable of handling at least 150 percent of the maximum expected continuous load. From the analysis it has been found that 150 percent of maximum expected continuous load was attained at a slightly higher voltage than LVD voltage for all the sample charge controllers. This complies with the standard given by TSC.

Circuit was connected as Figure 6. Keeping the DC source voltage at 11.7 V the Pot1, Pot2 and the Current knob of DC

source were varied until the Ammeter reading became 150% of the maximum expected load. Then the charge controller was observed whether it was capable of carrying this load.

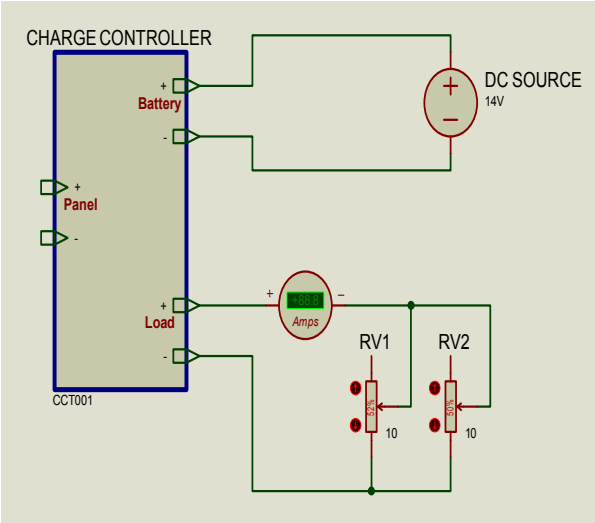

Fig. 6 Circuit connection for measuring current flow

All samples complied with IDCOL standard.

D. Over Current Protection

There must be a protection against excessive current flows through the load to protect it from damage. If not, then the circuit of charge controller will be damaged.

Resistances of both the potentiometer of Figure 6 were decreased so that total Resistance became very low. An Ammeter reading was taken at the moment of Load Out.

Testing results are shown in Figure 7.

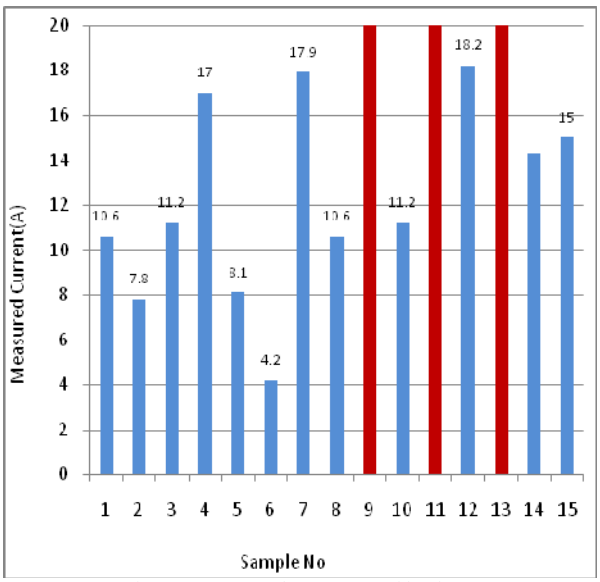

Fig. 7 Current at the moment of load out

As current rating for different charge is different, scale is not unique. From graphical representation it was seen that sample no.09, sample no.11 and sample no.13 did not have over current protection.

E. Current Handling Capability

According to IDCOL standard charge controller must handle 120% of rated current for 1 hour without any damage.

Circuit was connected as Figure 6. Keeping the DC source voltage at 14 V, Pot1, Pot2 and the Current knob of DC source were varied so that the Ammeter reading became 12A. Observation was made for 1 hour.

Over current protection for sample no.02, sample no.03 and sample no.04 were below the 120% of rated current. So they didn't comply with this standard but they have set points at different value.

F. Self Current Consumption

Every electrical device having MOSFET, BJT requires some current for internal circuitry. For charge controller self current consumption should be less then 20mA when no LED is on and it should be less then 50mA when one LED is on.

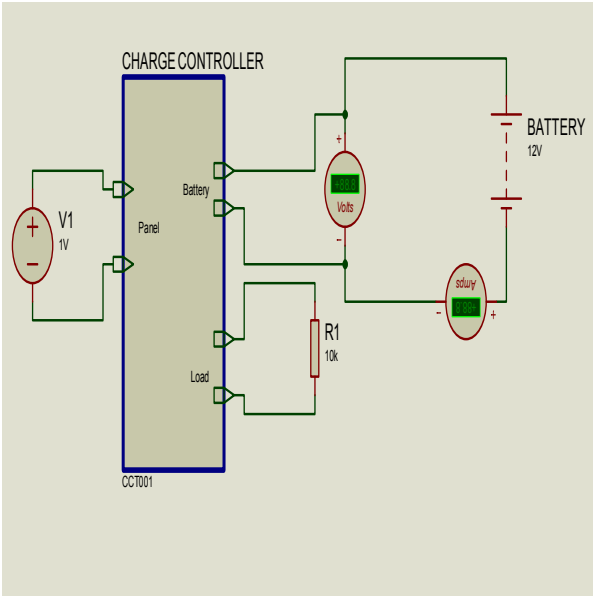

Fig. 8 Circuit connection for measuring self current consumption

Voltage at the panel side of Figure 8 was increased to maximum limit at which no LED was on and reading of the ammeter was taken. Then it was increased further so that one LED was on and reading of the ammeter was taken.

All samples complied with this specification.

G. Short Circuit Protection

Short circuit can cause overheating and can even be a fire hazard. Short circuit protection is mandatory at the load terminal according to the IDCOL standard. If load is short circuited then charge controller disconnects the load.

Circuit was connected as Figure 4 where load is short circuited by a thick wire having low resistance. The Load was out for satisfactory protection.

To protect load as well as charge controller unit every sample should include short circuit protection. Sample no.09 sample no.12 and sample no.13 didn't comply with this specification.

H. Reverse Polarity Protection

There may be opposite polarity connection at the panel side and at the battery side. IDCOL specifies it as a mandatory to have protection against reverse polarity so that no current flows from any direction.

The circuits were connected as Figure 9 and the Charge controller was observed whether there was any damage.

All samples complied with this specification.

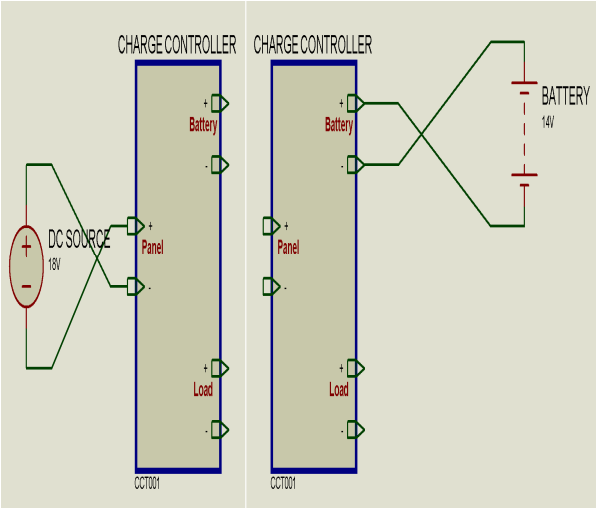

Fig. 9 Circuit connection for reverse polarity protection

I. *Reverse Current Leakage Protection*

PV works by pumping current through battery in one direction. When battery voltage goes higher than panel side voltage, the panels may pass a bit of current in the reverse direction, causing a slight discharge from the battery.

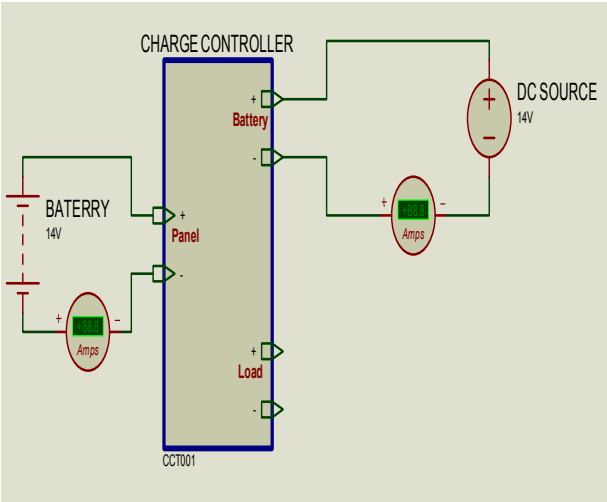

Fig. 10 Circuit connection for reverse current leakage protection

The DC source voltage of Figure 10 was higher than the battery voltage. Reading of both Ammeters were taken. Zero or very low reading indicates the protection was OK on both Panel and Battery side. According to IDCOL this leakage current should be 0Amp or very low.

All samples complied with this standard of IDCOL.

III. Features Of Observed Charge Controllers

According to connection, charge controllers can be of two types such as shunt controller and series controller. The series charge controller is connected in series between the solar panel and battery. The controller disconnects the battery from the panel by opening the switch. But shunt controller is connected in parallel to the battery and the load. When battery is fully charged, the controller interrupts current supply to the battery by making the panel short-circuited [1]. Among the charge controller we tested, all except sample no. 2 were series controllers. Sample no. 2 was shunt controller.

There are three types of charge controller such as ON-OFF, PWM and MPPT based charge controller. After testing the charge controller we found that, sample no. 5, 6 and 8 are PWM controllers. Others are On-off controllers.

Some extra features were observed during the testing process. Sample no. 5 has acoustic load disconnect pre-warning which sounds an alarm before disconnecting the load. Sample no. 6 has a built in cell phone charger which is very useful in the area where grid electricity is not available. Sample no. 6 and 7 are built using surface mounted technology which promises higher reliability and performance.

IV. Further Improvement

Among the tested charge controllers, only three were PWM charge controllers, where others are ON/OFF controller. Literature [4], [5] shows that PWM charging increases the charging efficiency and battery life. So, this technique should be implemented in the charge controllers. Also it was found that in some controllers, negative terminals of the panel and the battery have to be shorted for starting the controller. This common negative grounding feature helps to detect wrong connection at any of the terminals. This feature may be included in all the charge controllers.

It was also found that locally built charge controllers do not have maximum power point tracking (MPPT) system. This can increase the output of the solar panel from 10 to 30 percent. Though it needs an efficient DC-DC converter and capable microprocessor which are costly, it may be cost effective for larger systems.

V. Conclusions

Solar Home System (SHS) has become an effective and viable solution for the current energy crisis in Bangladesh. As a major component of solar home system, the performance of charge controller plays a vital role in the growth and popularity of solar PV system. In this paper, we randomly collected fifteen charge controllers available in the local market produced by both local and foreign manufacturer. We systematically tested these charge controllers and compared against the specification set by IDCOL. The testing data are presented in this paper. Some deviations were found from the standard values which can cause severe underperformance of solar home system. It was found that efficiency and performance of PWM charge controller is better in Bangladesh. Future work should incorporate large scale testing and evaluation of the locally available charge controllers at regular interval.

***Abstract*—The fossil fuel is decreasing rapidly and excessive use of such fuels is also hazardous for the environment. Hence, renewable energy usage is the inevitable alternative to meet up electricity demand for the developing country like Bangladesh. Although solar technology has nearly been successful in rural areas where most of the technologies are adopted based on Solar Home System(SHS), it has not yet been effective in urban areas after the imposed rule of installing solar system to get new electricity connection from power utility for various reasons. In this paper, the investigation result of the installed solar system in an area in Dhaka is presented. The overall problems regarding the connection of the system components are analyzed. Efficiency calculation for the active solar home systems is provided through cost comparison analysis by HOMER software. Some proposals are provided which can be implemented to make the concept of solar home system popular in urban ares of Bangladesh to decrease the pressure on our national grid.**

***Index Terms*—HOMER, COE , solar, urban, survey.**

I. Introduction

Energy crisis is regarded as one of the widely discussed and vastly concerned issues that is causing acute controversy as presently used conventional fossil fuels are the greatest pollutants and largest contributors of greenhouse gases. Rapid depletion of fossil fuels and enhanced environmental degradation has resulted in to the extensive use of renewable power sources for electric power generation. In developing country like Bangladesh, it is therefore necessary to investigate the prospect of renewable energy sources especially solar energy that do not pollute environment, is clean and inexhaustible.

Lying in semi-tropical region of the north eastern part in South Asia, Bangladesh is prone to abundant sun light round the year which is very favorable for solar PV based electricity production. Understanding the future prospect and many diverse opportunities of solar technology, Government of Bangladesh along with other concerned organizations are trying to comprehend and address the problem of energy scarcity through promoting and popularizing solar home systems (SHS) in both the off grid and on grid areas of the country.

According to the Renewable Energy Policy as per Ministry directive to all the utilities, all new connections with demand above 2KW now require installation of solar panels. For domestic purposes, solar energy should meet at least 2% of the demand, for commercial 7% and for industrial 10%.

Proper inspection of the system is always a must to ensure that the imposed rule is making the people benefited.It is an irony of fate that a government survey [1] recently pointed out that installation of solar panel on rooftop in urban areas would not add any additional power in the system rather it would create serious havoc in system management and cause huge financial loss to the consumers.The survey also pointed out that solar panel failed to catch public interest as the distributing agencies did not take any awareness program for the consumers as well as they faced serious obstacle to get service from the agencies. Considering the results from the survey, a detail survey was done on Lalmatia Area, Dhaka to inspect the working status of the installed solar systems. Some of the houses were DPDC (Dhaka Power Distribution Company) listed and others were not. Necessary possible data was measured from panel and battery. User feedback was also collected from every possible individual. The data collected was used to differentiate the effective and ineffective systems. The efficiency calculation was carried out using the modified parameters of HOMER software.

II. Details of the Survey

23 houses of Lalmatia were inspected for surveying purpose. Of those, only 6 of the houses were found having active solar home system.The inactive systems contains problems like mismatching of voltage levels of solar panels, incorrect connection of battery, oversized inverter with respect to load etc. Table I shows the data collected from the houses who have installed solar home system. Here

- Panel Voltage refers to voltage of the solar panel measured at Charge Controller (CC) terminal.
- Panel Current refers to incoming current from panel through CC.
- Battery Voltage refers to voltage of the battery measured at CC terminal.
- Battery Current refers to outgoing current to battery through CC.
- Inverter Voltage refers to AC output voltage of the inverter.
- NM, ND, NC stands for Not Measurable, No Data and No Connection respectively.

Here the comma separated values in the first column of Table I represent the voltage values for panels of different power and the comma separated values in the third column represent the voltage values for separate battery.

III. Discussion regarding the Inspected Houses

Specific problems were found out regarding the inspected houses like on arrangement of battery and solar panels and circuit connection through the CC.From Table I following conclusions can be made :

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

TABLE I
COLLECTED DATA FROM THE HOUSES

Sl no.	Panel Voltage		Panel Current	Battery Voltage		Battery Current	Inverter Voltage

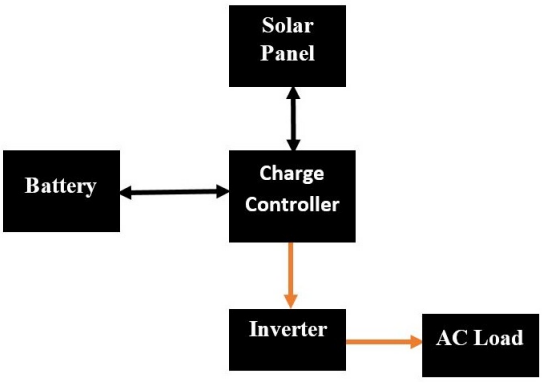

Fig. 1. Appropriate Connection among SHS Components

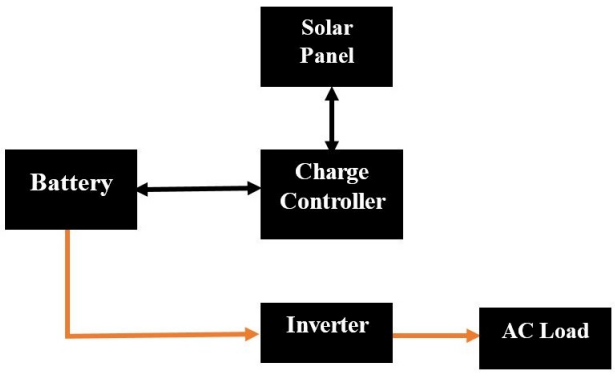

Fig. 2. Typical Connection found among SHS Components

- Only 6 of the 23 houses have active solar home system which is only 26.08 % of the total number of samples. Only 1 of the 6 samples had almost flawless system while the other ones had some design problems.
- For solar home system, a charge controller controls the charging and discharging level of a battery requiring a circuit connection between components shown in Fig. 1. But every inspected house has a circuit connection like Fig. 2, causing no control over battery discharging .
- Battery of different Ampere Hour (Ah) were found to be both in parallel and series configuration which is detrimental to battery. To increase the input DC voltage to inverter different ampere hour battery were found in series configuration where as different ampere hour battery was found in parallel configuration for increasing the total capacity. Figure 3 shows 6 130Ah batteries connected in a combination to match the input voltage of the inverter which is detrimental for the upper two batteries (Bat5 and Bat6).

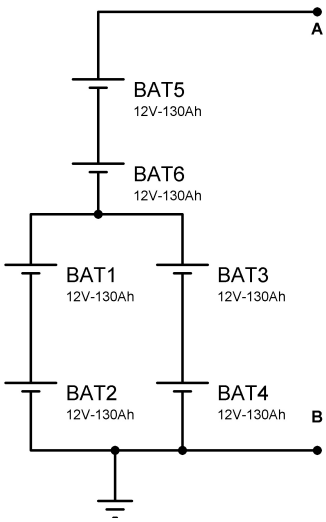

Fig. 3. Connection Found Between Batteries

- An inverter has to produce its no load voltage whether load is being served it or not. But most of the inverters were found off during the inspection time.
- From the observation of the systems, it is found that the charge controller and the inverter are oversized for that specific house. The installer company used an already available CC with an already produced inverter irrespective of the amount of the load the inverter has to handle. Due to this reason, most of the houses were manually operated by a person who had the responsibility of switching on and off the load which is not an efficient system and also responsible for battery damage.
- Panels of two different open circuit voltage were found out in parallel combination in some houses causing the solar panel of low open circuit voltage acting as load.

IV. Analysis of Active Systems & Efficiency Calculation

From the collected data, it was found that houses corresponding to serial no 8,9,10,11,12 and 16 of Table I had active solar home systems. But the systems were not designed in an efficient way. Moreover, some connection problems were also found regarding the connection of the solar panel. Every active houses were simulated in HOMER software and efficiency was calculated through detail analysis of the system.

A. Modification of HOMER Software

As this paper work has a purpose to design the Urban Solar System by using the local panels and batteries it is necessary to make the simulation software HOMER compatible to the available panels and batteries in Bangladesh. So, to start over the simulation work, necessary battery models were made in HOMER.

1) Battery Modeling in HOMER: HOMER has a built in battery resource but the batteries found are not available in the Bangladesh market. So it is necessary to remodel the batteries according to the availability of the batteries. The simulation process is performed after modeling the battery parameters to match with the performance of the 80Ah,100Ah and 130Ah batteries available in Bangladesh market.Capacity curve modeling was performed according to [3], [4] and the lifetime curve was modeled by collecting data from [2].Thus the battery modeled (Fig. 4)suits the present economic situation and is suitable for cost estimation of the investigated system.

2) Setting the Required Parameters: Table II shows the considered specifications for the purpose of efficiency calculation by HOMER.

After a market survey, battery and panel pricing were collected and are used for calculating the efficiency of the system. Inverter parameters were not found for all the installed systems. In such cases, the lowest required inverter capacity for meeting up the load is used which was being found by sensitivity analysis.

B. Defining Efficiency

For high watt load HOMER is used to measure the efficiency of the installed solar home systems in the active house. The efficiency of the system is measured by following the steps described.

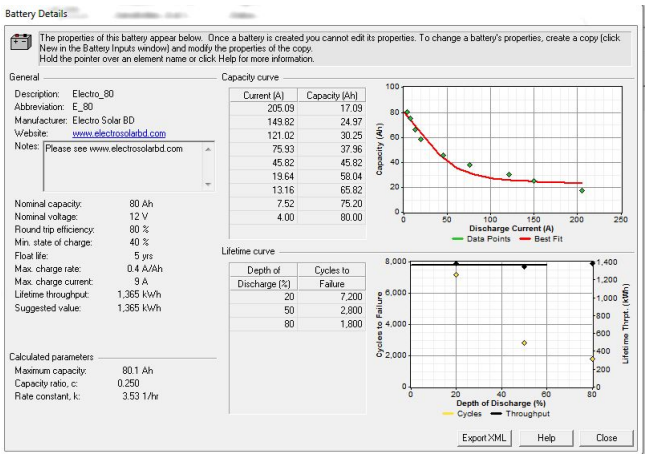

Fig. 4. Battery parameters for 80Ah Battery

TABLE II
Specifications used for Effeciency Calculation for Active Systems

Panel Lifetime	20 years
Derating Factor	80.00%
Slope	23.12
Ground reflectance	20%
Nominal operating cell temperature	25
Efficiency at standard condition	13.00%
Fixed Capital Cost	$100.00
Annual Interest Rate	6.00%
Inverter Efficiency	75.00%
Battery Lifetime	5 years
Inverter Lifetime	10 years
Inverter Price	$158 per kW
O&M Cost of Battery	$10

1) From the installed panel and battery of the house and the present running load, the COE (Cost of Energy) is calculated.
2) In the HOMER software, simulation is run by varying the load but keeping the battery and solar panel exactly same to the installed system with a purpose of finding the maximum possible load which can be run by the installed panel and battery. The simulation thus produces a minimum COE with a maximum possible load which can be served.
3) The relative change of COE in % returns the percentage by which the present system is inefficient.
4) The final efficiency of the system is = (100 − Relative Change of COE) %.

C. Efficiency Analysis for Sample No 10

1) Load specification: From the discussion with in-charge personnel of the system, it was found that some of the garage and stair case lights are PV-system driven and the load connected is approximately around 190W.

2) Battery and Panel Specification: Each battery is a 12V, 80 Ah one. Price of each battery is considered to be $127. There are 4 batteries in the system; two strings of parallel battery, each string containing two batteries in series . There were 28 panels each of 50W (each costs $45)resulting in a total panel size of 1400 W. These exact parameters are provided as input for the simulation purpose.

3) Efficiency Calculation: Figure 5 shows that 760Wh load is daily used in this house with a COE of $1.126 per

Pri. Load 1 (kWh/d)	PV (kW)	E_80	Conv. (kW)	Initial Capital	Operating Cost ($/yr)	Total NPC	COE ($/kWh)	Ren. Frac.
0.770	1.4	4	0.3	$ 2,002	138	$ 3,583	1.112	1.00
0.780	1.4	4	0.3	$ 2,002	138	$ 3,583	1.097	1.00
0.790	1.4	4	0.3	$ 2,002	138	$ 3,583	1.083	1.00
0.800	1.4	4	0.3	$ 2,002	138	$ 3,583	1.070	1.00
0.810	1.4	4	0.3	$ 2,002	138	$ 3,583	1.057	1.00
0.820	1.4	4	0.3	$ 2,002	138	$ 3,583	1.044	1.00
0.830	1.4	4	0.3	$ 2,002	138	$ 3,583	1.031	1.00
0.840	1.4	4	0.3	$ 2,002	138	$ 3,583	1.019	1.00
0.850	1.4	4	0.3	$ 2,002	138	$ 3,583	1.007	1.00
0.860	1.4	4	0.3	$ 2,002	138	$ 3,583	0.996	1.00
0.870	---	---	---	---	---	---	---	---
0.880	---	---	---	---	---	---	---	---
0.890	---	---	---	---	---	---	---	---
0.900	---	---	---	---	---	---	---	---
0.760	1.4	4	0.3	$ 2,002	138	$ 3,583	1.126	1.00

Fig. 5. Sensitivity Analysis in Tabular Form for Sample No 10

kWh(marked in red box in Fig. 5). But simulation results shows that maximum 860Wh load can be served by the installed solar home system with a COE of $0.996 per kWh (marked in green box in Fig. 5).

Efficiency of the sample=$100 - \frac{(1.126 - .996) \times 100}{.996} = 86.94\%$

Similar efficiency calculation is performed for the other active systems and presented in the Table III.

TABLE III
EFFICIENCY CALCULATION FOR THE ACTIVE SYSTEMS

	Serial No				
	8	9	10	11	12
Present Load(Wh)	400	680	760	600	800
Present COE($/kWh)	1.36	0.89	1.13	1.29	1.23
Optimized Load(Wh)	520	750	860	780	1150
Optimized COE($/kWh)	1.047	0.759	0.996	1.003	0.859
Efficiency (%)	70.11	83.34	86.94	71.09	56.81

V. PROPOSALS FOR IMPROVING THE PRESENT SCENARIO

- Feed In Tariff implementation is a path to success to improve the present condition. But as the necessary money that the Government has to pay is too high [6], Meter tempering and and corruption preventive steps will be required.
- For small load system,DC wiring can be successfully implemented using DC loads only [5]. But in case of distant loads the copper loss will be of significant amount.So inclusion of Optimizer (Boost Converter incorporated in a CC) can be a solution to such problems.
- Necessary schemes can be designed according to user needs like described in so that a person of an urban area is well known of the system being run by him. Commercial software can be used to include the shading effect and proper sizing of panels and battery can be made to meet the assigned load.
- A dedicated organization like IDCOL can be formed so that regular monitoring can be done and necessary actions can be taken against any irregularities to avoid any mismanagement .

VI. CONCLUSIONS

The paper presents a complete scenario of the existing solar home system in urban areas of Bangladesh. The irregularities found are described in a comprehensive way. Efficiency calculation has been provided with respect to the actual parameters found in Bangladesh. Some proposals are provided so that the urban solar home system can be made effective to fight against the power crisis in Bangladesh.

***Abstract*—Solar radiation at Patenga, Chittagong is predicted by using record of bright sunshine hours of that place. Monthly average solar radiation is calculated from Angstrom-Prescott equation. The coefficients of that equation is found as a = 0.1688 and b= 0.5869. Patenga is a coastal area of Bangladesh and has promising potential of hybrid solar-wind based electricity. Solar radiation data is required for planning and designing photovoltaic power plant. But Bangladesh Meteorological Department has no record of radiation data of that place. So, attempt has been made to estimate solar radiation from other available meteorological parameters. Accuracy of estimated radiation is determined by comparing with data obtained from NASA Surface Meteorology and Solar Energy (SSE). Also estimated radiation is compared with five widely accepted models used for calculating solar radiation. These models were developed considering wide range of geographical area so can be applicable for present location. Present model provide better error correction scheme compared to other considered models by generating more accurate coefficient for that place.**

***Index Terms*—solar radiation, sunshine hour, patenga, renewable energy**

I. Introduction

Bangladesh is situated between 20.30° and 26.38° north latitude and 88.04° and 92.44° east longitude with an area of 147,500 square km. Daily average solar radiation varies between 4 to 6.5 kWh per square meter [1]. So there is a good potential of producing electricity using solar energy conversion system. The knowledge of solar energy radiation is very vital for the optimal design and performance analysis of any solar energy conversion system for electricity generation. At present, solar energy data can be found from the following sources:

- Renewable Energy Research Centre (RERC), Dhaka University; it has recorded long-term hourly solar irradiance data of Dhaka city with Eppley Precision Pyrometer.
- Bangladesh Meteorological Department (BMD); it has 35 sunshine recording stations [2] situated generally in towns and cities.
- NASA Surface Meteorology and Solar Energy (SSE); it has recorded world-wide solar radiation data covering the period from 1983 to 2005 [3].

Solar radiation measuring technology is expensive and has instrumental hazard for developing countries. Like most of the developing countries, Bangladesh does not have adequate number of radiation measuring stations. Therefore, it is essential that some reliable mathematical models be developed to estimate the solar radiation for places where measurements records are not available. Solar radiation reaching the earth's surface depends upon climatic conditions of that place. Thus a mathematical model can be developed relating these climatic factors with solar radiation. A number of studies [4-6] compute solar radiation from observation of cloud cover. Other studies [8-10] estimate solar radiation from sunshine hours. In this study, solar irradiance at Patenga, Chittagong is estimated. Patenga is a coastal area and has good potential for solar-wind hybrid renewable energy based electricity generation. Solar irradiance data at Patenga is not available at Bangladesh Meteorological Department(BMD). But BMD keeps record of daily sunshine hour in Patenga. For this reason, in this study, solar radiation at Patenga is estimated using sunshine duration. The result of estimation is also compared with five other commonly used correlation models.

II. Methodology

A. Angstrom Model

Angstrom [15] was first to propose a linear relation relating ratio of monthly average daily solar radiation to clear day radiation and ratio of bright sunshine hours to total day length in hours, which is given by

$$\frac{\overline{H}}{\overline{H_c}} = a + b\frac{\overline{n}}{\overline{N}} \tag{1}$$

Where $\overline{H}$=monthly average daily global radiation (Wh/m^2/day), $\overline{H_c}$= monthly average clear sky daily global radiation for the location, $\overline{n}$= monthly average daily maximum bright sunshine duration in hours, $\overline{N}$= actual sunshine duration in a day in hours, and a, b are empirical coefficients. These coefficients are location specific coefficients and known as fractions of extraterrestrial radiation on overcast days and on average days respectively.

A basic difficulty in this model is to determine $\overline{H_c}$, clear sky radiation. To avoid this difficulty a modified model was presented by Prescott [7] in 1940.

B. Angstrom-Prescott Model

Popularly known Angstrom-Prescott model is given by

$$\frac{\overline{H}}{\overline{H_0}} = a + b\frac{\overline{n}}{\overline{N}} \tag{2}$$

Where, $\overline{H}$, $\overline{n}$, $\overline{N}$, a and b are same as equation (1) and $\overline{H_0}$=monthly average daily extraterrestrial radiation at the specific location. The ratio of solar radiation at the surface of the Earth (H) to extraterrestrial radiation ($\overline{H_0}$), that is, $\overline{H}/\overline{H_0}$, is called the clearness Index and the ratio n/N is referred to as the cloudless index.

Monthly average daily extraterrestrial radiation is calculated from following equation

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

$$H_0 = \frac{24}{\pi} G_{sc} \left(1 + \cos\frac{360n}{365}\right) \times \left(\cos\varphi\cos\delta\sin\omega_s + \frac{\pi\omega_s}{180^o}\sin\varphi\sin\delta\right) \quad (3)$$

Where, G_{sc}= the solar constant = 1.367 kW/m^2
n= the day of a year (a number between 1 to 365, starting from 1st January)
φ= the latitude in degree
δ= the solar declination in degree
ω_s=the sunset hour angle in degree.

The solar declination is calculated according to the following equation:

$$\delta = 23.45^o \sin\left(360^o \frac{284+n}{365}\right) \quad (4)$$

The sunset hour angle is calculated using the following equation:

$$cos\omega_s = -tan\varphi tan\delta \quad (5)$$

The average H_0 for the month is calculated as follows:

$$H_{0,avg} = \frac{\sum_{n=1}^{N} H_0}{N} \quad (6)$$

Where, $H_{0,avg}$=the average extraterrestrial horizontal radiation for the month in kWh/m^2/day
N=the number of days in the month

The maximum possible sunshine duration N in hours for a horizontal surface is given by

$$N = \frac{2}{15}\omega_s \quad (7)$$

In this study, monthly average bright sunshine hours, n is collected from Bangladesh Meteorological Department for the period 1983 to 2012. H_0 is calculated from equation (3). N is calculated from equation (7) and compared with data obtained from WeatherSpark beta [14], a weather website. Regression coefficient a and b are obtained from following equations

$$a = \frac{\sum(\frac{H}{H_0})}{m} - b\frac{\sum(\frac{n}{N})}{m} \quad (8)$$

$$b = \frac{m\sum(\frac{n}{N})(\frac{H}{H_0}) - (\sum(\frac{n}{N}))(\sum(\frac{H}{H_0}))}{m\sum(\frac{n}{N})^2 - (\sum(\frac{n}{N}))^2} \quad (9)$$

Where, m is number of month. As measured data of monthly average solar radiation for Patenga is not available from BMD, the values of H are taken from NASA Surface Meteorology and Solar Energy (SSE) [3].
In this study, the best five sunshine duration based radiation models [9-13] are compared with our new model in predicting solar radiation to target place.

III. Models

The five models that are used to compare are

A. Gopinathan's model

This model recommends the following equations for calculating regression coefficient a and b of Anngstrom-type correlation to predict solar radiation at any location around the world [10]

$$a = -0.309 + 0.539\cos\varphi - 0.0693h + 0.290\left(\frac{\overline{n}}{\overline{N}}\right) \quad (10)$$

$$b = 1.527 - 1.027\cos\varphi + 0.0926h - 0.359\left(\frac{\overline{n}}{\overline{N}}\right) \quad (11)$$

Where, φ is the latitude in degrees, h is the elevation of the location above sea level in kilometers.

B. The model of Benson et el

Benson et el proposed two different set of value for regression coefficient a and b for two intervals of a year. His proposed models are [11]

$$\frac{\overline{H}}{\overline{H_0}} = 0.18 + 0.6\frac{\overline{n}}{\overline{N}} \quad (12)$$

for the months January-March and October-December.

$$\frac{\overline{H}}{\overline{H_0}} = 0.24 + 0.53\frac{\overline{n}}{\overline{N}} \quad (13)$$

for the months April-September.

C. Rietveld's model

This correlation is believed to be applied with world-wide validity [9]

$$\frac{\overline{H}}{\overline{H_0}} = 0.18 + 0.62\frac{\overline{n}}{\overline{N}} \quad (14)$$

D. The model of Ögelman et el

Ögelman et el used daily measured data for a period of 3 years at Ankara in Turkey to develop following eqution for predicting solar radiation [12]

$$\frac{\overline{H}}{\overline{H_0}} = 0.204 + 0.758\frac{\overline{n}}{\overline{N}} - 0.250\left(\frac{\overline{n}}{\overline{N}}\right)^2 + \sigma^2_{n/N} \quad (15)$$

In case that, the original data is not available and only available data is monthly average (n/N) but not $\sigma_{(n/N)}$ they established another correlation

$$\sigma^2_{n/N} = 0.035 + 0.326\frac{\overline{n}}{\overline{N}} - 0.433\left(\frac{\overline{n}}{\overline{N}}\right)^2 \quad (16)$$

Relating two equations they suggested the final quadratic relation

$$\frac{\overline{H}}{\overline{H_0}} = 0.195 + 0.676\frac{\overline{n}}{\overline{N}} - 0.142\left(\frac{\overline{n}}{\overline{N}}\right)^2 \quad (17)$$

E. McCulloch's model

McCulloch proposed this model that considers the latitude effect of a location. This is given by [13]

$$\frac{\overline{H}}{\overline{H_0}} = 0.29\cos\varphi + 0.52\frac{\overline{n}}{\overline{N}} \quad (18)$$

TABLE I
ERROR COMPARISON IN DIFFERENT MODELS

Model	a	b	MBE	RMSE	MAPE	r
Gopinathan's	$-0.309 + 0.539cos\varphi - 0.0693h + 0.290(n/N)$	$1.527 - 1.027cos\varphi + 0.0926h - 0.359(n/N)$	54.13%	62.61%	12.10%	0.849
Benson's	0.18 From January- March and October- December 0.24 From April - September	0.6 From January- March and October- December 0.53 From April - September	33.47%	42.02%	7.89%	0.8968
Rietveld's	0.18	0.62	28.12%	34.89%	6.10%	0.9492
Ögelman's	$0.195 + 0.676(n/N) - 0.142(n/N)^2$		27.60%	36.15%	6.80%	0.9126
McCulloch's	$0.29cos\varphi$	0.52	59.66%	65.12%	13.30%	0.8926
Our	0.1688	0.5869	0.77%	18.81%	3.49%	0.9494

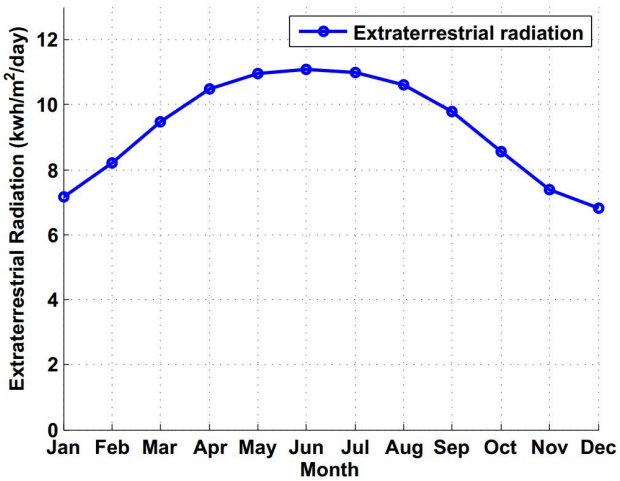

Fig. 1. Monthly extraterrestrial radiation at Patenga

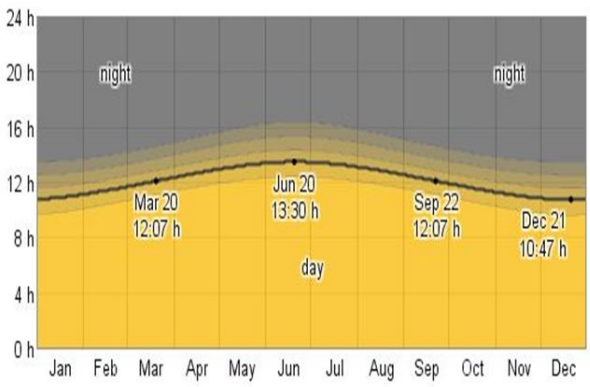

Fig. 2. Monthly average day length

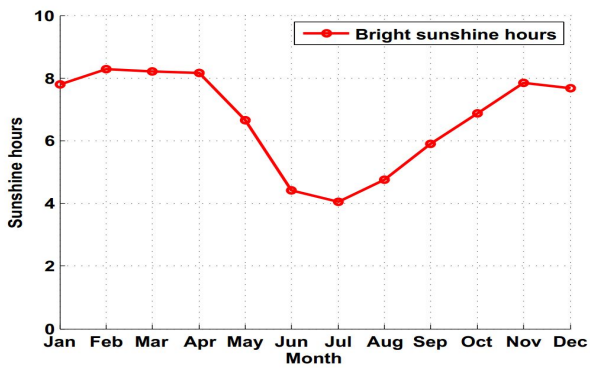

Fig. 3. Monthly average bright sunshine hours

IV. LOCATION AND DATA

Solar irradiance at Patenga, Chittagong in Bangladesh is estimated. The latitude and longitude of Patenga is 22.30^0 North and 91.80^0 East respectively. Extraterrestrial radiation over target location, obtained using equation (3) are shown in Fig. 1. Monthly average day length, N is shown in Fig. 2 [14]. Monthly average bright sunshine hours, obtained from BMD, are shown in Fig. 3.

V. COMPARISON TECHNIQUE

To make performance analysis and obtain degree of accuracy, Mean Bias Error(MBE), Mean Absolute Percentage Error (MAPE), Root Mean Square Error(RMSE) and correlation r for twelve months is calculated for each of the five models mentioned above. MBE, MAPE, RMSE and correlation r are given by following equations

$$MBE = \left(\sum_{i=1}^{n=12} (H_{ic} - H_{im}) \right) /n \tag{19}$$

$$MAPE = \left(\sum_{i=1}^{n=12} \frac{|H_{ic} - H_{im}|}{H_{im}} \right) /n \tag{20}$$

$$RMSE = \left\{ \left(\sum_{i=1}^{n=12} (H_{ic} - H_{im})^2 \right) /n \right\}^{1/2} \tag{21}$$

$$r = \frac{\sum_{i=1}^{n=12} (H_{ic} - \overline{H}_c)(H_{im} - \overline{H}_m)}{\sqrt{\left(\sum_{i=1}^{n=12} (H_{ic} - \overline{H}_c)^2\right)\left(\sum_{i=1}^{12} (H_{im} - \overline{H}_m)^2\right)}} \tag{22}$$

Where, H_{ic} and H_{im} are the estimated and measured monthly average solar radiation for the ith month respectively. The average of the deviations $E = (H_{ic} - H_{im})$ is MBE and gives information about the long- term performance of the correlations. MAPE is a measure of the goodness of each correlation, while RMSE measures the short-term prediction quality of the correlations.

VI. RESULTS AND DISCUSSION

From equations 8 and 9 regression coefficient a and b are calculated using MATLAB simulation. Final correlation equation of this study with this coefficient is

$$\frac{\overline{H}}{\overline{H_o}} = 0.1688 + 0.5869\frac{\overline{n}}{\overline{N}} \tag{23}$$

a and b values thus estimated are employed along with the fraction of bright sunshine duration to compute the monthly

average global solar radiation on a horizontal surface for target location. The accuracy of the estimated data of solar radiations is evaluated by calculating MBE, RMSE and MAPE values. The estimated data are also compared with the models proposed by Gopinathan, Benson et el, Rietveld, Ögelman et el and McCulloch. Percentage errors in predicting global solar radiation at target place by different models are shown in Table I .

As seen from the table, correlation is quiet high in each model which indicates that considered models can predict the pattern of monthly variation of solar radiation on target place quiet satisfactory. But except our model rest of the five models suffer from large %MBE, %RMSE. In present model %MBE and %MAPE is very low which indicates long-term global solar radiation for target place using this model can be predicted with high degree of accuracy. But %RMSE in present model is comparatively high than other errors, which indicates that short term prediction suffers from lack of accuracy. A comparison between estimated solar radiation data using present model and measured data from NASA SSE is shown in Fig 4.

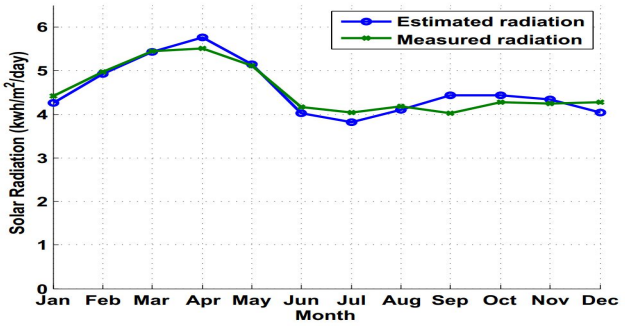

Fig. 4. Estimated and Measured solar radiation at Patenga

Monthly average global solar radiation estimated using five considered models along with present model is shown in Table II

TABLE II
MONTHLY AVERAGE SOLAR RADIATION ESTIMATED USING DIFFERENT MODELS

Month	$H_{measured}$	Gopinathan's Model	Benson's Model	Rietveld's Model	Ögelman's Model	McCulloch's Model	Our Model
January	4.4207	4.5136	4.4117	4.5157	4.3795	4.6327	4.2629
February	4.9811	5.1976	5.1019	5.2227	5.0544	5.3486	4.9304
March	5.4428	5.8436	5.6276	5.7583	5.627	5.9466	5.4354
April	5.5048	6.302	6.1263	6.1101	6.0206	6.3598	5.7668
May	5.1137	5.912	5.6048	5.4509	5.5228	5.8644	5.1421
June	4.1595	4.853	4.6089	4.2739	4.4733	4.8912	4.0277
July	4.0356	4.631	4.4192	4.0617	4.269	4.7019	3.827
August	4.1825	4.913	4.643	4.3618	4.5334	4.9088	4.1117
September	4.0227	5.1442	4.8646	4.7045	4.7903	5.0987	4.4374
October	4.2823	4.9524	4.5999	4.7019	4.685	4.9524	4.4369
November	4.2493	4.6227	4.4995	4.6051	4.4757	4.7329	4.3472
December	4.2811	4.2871	4.1848	4.2834	4.1569	4.3968	4.0435
Average	**4.5563**	**5.0977**	**4.8914**	**4.8375**	**4.8323**	**5.1529**	**4.5641**

It is evident from Table II that there is a very fine agreement between measured and estimated values obtained from present correlation model. A comparison between measured solar radiation by NASA SSE and estimated solar radiation by using all of these models considered in Table II is shown in Fig. 5.

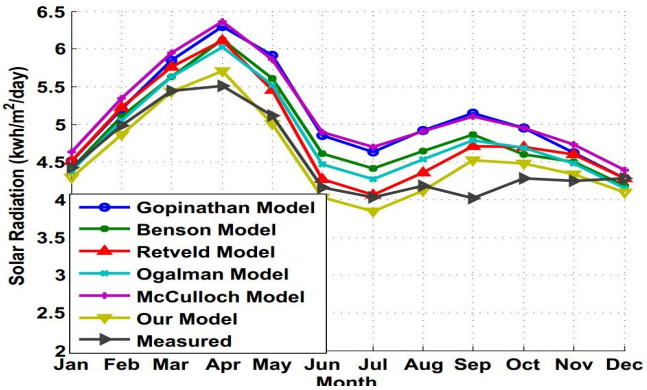

Fig. 5. Prediction of monthly solar radiation by different model

VII. CONCLUSION

In the present work, the low percentage error suggests that this model can be used with confidence for Patenga, Chittagong and also for other locations with similar climatic conditions. This statement is also supported by the high value of correlation coefficient. Solar irradiance is maximum at March-April which is dry season. Solar irradiance is minimum during June-July which is rainy season. This result shows that the prediction is practical. The accuracy of the model can be further improved by considering the fog density, cloud cover and atmospheric scattering effect.

Study and Protection of Lightning Overvoltage on DC Cables of Solar Power Generation

Md. Alamgir Hossain,* and Md. Raju Ahmed

Department of Electrical & Electronic Engineering, Dhaka University of Engineering & Technology (DUET)
Gazipur-1700, Bangladesh
* alamgir_duet@hotmail.com

Abstract— **In this paper, lightning induced overvoltage on DC cables of solar power panel, which was laid on the ground and an underground level with proper insulation thickness, was investigated when a lightning strike at a nearby place and its proper protection scheme was verified. The result shows that on ground cable voltage is approximately 28.83% more than that of the underground cable having soil resistivity 100Ω-m. Moreover, when soil resistivity increases to 1000Ω-m then the underground cable voltage is less about 48.50% than that of the on ground cable. The induced voltage caused by lightning electromagnetic interference on DC cables of solar power system at power conditioning subsystem (PCS) is analysed using electromagnetic field analysis approach. The FDTD method was applied to calculate induced voltage. Virtual Surge Test Lab (VSTL) is used for FDTD calculations, which solve Maxwell's electromagnetic equations with least approximations. The model of solar power system was represented with thin wires.**

Index Terms— **lightning induced voltage, DC cables, PCS, protective device.**

I. Introduction

The photovoltaic (PV) generation is increasing whole over the world dramatically because of its attractive contribution to power generation, no CO_2 emission, cost effective and easy installation to anywhere in the place. Keeping hand in hand with the world, Bangladesh is also progressing well in this sector because of lack of fossil fuel in the upcoming future [1]; however the number of increasing PV panels is now concern of its secure operation and safety issues for unexpected weather condition like lightning. The overvoltage in solar power system can be either cause of direct or indirect lightning effect, sudden load changing, electrical switching, etc., which are dangerous for damaging photovoltaic generator and its ancillary equipment. In most of the case, lightning is major reason for damaging electrical and electronic equipment in a system [2].

Lightning phenomena has been studied intensively in many researches [3-6] and found its fairly general behaviour, nonetheless precise illustrations are not foreseeable for specific incidents. Lightning induced voltage on solar power system was investigated in Martzloff work [7], and [8]. They conclude that lightning voltage is proportional to peak value of lightning current. In Z. Beesova et all [9] work they show that strike point carries major influence components for inducing voltage besides shape of lightning current and constructional size of solar panel. In order to optimize the solar protection system, lightning induced voltages need further study to design solar power system for secure, reliable, and economical operation.

To analyse lightning phenomena of solar power system, numerical electromagnetic analysis is applied successfully. In this application, The Finite Difference Time Domain (FDTD) [10] was utilized to compute induced voltages. For simulation purpose, frame of PV panels and DC wires are represented with thin wire model [11] and frequency dependency of soil is not considered.

To generate electricity commercially from solar; large size of PV panel is required, which is exposed in open field, have a chance to be affected by directly/indirectly lightning that lead to high voltage between DC line and Power Conditioning Subsystem (PCS) that is enough to damage the PCS [12]. The most of the damage occurred in electrical and electronic devices owing to indirect lightning. In our study, we analysed the indirect lightning induced voltage between DC cables of solar generator and PCS with varying soil resistivity.

II. Analysis Methodology

In this paper, numerical simulations are carried out using FDTD method which directly solves the Maxwell equation in the time domain form for solving electromagnetic propagation problems [13]. Base on the FDTD method the Virtual Surge Test Lab (VSTL) [14, 15] code was developed by the Central Research Institute of Electric Power Industry (CRIEPI) to analyse the surge related electromagnetic field problems. To represent open space to all the boundaries in the analytic space, second-order Liao's method was adopted in VSTL code for getting precise results and using less memory compared to other methods [16].

Lightning stroke channel having propagation velocity of return stroke is 1/3 of the speed of light [17, 18] is represented by engineering model built in VSTL. The current waveform used in this model was adopted from the analytical expression of ref. [19].

$$i(0,t) = \frac{I_0}{\eta}\frac{(t/\tau_1)^n}{1+(t/\tau_1)^n}\exp\left(-\frac{t}{\tau_2}\right) \quad (1)$$

Where,

$$\eta = \exp\left[-\left(\frac{\tau_1}{\tau_2}\right)\left(\frac{n\tau_2}{\tau_1}\right)^{\left(\frac{1}{n}\right)}\right] \quad (2)$$

I_0 = Amplitude of the channel-base current
τ_1= Front time constant
τ_2= Decay time constant
η= Amplitude correction factor
n = Exponent (2 ... 10)

The sum of two functions given in Eq. (1) was chosen so as to obtain the overall wave shape of the current as observed in typical experimental results.

In FDTD method the cell size and time step must satisfy the Courant stability condition [20]. Time step can be calculated using the following equation [14] when space step is known.

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

$$\Delta t = \Delta s\sqrt{\frac{\mu\epsilon}{3}}(1-\alpha)$$

Here,

α is small positive value, <1, which is used to avoid instability of the numerical integration due to rounding off error.

III. Analysis Model

A solar panel was modelled in VSTL shown in Fig. 1 having the height of 2.5m above the ground, width of 3m, length of 20m, and depth of grounding rods is 0.5m. In this model, panel wiring resistance of 2Ω has been considered in series connection with DC line. Power was transmitted to the Power Conditioning Subsystem (PCS), which was installed 17m away from the solar panel and 22m apart from DC cables, with 30m long insulated DC cables. Cables was placed on the ground with 0.1m thickness around it whose relative permittivity is 3 and separated by 0.1m distance having end open at the PCS side. The lightning channel is placed at the 17m away from the solar panel and 22m apart from PCS to represent as lightning stroke at nearby place.

In the analysis of VSTL, the simulation dimensions are 35.0m× 35.0m × 30.0m in the X, Y, and Z direction respectively. This space was divided into 270 ×170× 80 cells to shrink the calculation time. Soil was postulated homogeneously with resistivity 100Ωm and relative permittivity 10 in the Z direction of 10m height. In the six planes of the analysis space, Liao's second order absorbing boundary condition was established to keep open space [16]. The cell sizes for point of interest are kept 10cm and are increased gradually larger as they are further away from a point of interest. Therefore its ranges vary from 0.1 m to 1 m.

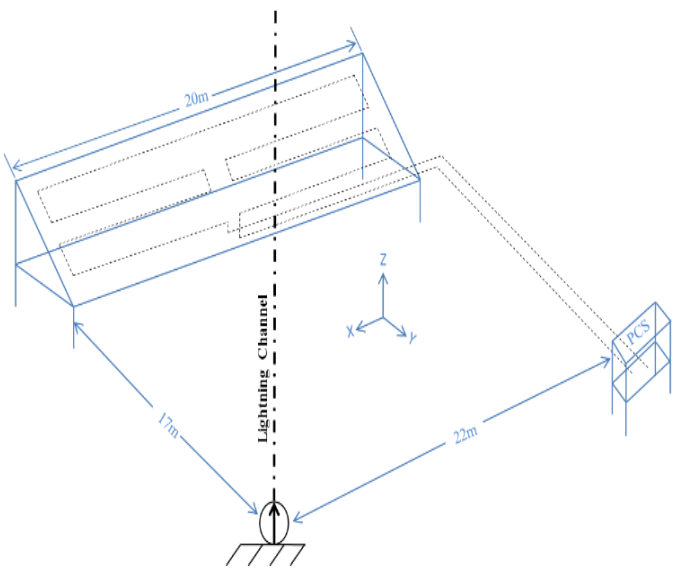

Fig. 1 Solar power system and lightning channel analytical model in VSTL

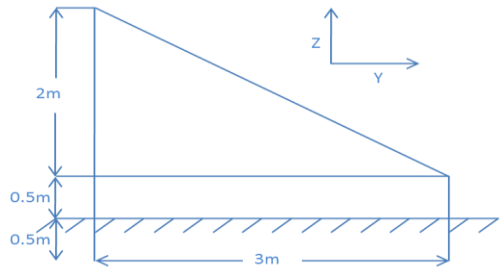

Fig. 2 Dimensions of solar panel installation from side view

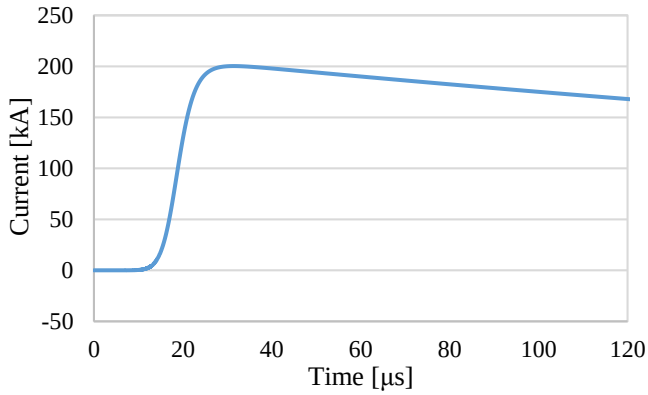
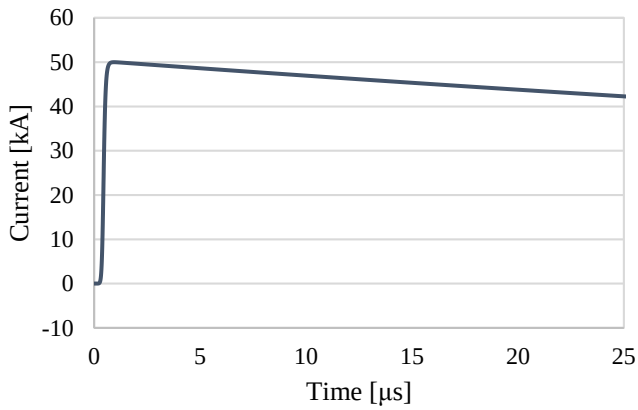


(a) First return-stroke current



(b) Subsequent return-stroke current

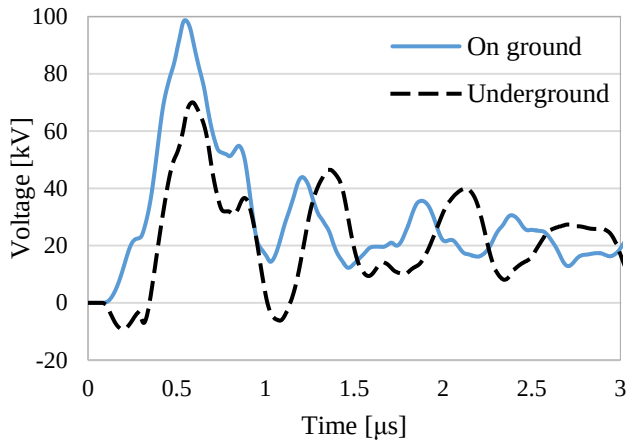
Fig. 3 Recommended test current [21] waveform for lightning (a) first return stroke current, 10/350μs, and (b) subsequent return-stroke current, 0.25/100μs.

Fig.3 shows the recommended test current waveform for lightning stroke. In our analysis, the subsequent return-stroke current was adopted because of high rising current i.e. the rate of change of current is very high compared to the first return-stroke current. Though the current magnitude of the first return stroke is 4 times that of the subsequent return-stroke, however induced voltage of subsequent return stroke current is severer than the first stroke current.

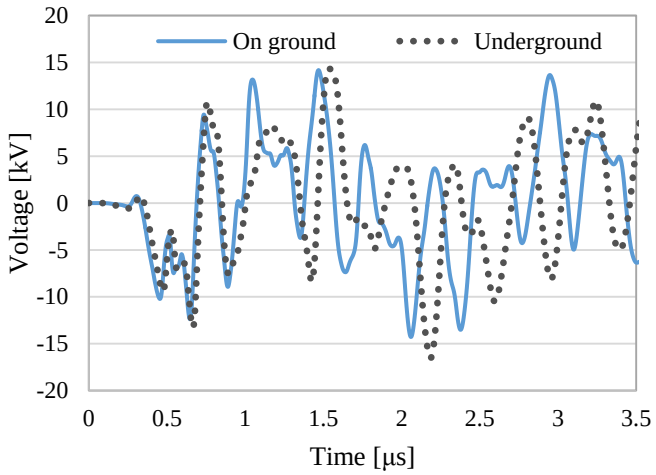
IV. Result and Discussion

A. *Effect of DC Power Cable Laying*

DC power cable which transfer power from solar panel to the PCS end can be set up on air or underground, for this reason the effect of induced overvoltage cause by nearby lightning was investigated on laying cables. The length of cable which was modelled with thin wire is 30m surrounded by 0.1m insulated cover. The insulation thickness is determined by the cell size in FDTD analysis.



(a) Line to PCS induced voltage (soil resistivity is 100**Ω**-m)



(b) Line to line induced voltage

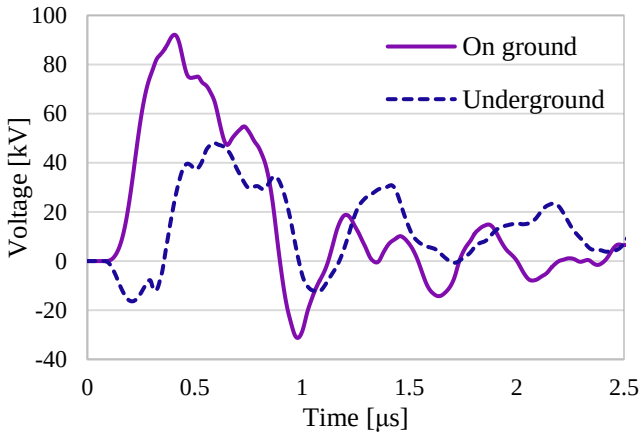
Fig. 4 Induced voltages on ground and 1m underground DC cables having soil resistivity 100**Ω**-m (a) Line to PCS and (b) Line to line.

The induced voltage on the cable depends on where it is placed; if the cables are placed on ground the voltage is higher than that of cable which is laid at 1m underground level. In Fig. 4(a), the maximum induced voltage on ground cable between line and PCS is 98.36kV at time 0.56µs with oscillating frequency 3.44MHz where peak induced voltage for underground cable is around 70kV which is 71.17% of the on ground cable voltage. Therefore underground cable reduces overvoltage 28.83% of the on ground cable induced voltage.

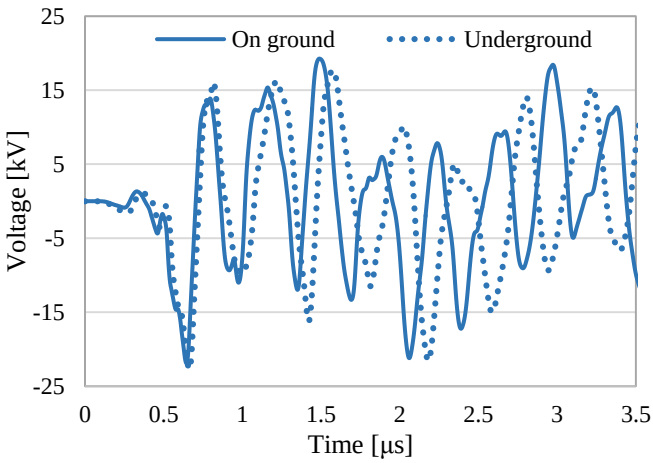
The line to line induced voltage for cable placed on ground and underground is more or less same where maximum voltage magnitude was recorded for underground is 16.5kV with oscillating frequency 4.55MHz. The reason behind is that voltage induced in the wires is similar nature except magnitude changes.

In Fig. 4 it is observed that line to PCS voltage is oscillating with high frequency i.e. MHz ranges because of sharp rising (0.25µs) injected current in the lightning channel as well as electric field reflection from the ground is more at the high rising time front of lightning test current.

In Fig 5 (a) indicates that induced overvoltage between line and PCS having soil resistivity 1000**Ω**-m is low comparatively with soil resistivity 100**Ω**-m. The line to PCS maximum overvoltage for cable placed on ground is found at time 0.41µs is around 92kV with oscillating frequency 3.13MHz, where underground cable voltage is only 47.38kV. The induced voltage of 1m underground cable is 51.5% of the on ground cables which shows voltage reduction 48.5%.



(a) Line to PCS induced voltage (soil resistivity is 1000**Ω**-m)



(b) Line to line induced voltage

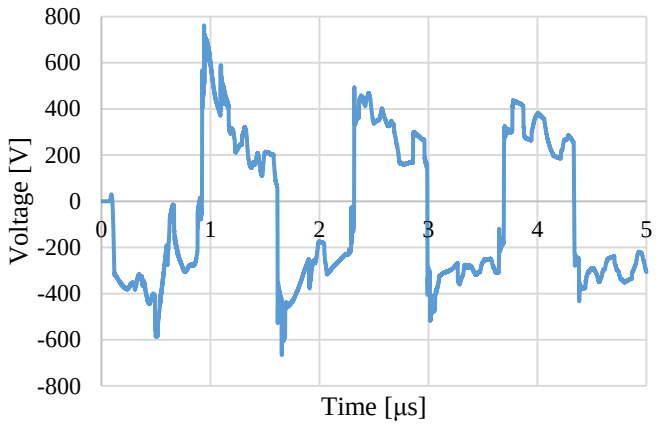
Fig. 5 Induced voltages on ground and 1m underground DC cables having soil resistivity 1000**Ω**-m (a) Line to PCS and (b) Line to line.

The line to line induced voltage is also more or less similar for both wires laying. The maximum magnitude of induced voltage for underground cable was observed at time 0.66µs is 22.62kV with oscillating frequency 3.12MHz.

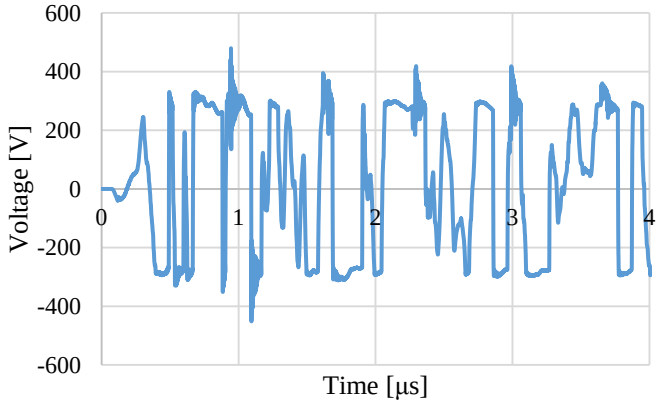
It is noticeable that with the increasing soil resistivity the induced voltage for line to PCS is reduced for both on ground and underground cables. Why? With the increasing soil resistivity; the behaviour of soil, which is inductive, is dominated that reflect the electrical field from the surface of the ground i.e. the penetration of electric field in the ground is less when soil resistivity is high. This is the reason why voltage is found in reduced form.

B. Design of Protection System

Surge Protection Device is used to limit the induced voltage/Overvoltage in the lines or electrical devices by passing surge current associated with surge voltage. In our analysis, SPD was installed between the wires of DC cables and between wires of DC cable and ground. The SPD model used in our study have an operating voltage V_{th}= 300V, resistance for preventing normal current to flow through SPD is 1M**Ω** and resistance that helps to flow current through SPD is 0.1**Ω**.



(a) Line to PCS induced voltage



(b) Line to line induced voltage

Fig. 6 After installing surge protection device in between line to line and line to ground for 1m underground cables having soil resistivity 100**Ω**-m, (a) Line to PCS induced voltage and (b) Line to line induced voltage.

Fig.6 (a) shows that induced voltage between line and PCS is reduced in normal voltage ranges where the maximum induced voltage because of nearby lightning was about 70kV at time 0.6μs with oscillation frequency1.43MHz for 1m underground cable with soil resistivity 100**Ω**-m. The maximum voltage amplitude between line and PCS after installing SPD is only 762V at time 0.94μs with 0.725MHz oscillation frequency, which abridged to 98.91% of the maximum voltage. In the case of line to line voltage, the maximum voltage amplitude was appeared at time 2.18μs is 16.52kV with oscillating frequency 4.55MHz for 1m underground cables with soil resistivity 100**Ω**-m; this voltage magnitude, after installing arrester, has been reduced to 480V with higher oscillating frequency11.11MHz. Hence, the voltage reduction in line to line is 97.10% after setting SPD between two DC power lines.

V. Conclusion

The effect of nearby lightning was investigated in two cases and their protection system was described with the help of VSTL. It is found that when DC cables are placed on ground the induced voltage is more, approximately 28.83%, than that of the underground cables while soil resistivity is 100**Ω**-m. The line to PCS induced voltage for underground cables having soil resistivity 1000**Ω**-m is found in extra reduction form nearly 48.50% less than that of the on ground cables. Therefore it can be concluded that underground cable line is preferable to limit the induced voltage from a nearby lightning strike. Moreover, we analysed protection scheme (Surge Protection Device, arrester) to overcome the induced overvoltage of the line to PCS and line to line for secure operation of the solar power system, and it is recommended that to use arrester in between line and ground to pass the overvoltage safely.

***Abstract*—Photovoltaic is a sustainable and environment friendly energy source. However due to dynamic changes in solar irradiance and temperature, this infinite and free energy cannot be converted with high efficiency. This paper illustrates a control strategy to design and implement Maximum Power Point Tracking (MPPT) in a photovoltaic system using Incremental Conductance algorithm. The PSIM simulation results verify proper functioning of the proposed MPPT sub-circuit. A constant 312V DC output is generated from irregular voltage of solar panel by changing the duty cycle of the MOSFET of the 24V-312V boost converter. The filtered output waveform of the SPWM driven H-bridge inverter via the L-C low pass filter is found to be a pure sine-wave of 312V_{peak} (220V_{rms}) and 50 Hz frequency with a total harmonic distortion (THD) of 0.002 which is significantly lower than the IEEE519 standard.**

***Keywords*—MPPT, Boost converter, PWM, H-bridge inverter, PSIM, SPWM, IncCond**

I. INTRODUCTION

The steep increase of the world's energy intake and the degradation of environmental conditions due to various energy generation processes, raise a burning concern for green and efficient energy production. Solar energy is one of the best solutions for energy crisis as it is inexhaustible and has a clean nature. As the solar panel outputs are irregular and vary with changes in irradiance, photovoltaic (PV) systems are continuously being made more efficient. Maximum Power Point Tracking (MPPT) techniques play a vital role to maximize the PV array output power in fluctuating conditions. MPPT is a fully electronic system that tracks the maximum power point of a PV module and tries to keep it at that point. The concept is to continuously monitor the terminal voltage and current, calculate the change in power simultaneously and then to take necessary steps to achieve Maximum Power Point [1]. Several algorithms exist for tracking MPP like Perturb and Observe (P&O), Incremental Conductance (IncCond), Neural Network, Current Sweep, Fuzzy Logic Method, etc [2], [3]. However, IncCond is more ideal as P&O method has certain disadvantages like the oscillations around MPP which result in tracking the MPP in the wrong direction during varying atmospheric conditions [4].

This paper demonstrates a control circuit for MPPT in a photovoltaic system using the IncCond method due to its simple implementation and high performance characteristics as described in section IIB. The proposed photovoltaic system is composed of a solar panel, a DC-DC boost converter driven by MPPT sub-circuit, an SPWM driven H-bridge inverter [5] and a low pass L-C filter to remove harmonics and produce a pure sine wave output with fundamental frequency of 50 Hz.

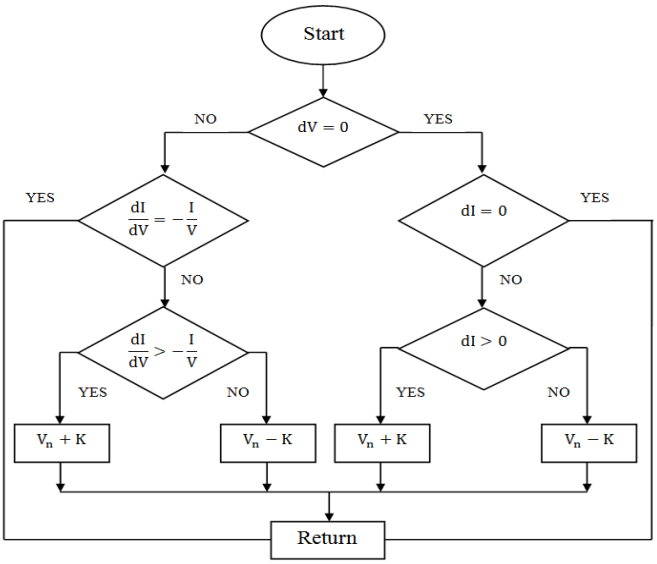

Fig. 1. Flow chart of InCond algorithm.

The topology is called incremental conductance because adjustment of the instantaneous voltage is done according to the MPP voltage which eventually is based on the incremental and instantaneous conductance of the PV module. The basic concept is that the slope of the P-V module power curve is zero at the MPP (dP/dV=0), greater than zero on the left side of MPP (dP/dV>0) and less than zero (dP/dV<0) on the right hand side of the MPP. Applying the chain rule for the derivative of products yields to dP/dV = [d(VI)]/ dV. As dP/dV=0 at MPP, the above equation could be written in terms of array voltage V and array current I and derive into dI/dV = -I/V.

The flowchart of the IncCond MPPT algorithm is shown in Fig.1. Initially, the values of instantaneous current (I_n) and voltage (V_n) are considered and then judged whether the change in voltage (dV) is zero, and if it is true then whether

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

change in current (dI) is equal to zero. If both are true then it means that the PV is operating at the MPP, so no change needs to be done [6]. However, if dI is positive then a constant voltage **K** is added to V_n and if dI is negative then a constant voltage **K** is deducted from V_n and this adjustment is done to move the array terminal voltage towards the MPP voltage.

On the other hand, if dV is not zero then it is checked whether dI/ dV is equal to –I/V. If it is true then no alteration needs to be done since this is the suitable condition at MPP. A constant voltage **K** is to be added or deducted to or from V_n if dI/dV is greater or less than –I/V respectively.

II. PROPOSED INVERTER

A. Photovoltaic Panel Modeling

Photovoltaic panel modeling is done using two physical models of solar modules and a triangular DC voltage source as shown later in Fig.6. The modules are positioned in series using capacitors and reverse parallel diodes to provide the desired input to the system. Furthermore, a triangular voltage source of 24 V_{p-p} with a diode in series is put in parallel with the panels to represent the fluctuating nature of solar panel's voltage.

B. MPPT Sub-Circuit

Here, the IncCond MPPT method is chosen to track the maximum power and the PSIM sub-circuit is divided into two parts for clear explanation. To perform IncCond algorithm, a series of values are needed initially and Fig.2 shows the first part. At first, this sub-circuit measures the change in voltage (dv) and it is turned into an absolute value which is eventually feed into the positive terminal of the comparator. If dv is not equal to zero then logic 1 will be the output otherwise logic 0. Correspondingly, with the same strategy it is determined whether di is equal to zero or not and whether di is greater or less than zero. For the last two cases a voltage of 1v is used in the negative terminal as the reference voltage instead of ground to obtain less oscillation. The fourth comparator determines whether di/dv>-i/v or di/dv<-i/v and the summer with the not gate calculates whether di/dv=-i/v.

Fig.3 shows the second part of the sub-circuit. Here A1, B1, C1 and D1 are the AND gates with inputs of no change condition and a NOT gate is used in front of each of them so that the value is inverted and no alteration is done if it is true. A3, B3, C3 and D3 will be 1 only when "no change conditions" are 0 and "change conditions" are 1. The input logic combination activates either V_n+K or V_n-K and this turns on the desired switch for either addition or subtraction of voltage to or from the V_n. The total voltage is then passed on to the fifth comparator which compares it with a DC reference voltage. The output of this comparator is the PWM control signal which is used to operate the boost converter. The proposed MPPT sub-circuit helped to achieve the 312V_{peak} ac at the inverter output from the fluctuating solar panel voltage (~24V) by varying duty cycle of the boost converter.

Figure 4(a) shows the 24 V_{p-p} half-wave triangular input voltage (V_n) which represents the fluctuating voltage of the solar panel. Here half-wave input is chosen so that the condition for no change can be examined. Fig. 4(b) shows the input current (I_n).The output voltage from the summer (V_{sum}) and a DC reference voltage of 15V(V_{ref}) are demonstrated in Fig. 4(c). For clear verification the frequency of V_n is chosen to be low as 25Hz and the timescale is fixed to 0.08s. Here **K** is considered as a high value just to verify clearly the addition and subtraction of voltage K from the instantaneous input voltage. Depending on the combination result the graph in Fig. 4(c). The PWM signal generated by the process is shown in Fig. 4(d), which is used for switching the boost converter.

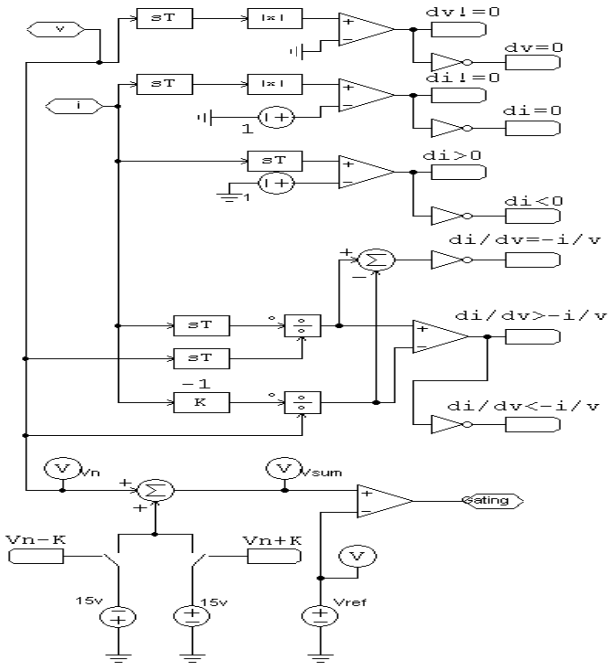

Fig. 2. Schematic diagram of MPPT sub-circuit in PSIM.

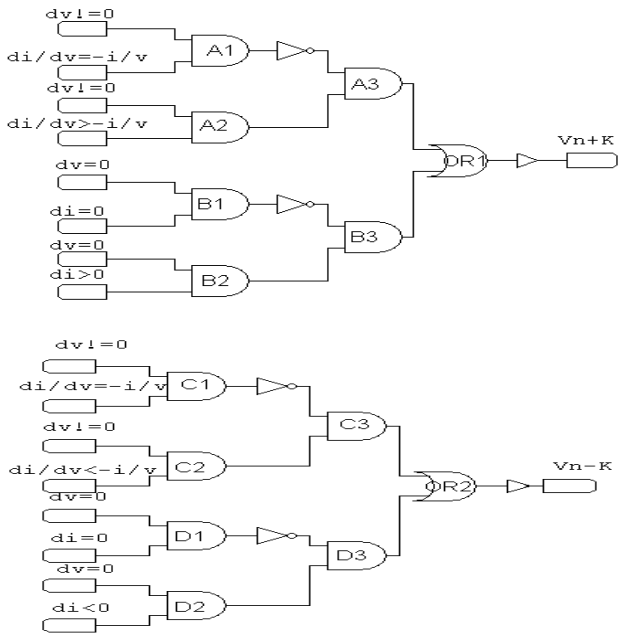

Fig. 3. Logic circuit of IncCond PSIM sub-circuit.

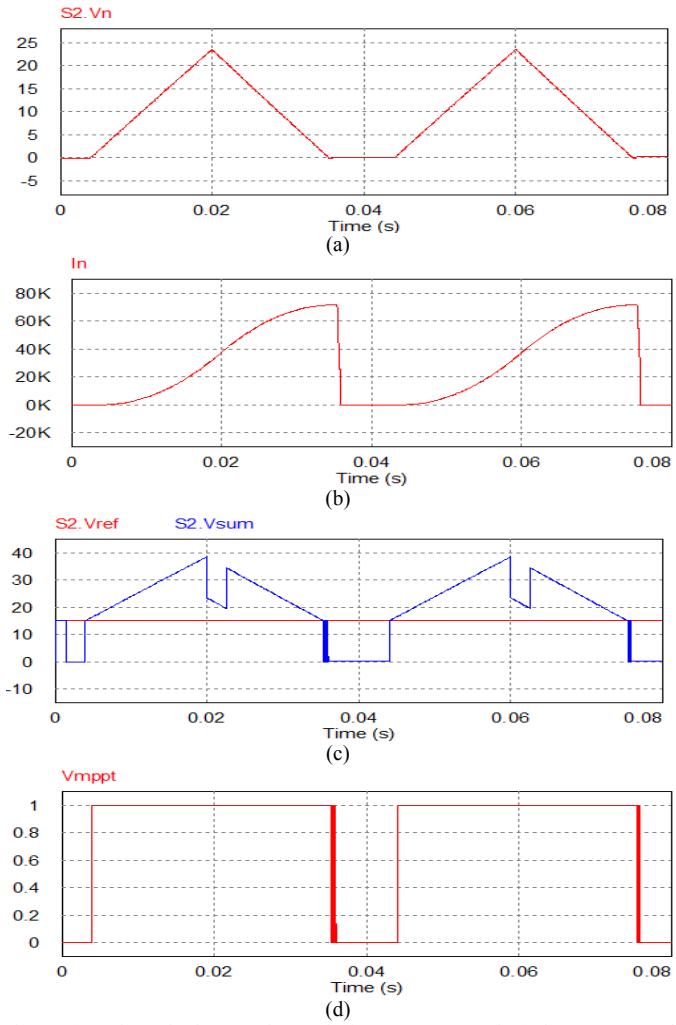

Fig. 4. (a) Triangular input voltage, (b) input current, and (c) the summer and reference voltages (d) PWM pulses to the boost converter.

C. DC-DC Boost Converter

To step up the unregulated voltage of the photovoltaic panel (~24V dc) to a desired output voltage for grid application (312V ac or 220V_{rms}) a boost converter has been designed and implemented. The designed parameters for the boost converter are listed in Table-I. The 312V output (V_{boost}) of the boost converter from a varying (~24V) dc source is demonstrated in Fig.5. Pulse width modulation (PWM) of gating signal is applied to the switch which is produced using the MPPT control strategy as described in section IIB. As the voltage fluctuates, the duty cycle also changes accordingly to produce the desired output voltage.

TABLE I. BOOST CONVERTER'S PARAMETERS

Symbol	*Actual Meaning*	*Value*
V_{in}	Given input voltage	24V
V_{out}	Desired average output Voltage	312V
f_s	Minimum switching frequency	21KHz
I_{LMax}	Maximum inductor current	230A
ΔI_L	Estimated inductor ripple current (2.6% of I_{LMax})	6A
ΔV_{out}	Desired output voltage ripple (0.1% of V_{out})	0.35V
I_{out}	Maximum output current(V_{out}/R)	10.4A

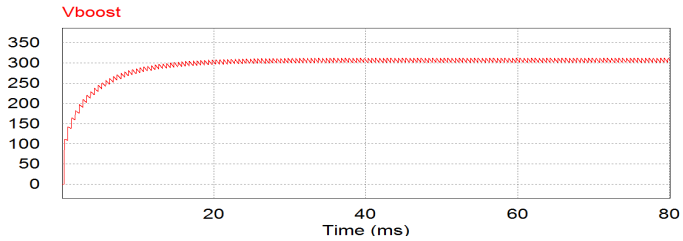

Fig. 5. Boost converter output.

D. H-bridge Inverter

An H-bridge inverter [6] is used to convert the 312V DC voltage of the boost converter to 312V_{peak} AC (220V_{rms}) voltage which matches the specifications for grid connection. Sinusoidal pulse width modulation (SPWM) is applied for operating the four transistors A,B,C and D.

E. Low Pass Filter

To match the output of the proposed PV system with the specification of the national grid of Bangladesh [6], an LC low pass filter is integrated in the design. The inductor and capacitor values of 95.95 mH and 106uF respectively are calculated using equations (1) and (2) for a characteristic impedance of 30Ω and a cut-off frequency of 50 Hz.

$$R = X_c = \frac{1}{2\pi f C} \quad (1)$$

$$f_c = \frac{1}{2\pi\sqrt{LC}} \quad (2)$$

III. RESULTS AND DISCUSSIONS

Figure 6 depicts the entire PSIM schematic of the proposed PV system. The non-sinusoidal output of the H-bridge inverter is shown in Fig.7(a), which contains high frequency components with a total harmonic distortion (THD) of 0.733. To achieve harmonics free output, a low pass L-C filter is incorporated with the proposed PV system. The 220V_{rms} and 50Hz pure sinusoidal output which emerges from low-pass LC filter is shown in Fig.7(b). After filtering, the THD significantly reduces from 0.733 to 0.002 which is much lower than the IEEE519 standard. The equation which is used to calculate THD is:

$$THD = \frac{\sqrt{Harmonics^2}}{Fundamental\ Voltage} \quad (3)$$

Fig. 8(a) and (b) shows the Fast Fourier Transform (FFT) of the inverter output before and after filtering. From the FFT analysis, it can be seen that extra harmonic spectra is present together with fundamental component at 50Hz. Nevertheless, after filtering the higher harmonics are seen to be vanished with only the 50 Hz component still remaining. This confirms that a pure sinusoidal wave has been produced.

The performance of the proposed photovoltaic inverter is tested by varying the output load from 5Ω to 100Ω at an interval of 5Ω as shown in Fig.9. The testing result shows that the output current remains almost constant with changing load, which confirms the applicability of the proposed PV system for dynamic loads.

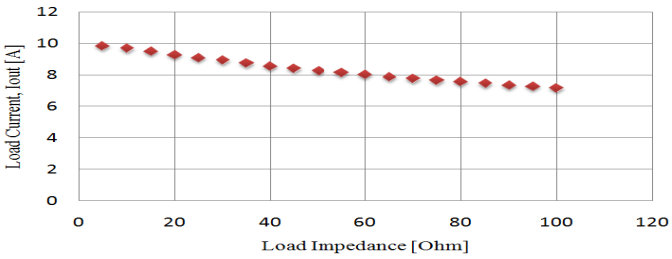

Fig. 9. Output current variations with increasing load.

IV. Conclusion

This paper demonstrates the design and simulation of a transformer-less PV system with an incorporated maximum power point tracking (MPPT). The designed MPPT circuit satisfies all the conditions of the IncCond algorithm and accurately adds or subtracts K voltage to the input voltage as per requirement of the situation. A perfect sinusoidal wave with 220 V_{rms} and 50 Hz is successfully achieved. After filtering, the THD is found to be 0.002 which is a lot lower than the IEEE 519 standard. The efficient functioning of the filter can be seen from the FFT of the inverter output prior to and after filtering. With varying load the output current remains more or less constant. This confirms the application of the proposed system for dynamic loads.

***Abstract*—The counterfeit coin problem is well-known and truly interesting in Computer Science, Game theory, and also in Mathematics. In this problem the objective is to detect the fake coin(s) of identical appearance but different weight in minimum number of comparisons. The word *counterfeit* most frequently describes forgeries of currency or documents, but can also describe software, pharmaceuticals, clothing, and more recently, motorcycles and cars, especially when these result in patent or trademark infringement. Finding one fake coin among *n* coins is tricky enough and complex. The problem becomes rigorous when there are two fake coins, as the false coin pair may form several different combinations that make the problem particularly tricky and complex to solve. In this paper we have developed a new algorithm for solving two versions of the two counterfeit coins problem in O(log *n*) time, where *n* is the number of coins given.**

Keywords: Coin counterfeiting; Problem; Weighing; Algorithm; Complexity; Applications.

I. Introduction

Computing a solution of the counterfeit coin problem has immense importance not only in theoretical domain but in commercial sphere as well to prevent forgery in different fields. The objective of a minimum number of weighing for which it is sufficient to determine the defective coin(s) in a set of n coins given that are identical in appearance but different in weight (either heavier or lighter than a true coin) using only an equal arm balance, when precisely the number of odd coins is known. In addition, the complexity of the problem increases with the increment of the number of false coins.

If p is the number of false coins in a set of n coins, it is not only sufficient to consider whether they are heavier or lighter than a true coin individually, but we must take into account their relative weights as well. In this paper we consider that there are two false coins in a set of n coins. By comparing the weight of the coins we have to detect the odd coins. Moreover, the objective is to identify the counterfeit coins using a minimum number of comparisons (or weighing) and also recognizing whether they are lighter or heavier in comparison to a genuine coin.

II. Literature Survey

In paper [4], the problem has been introduced in two ways. In the first case we do not know if there is a fake coin in the given set. The process is supposed to check it first, and if yes, then identify the targeted coin by means of a minimum number of weighing. In the second case, it is told that there is a counterfeit coin and the objective is only to find the coin through minimum number of weighing. At times, a standard coin may also be given.

In the first case, if a lighter coin is there in the given set S of n coins, then it is proved that the least number of weighing to find out the fake coin satisfies $3^{d-1} < n \leq 3^d$ for some unique value of d, where $|S| = n$, the cardinality of S. In the second case, we are given a set S of n coins plus a standard coin, where only one coin in S is of different weight. Then it is proved that $(3^{d-1}-1)/2 < n \leq (3^d-1)/2$.

Let S be a set of more than two coins, out of which only one is a counterfeit coin. In this case, the least number of weighing to find out the odd coin satisfies $(3^{d-1}-3)/2 < n \leq (3^d-3)/2$, for some sole value of d.

The paper claims that a lighter coin can be found in $\lceil \log_3 n \rceil$ weighing, if there are n coins in the set. Moreover, according to the paper, $\lceil \log_3(2n+1) \rceil$ is the complexity of the algorithm for solving the problem, if an additional standard coin is given; otherwise, the complexity is $\lceil \log_3(2n+3) \rceil$.

In paper [1], the problem has been addressed as an application of dynamic programming and the associated analysis has been made through optimal and suboptimal testing policy. Here also only one coin is defective out of n given coins. This technique always assumes $k < n$ coins in each pan for each weighing, where the value of k in effect depends on the value of n. If the two groups balance, the defective coin must be in the remaining $n-2k$ coins; otherwise, the false coin is in one of the k groups. After each weighing, the number of coins to be examined reduces, but the problem remains the same. This allows the authors to apply dynamic programming to this problem.

One classical solution is available in the form of a *decision tree* that represents a set of all possible decisions by which we can acquire the desired solution(s) of the problem [2, 3]. In this solution, each internal vertex (that is not a leaf vertex) symbolizes a comparison between a pair of equal sets of coins using an equal arm balance. Here the problem under consideration is more generalized; the fake coin can either be heavier or lighter. So, for n given coins, there are $2n$ leaf vertices in the tree as probable solutions.

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

In paper [5], the problem of ascertaining the minimum number of weighing that suffices to determine the false (heavier) coins in a set of n coins of the same appearance, given a balance scale and the information that there are exactly two heavier coins present, has been considered. Both the heavier coins are of equal weight and they are not heavier by 1½ times than a true coin. The paper developed an algorithm with lower bound $\lceil \log_3({}^nC_2) \rceil$ on p, where p is the maximum number of comparisons required to find out the two false coins that are equally heavier. In this paper, an infinite set of n coins has been determined for which this lower bound is reached, and the upper bound is at most one more than the lower bound attained.

III. Problem Formulation and the Algorithm

In this section, we formulate and develop a comprehensive algorithm to solve two counterfeit coins problem. Here we are to devise an algorithm to find two false coins among n coins. Two issues are to be considered in this context. The minimum value of n as given coins is important such that we can find out the two false coins among them and the kind of false coins as heavier and/or lighter are also computed without using any additional standard coin.

As a counterfeit coin means that it is either heavier or lighter than a true coin, finding out two false coins introduces several cases, i.e., different combinations of false coin pairs, such as heavier-heavier, lighter-lighter, heavier-lighter, etc. In our paper we shall consider the case where one false coin is heavier and another is lighter than a true coin. Let us consider that a true coin is denoted as T and its weight is w(T), whereas a heavier and a lighter coin are denoted as H and L, respectively. Then, $w(H)-w(T) = \Delta H$ and $w(T)-w(L) = \Delta L$ convey the following cases that may arise in practice: $\Delta H > \Delta L$, $\Delta H < \Delta L$, and $\Delta H = \Delta L$.

In this paper, the first two cases are considered to solve the problem of two coins counterfeiting. By the way, the following lemma tells about the minimum number of n given coins out of which $p < n$ coins are fake coins.

Lemma 1: To find p coins counterfeiting among n given coins, n must be as minimum as $2p+1$.

Proof: If there is one false coin out of two coins, a true coin must be provided to detect the false coin unless the weight of the correct coin is given. So if the number of false coin(s) $p = 1$, the minimum value of $n = 3 = 2p+1$. Now, if there are two false coins we can identify them from four coins if and only if the two false coins are of different weight. If they are of same weight, we cannot conclude which pair of coins are true, as there are equal number of false and true coins. So, for $p = 2$, the minimum value of $n = 5$ (i.e., same as $2p+1$).

In general, if there are p counterfeit coins we can detect them from $p+2$ coins only if all the p coins are of distinct weights, but if at least two false coins are of same weight we cannot distinguish them among the set of genuine coins and false coins. So, to satisfy the above cases, specially the case where all the false coins are of same weight we need at least one more true coin than the false coin, i.e., the minimum number coins required is $p+p+1 = 2p+1$. □

Our algorithm proceeds by dividing the coins into three subsets $K1$, $K2$, and $K3$ such that the cardinality of set $K1$ is equal to the cardinality of set $K2$ are equal. At first these sets are put on the two pans of an equal arm balance for weighing. Depending on the result of this weighing and the specification of the counterfeit coins, i.e., both are equally heavier or equally lighter or one is heavier than the other, etc. which we get, we decide the subsequent set(s) to be compared next.

The algorithm starts by considering the fact that any positive integer n can be assumed into either of the three categories as follows: (i) n is divisible by 3, i.e., $n|3$, (ii) $n+1$ is divisible by 3, i.e., $(n+1)|3$, and (iii) $n-1$ is divisible by 3, i.e., $(n-1)|3$. Thus, the set of n coins can easily be checked to which group it belongs to and precisely which variant of the algorithm can be applied on the given set of coins. We may presume that the coins are indexed by natural numbers 1 through n (on any sequence of n coins). For the first case, $|K1| = |K2| = |K3| = n/3$. For the second case, $|K1| = |K2| = (n+1)/3$ and $|K3| = n-2(n+1)/3 = (n-2)/3$. So, there is a difference of one coin between $K1$ (or $K2$) and $K3$. For the third case, $|K1| = |K2| = (n-1)/3+1 = (n+2)/3$ and $|K3| = n-2(n+2)/3 = (n-4)/3$. So, there is a difference of two coins between $K1$ (or $K2$) and $K3$.

After creating the sets $K1$, $K2$, and $K3$, at the beginning sets $K1$ and $K2$ are compared. Depending on the outcome, three versions of the algorithm proceed towards the next weighing taking different sets for finding out the false coins. At each internal node, some weighing is performed considering the result of its parent node. At a leaf node we perform two operations: OCPH(K_i) (OCPL(K_i)) that denotes the operation to locate one heavier (lighter) counterfeit coin in set K_i. We call it whenever we are sure that there is only one heavier (lighter) false coin in K_i. When we are convinced that there are two false coins in K_i, then the algorithm is recursively applied to set K_i, considering its steps of operation as TCP(K_i) in general; here OCP (TCP) ≡ one (two) counterfeit coin(s) problem.

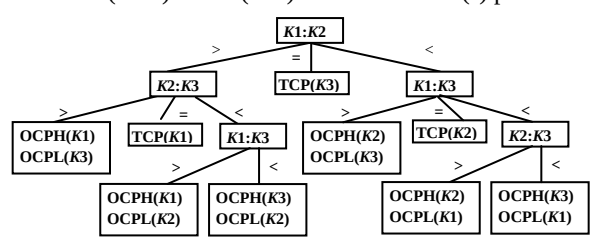

Fig. 1: The decision tree of the algorithm for $n|3$.

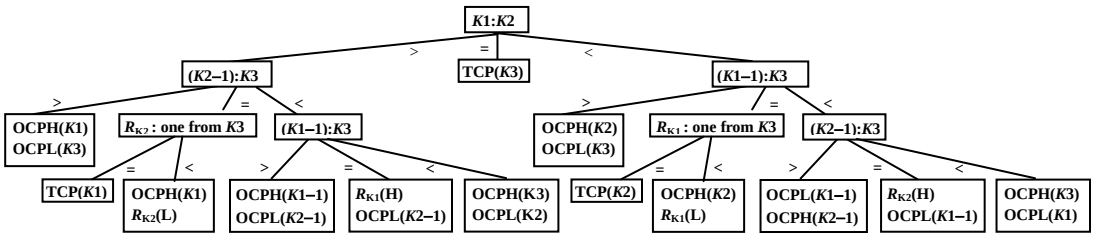
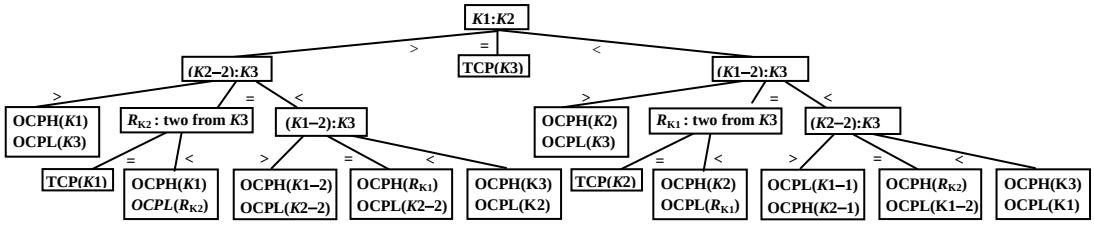
If $n|3$, then the decision tree that we obtain following the algorithm is shown in Fig. 1. At the root node, $K1$ and $K2$ are compared and the result is analyzed as follows. If $w(K1) = w(K2)$, then we are certain that they contain only true coins; this is because if any (one) pan contains at least one false coin, they would never equalize. Hence we can conclude that $K3$ contains both the false coins. So we perform TCP on the set $K3$ of coins. On the other hand, if $w(K1) > w(K2)$, then the possibilities are:

- $K1$ contains the heavier coin while $K2$ contains the lighter one and $K3$ contains only the true coins.



(a)



(b)

Fig. 2: (a) The decision tree of the algorithm for $(n+1)|3$. (b) The decision tree of the algorithm for $(n-1)|3$.

- Both the false coins are in $K1$, as the sum of the two false coins exceeds the sum of two true coins being $\Delta w(H) > \Delta w(L)$.
- $K1$ contains the heavier coin and $K3$ contains the lighter coin while $K2$ is the set of true coins only.
- $K1$ contains only true coins and $K2$ contains the lighter coin while the heavier coin is in $K3$.

Since $K2$ does not contain both the false coins (as $w(K1) > w(K2)$), next we check $K2$ against $K3$. If they are equal, $K1$ contains both the false coins and we call TCP($K1$). On the other hand, if $w(K2) > w(K3)$, the heavier coin must be in $K1$, as in the previous level of comparison $K1$ is heavier than $K2$ and the lighter coin is in $K3$. Accordingly, we call OCPH($K1$) and OCPL($K3$) at the leaf. If $w(K2) < w(K3)$, we are sure that the lighter coin is in $K2$ as this set is lighter than both $K1$ and $K3$, but to be definite of the heavier coin, we have to compare $K1$ and $K3$ now. If $w(K1) > w(K3)$, the heavier coin is in $K1$; otherwise, this is in $K3$. Following the result of this weighing, we either call OCPH($K1$) and OCPL($K2$), or OCPH($K3$) and OCPL($K2$) at the associated leaves.

When we call OCPL(K_i) or OCPH(K_i), the algorithm proceeds dealing with the set of coins(K_i) and we divide it into two equal subsets for further weighing. If this set contains even number of coins we put half of them on the left pan and the remaining half on the right pan and weighing (i.e., comparison) is performed. Again, if we are searching for a heavier coin at this stage, i.e., in case of OCPH(), after the weighing we deal only with the coins in the heavier pan. If the number is odd, we divide them into two equal halves and one coin remains out of weighing. If the weighing results in inequality, we focus on the pan with more weight for subsequent assessment.

The second variant of the algorithm is applicable when $(n+1)$ is divisible by 3. In this case the algorithm follows the same logic as for the version n|3 except the second level of comparisons, it takes $(|K2|-1)$ coins instead of $|K2|$ and $(K1-1)$ coins instead of $|K1|$. To make the algorithm deterministically faster, we always take the coins from set K_i except the last coin in the set. The comparisons in the successive levels are shown in the form of a decision tree in Fig. 2(a).

There is another difference of this version of the algorithm. In the left (or right) branch from the root of the decision tree, $K2-1$ (or $K1-1$) coins are compared to that of $K3$, and if it results in equality, we cannot conclude whether both the false coins are in $K1$ (or $K2$), though we are sure that $K3$ contains only true coins. The reason is that one coin from set $K2$ (or $K3$) is still remaining to be compared. So, in the third level, the remaining coin is compared to the first coin of $K3$ (which is obviously a true coin). Depending on the result of this comparison we can conclude that either both the false coins are in $K1$ (or $K2$) or a false coin is in $K1$ (or $K2$) and the other false coin is in $K2$ (or $K1$).

For $(n-1)|3$, the algorithm proceeds in the same way as for the version $(n+1)|3$ with a difference in the second level of comparison in the left and right branch of the decision tree. As $K3$ contains two coins less than that of $K2$ (or $K1$), it takes $(|K2|-2)$ (or $(|K1|-2)$) coins instead of $|K2|$ (or $|K1|$). The operations in the consecutive levels are depicted in the form of decision tree as shown in Fig. 2(b).

So far we have developed an algorithm to find out two false coins among a set of n given coins where one is heavier and the other is lighter satisfying the condition $\Delta H > \Delta L$. For the variant, i.e., $\Delta H < \Delta L$, the algorithm works as well. The only difference lies within the fact that the sum of both the false coins is less than the weight of two true coins. Considering this fact, the algorithm chooses the set to be weighed at each level of comparison.

IV. Experimental Results

In this section, we decide to accept some values for n such that it covers all the three categories for the subdivision of

n and calculate the average number of comparisons required. Here, we have considered all the possibilities, i.e., any coin may be a counterfeit coin, either heavier or lighter, and it could be placed at any indexed location of the given sequence of n coins. To compute the average case complexity we have to consider all the possible false coin pairs. Thus for a given value of n, there are ${}^nC_2$ pairs of combinations as for coin pair $\{i, j\}$, the ith coin could be heavier whereas the jth one is lighter, or the reverse. Hence, there are $2\times{}^nC_2$ leaves in the decision tree.

The results show that on an average the number of comparisons required is O(log n).

Table 1: The average number of comparisons to find out two counterfeit coins, for some values of n.

Number of coins, n	Total number of comparisons, S	Possible number of false coin combinations, C ($2\times{}^nC_2$)	Average number of comparisons, AVG = S/C

V. Computational Complexity

At each iteration, n is divided into nearly three equal parts, and the cardinality of the set of coins on which the operations are performed, always reduces by a factor of three. Let us consider the case $n|3$. As we see at the ith level each set is of cardinality $n/3^i$. Now if we reach to a set with five coins, then we can solve it using only four comparisons. So, let at ith level of comparison the cardinality of the set reduces to five. Thus, $n/3^i = 5$, i.e., $3^i = n/5$. Hence, $i = \log_3(n/5)$. Again, if TCP(K_i) is applied at each iteration before reaching a set with five coins, then $2\times i$ comparisons are required resulting in a total of $2\times i+4$ comparisons.

If OCPH(K_i) or OCPL(K_i) is applied at the kth level of comparison, then it is sure that before this iteration TCP() is applied for (k–1) times. We know that OCPH() or OCPL() requires $\lceil \log_2 n \rceil$ comparisons and at the kth level it is to be applied on $n/3^k$ coins. Hence, it would require total number of $2|K|+2\log_3(n/3^k)$ comparisons. So, in the worst case it would take $O(2|K|+2\log_3(n/3^k))$ + $O(2\times\log_3(n/5)+4)$, i.e., O(log n) comparisons as a whole.

VI. Applications of the Problem

The application of the problem under consideration is not only limited to coins, but to any kind of valued article that are frequently counterfeited, like ornaments, watches, metal (like gold), jewellery, etc. The word *counterfeit* most frequently describes forgeries of currency or documents, but can also describe pharmaceuticals, software, clothing, and more recently, motorcycles and cars, especially when these result in patent or trademark infringement.

Coin counterfeiting occurs regularly in the antique coin market, but there are various modern forgeries that also make it into general circulation [3, 4]. Counterfeit antique coins are generally made to a very high standard so that they often fool collectors; this is not easy and many coins still stand out.

VII. Conclusion

In this paper we have introduced an algorithm to detect two false coins among a set of n coins with identical appearance. In this case we have assumed that one of the false coins is heavier than the true coin while the other false coin is lighter. Two variations of the problem, i.e., the weight difference between the heavier and the true coin may be greater (less) than the difference in weight of the lighter and the true coin, may be solved using this algorithm. The algorithm solves the problem with time complexity O(log n). The very fact that the decision tree structure can be used to solve such problems of large size, by eliminating a part of the solution domain after each step of decision making, is of utmost importance. Especially as our algorithm works for any value of n, it does not matter if the value of n is not known a priori. This is, in fact, a new innovative work, and important in solving problems using the decision tree structure.

***Abstract*—Counterfeit coin problem is of utmost importance and it is truly interesting in Computer Science and Game theory as well as in Mathematics. In this problem the objective is to detect the fake coin(s) of identical appearance but of different weight in minimum number of comparisons. The word *counterfeit* is most frequently applicable to forgeries of currency or documents, but can also describe software, pharmaceuticals, clothing, and more recently, motorcycles and other vehicles, especially when these result in patent or trademark infringement. In this paper we have developed a new algorithm for solving two counterfeit coins problem in linear time, where *n* is the total number of coins given. However, this is the first algorithm that identifies and solves the problem, given the false coins with type ω(ΔH) = ω(ΔL), i.e., one false coin is heavier and another is lighter than a true coin, and their difference in weight from the true coin is equal. However, this is the degenerate case in the field of two counterfeit coins problem.**

Keywords: Counterfeit coin problem; Two coins counterfeiting; Weighing; Algorithm; Complexity; Applications.

I. Introduction

Computing a solution of the counterfeit coin problem has immense significance and relevance not only in theoretical domain but in commercial sphere as well to prevent forgery in different. The objective of a minimum number of weighing for which it is sufficient to determine the defective coin in a set of n coins given that are identical in appearance but different in weight (either heavier or lighter than a true coin) using only an equal arm balance, when precisely there is one odd coin present. By comparing the weight of the coins we have to detect the odd one. In this paper, our objective is to identify two false coins using a minimum number of comparisons when the surplus amount in a heavier coin is same as the amount deficient in a lighter coin comparing a true one.

II. Literature Survey

In paper [1], the problem has been introduced as an application of dynamic programming and the associated analysis has been made through optimal and suboptimal testing policy. It also considers single counterfeit coin problem. This technique always assumes $k < n$ coins in each pan for each weighing, where the value of k essentially depends on the value of n. If the two groups balance, the flawed coin must be in the remaining $n–2k$ coins; otherwise, the false coin is in one of the k groups. After each weighing, the number of coins to be examined reduces, but the problem remains the same. This allows the dynamic programming concept to solve this problem.

In paper [4], the author introduces the problem in two ways. In the first case, it is not sure whether there is a fake coin in the given set. The algorithm is supposed to check it first, and if any, then identify the false coin by means of a minimum number of weighing. In the second case, it is known that there is a counterfeit coin and the objective is to find the coin through minimum number of weighing. At times, a standard coin may also be given. In the first case, if a lighter coin is there in the given set S of coins, then it is proved that the least number of weighing to find out the fake coin satisfies $3^{p-1} < |S| \leq 3^p$ for some unique value of p, where $|S| = n$ is the cardinality of set S. In the second case, we are given a set S of coins plus a standard coin, where only one coin in S is of different weight. Then it is proved that $(3^{p-1}–1)/2 < |S| \leq (3^p–1)/2$.

Let S be a set of more than two coins, out of which only one is a counterfeit coin. In this case, the least number of weighing to find out the odd coin satisfies $(3^{p-1}–3)/2 < |S| \leq (3^p–3)/2$, for some sole value of p. The paper claims that a lighter coin can be found in $\lceil \log_3 k \rceil$ weighing, if there are k coins in a set. According to the paper, $\lceil \log_3(2k+1) \rceil$ is the complexity of the algorithm for solving the problem, if an additional standard coin is given; otherwise, the complexity is $\lceil \log_3(2k+3) \rceil$.

In papers [2] and [3], one classical solution for single counterfeiting is available in the form of a *decision tree* that represents a set of all possible conclusions by which we can acquire the desired solution(s) of the problem. In this tree, each internal vertex (that is not a leaf vertex) symbolizes a comparison between a pair of same number of coins using an equal arm balance. Here the problem under consideration is more generalized; the fake coin can either be heavier or lighter. So, for n given coins, there are $2n$ leaf vertices in the tree as probable solutions.

In paper [5], the problem of discovering the minimum number of weighing that suffices to determine the forged (heavier) coins in a set of n coins of the same appearance,

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

given a balance scale and the information that there are exactly two heavier coins present, has been considered. Moreover, both the heavier coins are of equal weight and they are not heavier than 1.5 times than a true coin. If P is the maximum number of comparisons required to find out two false coins (equally heavier), the paper introduces an algorithm which has the lower bound $\lceil \log_3({}^nC_2) \rceil$. In this paper an infinite set of n coins, has been determined, for which this lower bound is reached, and the upper bound computed is merely one more than the lower bound.

III. Problem Formulation and the Algorithm

In this section, we formulate an effective algorithm to solve two counterfeit coins problem, i.e., to find two false coins among n coins. Two issues are to be considered in this context. The minimum value of n such that we can find two false coins among them without using any spare genuine coin and the kind of false coins, i.e., heavier and/or lighter than a true coin through their mutual comparisons of weight. The term 'mutual comparison' is explained as follows.

By a false coin we mean that it is either heavier or lighter than a true coin. Finding out two false coins introduces several cases, i.e., different combinations of false coin pairs. Let T denote a true coin whose weight is w(T). Also heavier and lighter coins are denoted as H and L, respectively. Then, $\omega(H)-\omega(T) = \omega(\Delta H)$ and $\omega(T)-\omega(L) = \omega(\Delta L)$. Two coins counterfeiting introduces several other cases but when $\omega(\Delta H) = \omega(\Delta L)$, it becomes very much troublesome in the sense that the false coin pair always gets the weight-sum of two true coins. Thus at any level of weighing if the false coin pair is at one side of the balance, from that weighing we possibly fail to conclude about the pan where both the false coins may reside. In this paper we consider the case where one false coin is heavier and the other is lighter than a true coin and their individual difference in weight from a true coin is equal, which is the most typical case in the realm of two counterfeit coins problem as we are even puzzled about a set of coins that may contain them.

The algorithm begins by dividing the coins into three sets $K1$, $K2$, and $K3$ such that the cardinality of set $K1$ and $K2$ are equal. At first $K1$ and $K2$ are put on the arms for weighing. Depending on the result(s) of this weighing and the specification of the counterfeit coins, we decide to choose the set that (may) contain the false coin(s).

The algorithm also considers the fact that any positive integer n can be categorized into either of the following three cases: (i) n is divisible by 3, i.e., $n|3$, (ii) $n+1$ is divisible by 3, i.e., $(n+1)|3$, and (iii) $n-1$ is divisible by 3, i.e., $(n-1)|3$. Thus, the set of n coins can easily be checked to which group it belongs to and precisely which variant of the algorithm can be applied on the given set of coins. We assume that the coins are indexed by natural numbers 1 through n. For the first case, $|K1| = |K2| = |K3| = n/3$. For the second case, $|K1| = |K2| = (n+1)/3$, and $|K3| = n - 2(n+1)/3 = (n-2)/3$. So, there is a difference of one coin between sets $K1$ (or $K2$) and $K3$. For the third case, $|K1| = |K2| = (n-1)/3+1 = (n+2)/3$ and $|K3| = n-2(n+2)/3 = (n-4)/3$. Hence, there is difference of two coins between $K1$ (or $K2$) and $K3$.

After creating the sets $K1$, $K2$, and $K3$, $K1$ and $K2$ are first compared. Depending on the outcome, three versions of the algorithm proceed towards the next weighing taking different sets. At each internal vertex some weighing are performed considering the result of its parent vertices. At each leaf vertex we perform two operations: OCPH(K_i) (OCPL(K_i)) that denotes the operation to find one heavier (lighter) counterfeit coin in set K_i being sure that there is only one heavier (lighter) coin in K_i . When we know that there are two false coins in K_i, the algorithm is recursively applied to K_i, considering its version TCP(K_i) that tells that set K_i contains both the counterfeit coins.

If $n|3$, then the decision tree we obtain for this version of the algorithm is shown in Fig. 1. At the root of the tree, $K1$ and $K2$ are compared and the result is analyzed as follows. If $\omega(K1) > \omega(K2)$, there are several possibilities:

- The heavier coin may be in $K1$ whereas the lighter coin may be in $K2$.
- The heavier coin may be in $K1$ but $K2$ contains only true coins.
- The lighter coin may be in $K2$ but $K1$ contains only true coins.
- Both the false coins are definitely not on the same pan.

Now we like to check the type of the coin set $K3$ by comparing it with set $K2$. So in the second level of comparison if we obtain $\omega(K2) > \omega(K3)$, again there are some possibilities:

As set $K2$ can never contain a heavier coin, from the outcome of this comparison it is clear that set $K2$ is the set of true coins only. Hence, $K3$ certainly contains a lighter coin and $K1$ definitely contains a heavier coin. Thus, OCPL($K3$) and OCPH($K1$) are applied.

Again, if at the second level of comparison we find that $\omega(K2) < \omega(K3)$, then no further information is gained for $K2$ as at the root level comparison it is clear that it can contain either only true coins or a lighter coin, and $K3$ contains either only true coins or a heavier coin. Thus we go on the third level, and compare $K1$ and $K3$.

If $\omega(K1) > \omega(K3)$, $K3$ cannot contain a heavier coin and thus it is the set of true coins only and a heavier coin is in set $K1$ and $K2$ contains a lighter coin. So, we apply OCPH($K1$) and OCPL($K2$). If $\omega(K1) < \omega(K3)$, then $K1$ contains only true coins as it would never contain a lighter one. So, a heavier coin is in set $K3$ and a lighter coin is in set $K2$, and hence we apply OCPH($K3$) and OCPL($K2$).

Now we check the root level comparison when $\omega(K1) < w(K2)$; we compare $K1$ and $K3$ at the second level.

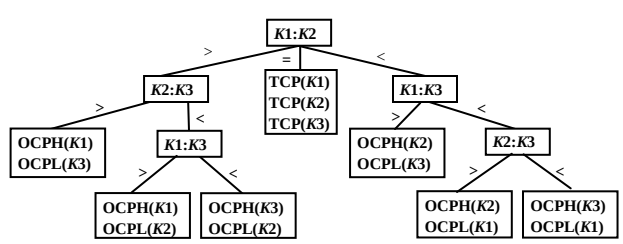

Fig. 1: The decision tree of the algorithm when $n|3$.

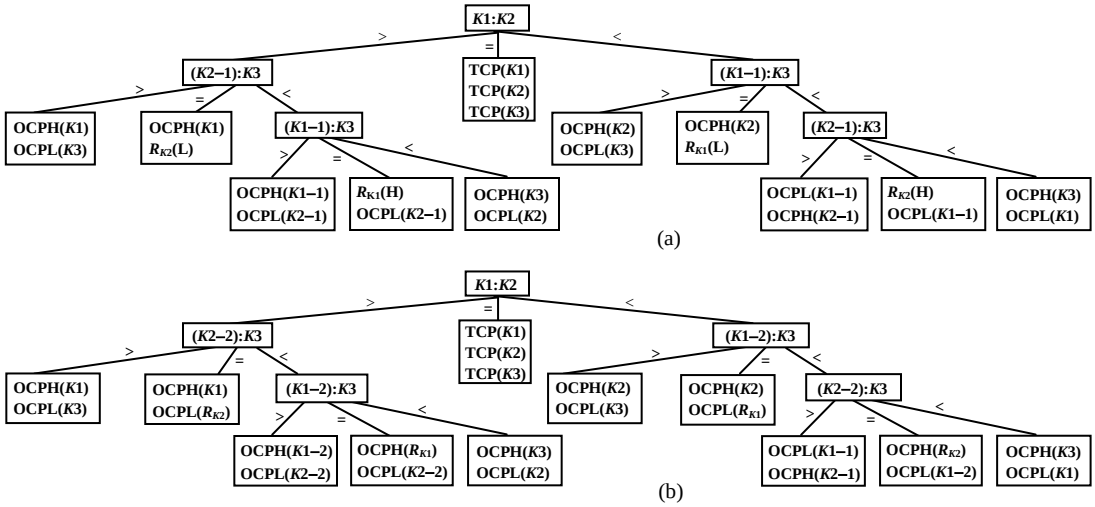

Fig. 2: (a) The decision tree of the algorithm for $(n+1)|3$. (b) The decision tree of the algorithm for $(n-1)|3$.

As previously addressed, we consider the possibilities and apply the same logic to reach at a leaf vertex where OCPH() and OCPL() are called for the respective sets of coins in K_i.

The expected most critical situation occurs if at the root level we find $\omega(K1) = \omega(K2)$, then we know both $K1$ and $K2$ are the true coin sets (and $K3$ contains both the false coins), or both the false coins are in any one of the sets $K1$ and $K2$. So, there is no scope in the reduction of sample space. Hence, we have to apply TCP() on the three sets $K1$, $K2$, and $K3$ one after the other. It may so happen that TCP(K_i) reports both the false coins or no existence of the false coins in K_i. We also apply TCP(K_{i+1}) if and only if TCP(K_i) reports that K_i contains no false coins.

If $(n+1)|3$, the algorithm does the same thing as for the version n|3 except the second level of comparisons; it takes only $(|K2|-1)$ coins instead of $|K2|$ and $(|K1|-1)$ coins instead of $|K1|$. For the sake of ensuring determinism we always take the first $|K_i-1|$ coins from the set K_i. The operations or tasks executed in the consecutive levels are depicted in the decision tree as shown in Fig. 2(a).

There is another difference of this version from the previous one. In the left (or right) branch from the root, $K2-1$ (or $K1-1$) coins are compared to that of $K3$, and if they result in equality, a false coin is in $K1$ (or $K2$) and the other false coin is in set $K2$ (or $K1$). If $\omega(K2-1) < \omega(K3)$, we are certain that the lighter coin is in set $K2$ or set $(K2-1)$. To be definite about the heavier coin, we compare $(K1-1)$ coins with that of set $K3$ at the third level. If $\omega(K1-1) > \omega(K3)$, the heavier coin is in $(K1-1)$; or else, it is in $K3$. If this is not the case, the remaining coin of set $K1$ that has not been weighed in the third level of comparison, is the heavier coin. Accordingly, OCPH() is called on the corresponding set of coins.

The algorithm for the values of n satisfying $(n-1)|3$ proceeds in the same way as for the version $(n+1)|3$ with a little difference in the second level of comparison in the left and right branches of the decision tree. As $K3$ contains two coins less than that of $K1$ or $K2$, it takes $(|K2|-2)$ coins instead of $|K2|$ and $(|K1|-2)$ coins instead of $|K1|$. The operations performed in the consecutive levels are revealed in the decision tree shown in Fig. 2(b).

IV. Experimental Results

In this section, we settle on using some relevant values of n such that it covers all the three categories for the subdivision of n and calculate the average number of comparisons required. Here, we have considered all the possibilities, i.e., any coin may be a counterfeit coin, either heavier or lighter, and it could be placed at any indexed location of the given sequence of n coins. To compute the average case complexity, we have considered all the possible false coin pairs. Thus, for a given value of n, there are $2\times{}^{n}C_2$ combinations as ith coin heavier and jth coin lighter is different from the combination ith coin lighter and jth coin heavier. Hence, there are $2\times{}^{n}C_2$ leaves in the decision tree. The results in Table 1 show that on an average the number of comparisons required is O(log n).

Table 1. Average number of comparisons for different values of n.

Number of coins, n	Total number of comparisons, S	Possible number of false coin combinations, $C = 2\times{}^{n}C_2$	Average number of comparisons, AVG = S/C
3	16	6	2

V. Computational Complexity

At each iteration, n is divided into three nearly equal parts, and the cardinality of the set of coins on which the operations are essentially performed, always reduces by a factor of three. We notice that at the ith level each reduced set has cardinality $n/3^i$. The best case occurs when the root level comparison results in inequality. The subsequent comparisons lead to a leaf node where only OCPH() and OCPL() are applied on two different sets and each of them takes O(log n) time. OCPH() or OCPL() can be applied at one of the leaves that takes at most three comparisons from the root vertex which is a constant. Hence the best case complexity is O(log n).

On the other hand, if the root level comparison results in equality, all the coin sets are suspected to contain the false coin pairs. Thus the sample space to be further considered is not reduced. In our algorithm, TCP(K_i), TCP(K_{i+1}), and TCP(K_{i+2}) are applied sequentially only when the first comparison shows equality in each recursion of TCP(). As at the beginning we divide the initial set into $K1$, $K2$, and $K3$, we call TCP($K2$) if and only if TCP($K1$) reports 'no false coin', and we call TCP($K3$) if and only if both $K1$ and $K2$ contain no false coin. Now if we reach to a set with only 5, or 4, or 3 coins, then we may conclude whether the corresponding set contains either both the false coins or none of them. It takes at most four comparisons. Thus, in the worst case to find the two false coins we have to apply TCP() on $K1$, $K2$, and $K3$ that requires O(n) time.

Lemma 1: The algorithm for two coins counterfeiting takes linear time, when $\omega(\Delta H) = \omega(\Delta L)$.

Proof: We assume that the algorithm uses only equal number of coins on both the pans. The case $\omega(\Delta H) = \omega(\Delta L)$ leads to a confusion as the sum of the weights of two false coins of that kind results in the weight-sum of two correct coins. If there are n coins in a set, there are at most $2\times{}^{n}C_2$ combinations of the two false coins' position in any indexed sequence of n coins. Now at any instant of the algorithm, there might have equal number of coins shared by two pans of the equal arm balance, and hence both the false coins may reside in any one of the pans. The purpose of this algorithm is to verify two sets of coins together and depending on the weighing it proceeds to the next step by reducing the number of coins in each set next to be considered for further checking. However, if both the false coins are always in one set, i.e., in one pan, the checking of the sets results in equality. If we divide the given set of coins into $p \leq n/2$ subsets and weigh them pairwise, we may get all these sets equal in weight. Thus, the weighing process may result in equality until we reach a case where a set of coins under concern has only one false coin that certainly results in inequality; here the false coins may share the pans or at least one of them must be in one pan. Hence, the sample space cannot be reduced below a factor of n. So, running time of the algorithm is linear. □

VI. Applications of the Problem

The word *counterfeit* most frequently describes forgeries of currency or documents, but can also describe software, pharmaceuticals, clothing, watches, effigies, and recently bikes and automobiles, especially when these result in intellectual property like patent or trademark infringement. Coin counterfeiting occurs regularly in the antique coin market, but there are various modern forgeries that also make it into general circulation [1, 3]. Counterfeit antique coins are generally made to a very high standard so that the collectors often become fool; this is not easy and many coins still be conspicuous. The application of the problem under consideration is not only limited to coins, but to any kind of valued article that are frequently counterfeited, like ornaments, timepieces, metal (like gold), jewellery, etc.

VII. Conclusion

In this paper we have introduced an algorithm to detect two false coins among a set of n coins with identical appearance. In this case we have assumed that one false coin is heavier and the other is lighter than a true coin and their difference in weight from the true coin is equal. We addressed that this is the most critical case in the domain of two coins counterfeit for its inherent characteristics. This is the first algorithm that considers this type and solves the problem in linear time. The very fact that the decision tree structure can be used to solve such problems of large size, by eliminating a part of the solution domain after each step of decision making, is of utmost upshot. Especially as our algorithm works for any value of n, it does not matter if the value of n is not known a priori. This is, in fact, a new innovative work, and important in solving problems using the decision tree structure.

***Abstract*—We investigate the current state-of-art performance of lattice reduction algorithms. We perform experiments to examine the limit of the practical lattice reduction algorithms such as Recursive-BKZ. We report a better attack on SWIFFT lattices based on a recent improvement of BKZ reduction. We also participate in several lattice challenges that evaluate the performance of the lattice-reduction algorithms. Our experimental results thus compare and sometimes concretize the previous similar work in this area.**

***Index Terms*—Cryptosystem, Lattice Reduction, Lattice Challenge, BKZ, SWIFFT.**

I. Introduction

The *Lattices* we are interested in are integer or point lattices; discrete subgroups of $\mathbb{R}^n$. A lattice L is defined as all integer linear combinations of some linearly independent vectors $(\mathbf{b}_1, ..., \mathbf{b}_n)$ of the form: $\sum_{i=1}^{n} x_i \cdot \mathbf{b}_i$, where $x_i \in \mathbb{Z}$ for all i. The vectors $(\mathbf{b}_1, ..., \mathbf{b}_n)$ are called a basis of the lattice. The number of vectors n is the dimension of the lattice L.

The goal of lattice reduction is to find a "good" basis for the applications which is usually the one that contains short vectors. Clearly, it is an interesting problem to find a short basis or even to try to find a shortest basis. The SVP or Shortest Vector Problem is the most common and fundamental algorithmic lattice problem on which many cryptosystems rely. It is an NP-hard problem under randomized reductions [2].

Lattice problems are considered to be building blocks in many public-key cryptographic constructions. The most significant examples of cryptographic constructions that use lattices include: public key encryption based on knapsack problem; variant of RSA and DSA signatures schemes; encryption schemes based on LWE (Learning with Error) problems [3]; fully homomorphic cryptosystems [4]; the SWIFFT hash function [5] as well as many others. If one knows how to solve lattice problems, then one can break some cryptosystems.

Lattice reduction algorithms are one of the few exciting recent techniques in cryptography. The most popular lattice reduction algorithms are the LLL (Lenstra-Lenstra-Lovász) [6] and BKZ (Block Korkine-Zolotarev) [7] algorithms and their variants. They are called *approximate algorithms*; another category is known as *exact algorithms* includes Enumeration.

In this paper, we perform extensive experiments with the variants of BKZ algorithm. We study similar experimental work and summarize their results to better understand the current state of the practical lattice reduction algorithms. We evaluate one of the best variants of BKZ (aka Recursive-BKZ) through our participation in several Lattice Challenges[1]. Finally, we use the algorithm to improve the attack time in one of the SHA-3 contestant[2], SWIFFT hash function.

II. Related Experimental Work

In this section we review some of the experimental work on lattice reduction for various types of lattices. The first two works are on random lattices, followed by the work on SIS lattice and ideal lattice.

A. Gama-Nguyen Experiments

In 2008, Gama and Nguyen reported the results of their experiments on the actual behaviour of lattice reduction algorithms. The result published in [8] has been widely accepted since then and cited in several similar works. The experiments reveal the state of lattice reduction algorithms in terms of their efficiency and the accuracy of solutions. The work helps to close the gap between the theory and practice. One of the conclusions is that in a higher dimension, say $n > 100$, the Hermite factor (quality of reduction) achievable is no better than $\sim 1.01^n$. Interestingly, It is still more or less true for current lattice reduction techniques.

In their experiments, Gama and Nguyen used random lattice of instances at least 20 to get an average behaviour (reduction quality and time). The experiment is conducted on the NTL package [9] with version-5.4.1 on 1.7 GHz (64-bit processor) machine. The average Hermite factor they achieved for BKZ-28 is approximately 1.0109^n. They determined the experimental complexity for both the exact algorithm (exhaustive search in the enumeration [7]) and the approximate algorithm (BKZ). Using enumeration they were able to solve SVP within an hour for dimension 60 with BKZ-25 preprocessing. But the graph they constructed demonstrates that the algorithm fails to solve SVP instances of the dimension bigger than 100. For the BKZ algorithm they experiment with dimension (n) as high as 200 and block size, $k \in (10, 40)$. A summary of their results is given in Figure 12 and Figure 13 in [8]. It shows the average runtime required for higher dimension (≥ 100) with moderate block size (≤ 30) and for smaller dimension (< 100) with higher block size (> 30). They noticed a sudden increase of runtime for block around 20 to 25 in high dimension and this is because of the huge number of calls to the enumeration routine. This invalidates the use of higher block size with a high dimension for the original BKZ algorithm.

B. Schneider-Buchmann Experiments

The goal of the experiments performed by Schneider and Buchmann in [10] was to go beyond the results of Gama-Nguyen [8]. They experiment with the same BKZ lattice reduction algorithm using random lattices. Another goal was to find the right parameter (blocksize etc.) for the BKZ algorithm. In particular, they revisit a common practice in BKZ reduction, namely the increasing or progressive blocksize approach. The idea is to start from a smaller block and increase the blocksize successively on the same full-basis until a desired Hermite factor is achieved. They conduct an experiment to compare the performance of this approach with the normal approach (i.e. to start with a fixed higher blocksize). Their experiment shows that the direct or fixed block approach performs slightly better than the increasing blocksize approach for both quality and runtime.

We know that for a high dimension, the use of a large block size is far from being practical for current algorithms which is also mentioned in [8]. Schneider and Buchmann provide evidence confirming the observation by running experiments for 5 instances of random lattices using the NTL software. For dimension 90 and blocksize 50, on the average the required runtime is approximately 12 days.

They also show an approach to obtain the Hermite factor achievable for a particular block size. Using curve fitting and extrapolation on the graph of Hermite factor versus block size, they find the following function:

$$\delta(k) = 1.01655 - 0.000196185 \cdot k \tag{1}$$

where $\delta(k) = \left(\frac{\|\mathbf{b}_1\|}{\mathrm{vol}(L)^{1/n}}\right)^{1/n}$ is the root-Hermite factor for blocksize k and dimension n.

C. Buchmann et al. Experiments

In [11] Buchman et al. proposed a method to generate hard lattice instances. Their proposal is based on the popular construction of Ajtai [12] and therefore also relates to the SIS problem. They first launched the *lattice challenge* (see next section) site based on these hard lattices (*aka* SIS lattice) to solve the SVP problem. The goal was to evaluate the performance of the current lattice reduction algorithms. Based on the experiment of Micciancio and Regev in [13], they generated a table (Table 1 in [11]) to find the necessary root-Hermite factor δ_m required for a parameter set (lattice dimension m, reference dimension n and a modulus q). The table showed that for a SIS-lattice of dimension 700, the required δ_m is equivalent to 1.0055. They performed an experiment with NTL (version 4.3.2) on AMD Opteron 2.6 GHz single-core processor. They found that for dimension 700 using BKZ-20, the short vector length is approximately 148, which is equivalent to a root-Hermite factor of ≈ 1.0062. The corresponding runtime is $\approx \mathrm{e}^{8.5}$ in seconds.

D. Plantard-Schneider Experiments

Plantard and Schneider proposed the third challenge in this series on ideal lattices. In [14], they describe the rules of participating in this challenge with some practical experiments on ideal lattices. Recall that an ideal lattice is defined as a polynomial ring over integers. It has special properties and therefore experimental evidence is required to investigate this effect for major algorithms. They experiment with multiple instances of ideal lattices on AMD Opteron platform with 2.3 GHz processor.

TABLE I
SUMMARY OF RECENT PUBLISHED RESULTS ON BKZ REDUCTION

Reference	Lattice	Dim. (n)	Block (k)	Hermite Factor	Runtime [s]
Gama-Nguyen [8]	Random	120	28	$\sim 1.0109^n$	$\sim$ 32500
Schneider-Buchmann [10]	Random	300	15	$\sim 1.0137^n$	$\sim$ 5700
Buchmann et al. [11]	SIS	700	20	$\sim 1.0062^n$	$\sim$ 5500
Plantard-Schneider [14]	Ideal	100	30	$\sim 1.011^n$	$\sim$ 80000

There are two ways of entering into the hall of fame of this challenge. In the SVP version one has to find a vector of norm $\|\mathbf{b}_1\| \leq 1.05 \cdot GH(L)$. In more relaxed version one has to solve α-SVP, that is find a longer vector of norm $\|\mathbf{b}_1\| \leq n \cdot \mathrm{vol}(L)^{1/n}$.

For SVP, they experiment with the extreme pruning implementation of [15] with BKZ-35 preprocessing. For a dimension 80, the best result they have achieved is the root-Hermite factor approximately 1.0107 with the runtime around 300 seconds on the average. This also satisfies the bound for SVP in the challenge.

For α-SVP instances with dimensions smaller than 300, Plantard and Schneider experiment with the BKZ algorithm implemented in NTL. The experiment demonstrates that a root-Hermite factor approximately of 1.011 can be achieved with a block size 30 on dimension 100. But the required α-SVP bound in this case is slightly less than 1.01. For a high dimension, the Hermite factor becomes far worse than the required bound, showing the impracticality of running the algorithm in higher blocksizes. This gives the limitation that BKZ reduction in higher dimensions is intractable for ideal lattices as well.

Finally, Table I gives a short summary of the above experiments for BKZ lattice reduction.

III. RECURSIVE-BKZ

In this section, we describe the current, one of the best variants of BKZ algorithm, the Recursive-BKZ (RBKZ in short) reduction algorithm. In [1], the algorithm for the RBKZ reduction is called BKZ2.0. We would like, however, to emphasize the role of preprocessing, as the preprocessing notion has not been fully explained in previous publications. In lattice reduction algorithm, preprocessing is required to give a relatively bad basis a good shape. Actually, the most classical form of preprocessing we always observe is with polynomial time LLL algorithm to work with a slow enumeration-based algorithm like BKZ. In BKZ reduction, LLL is used before the enumeration routine to produce a preprocessed basis. Then the enumeration will run more efficiently. The preprocessing in the RBKZ can be defined as follows:

Definition 1 (RBKZ preprocessing): Let M_i be the projected block basis of index i such that $1 \leq i \leq n-1$ where n is the lattice dimension, parameter s is a step size and k_{min} is the minimum blocksize for recursion then before running enumeration on each block lattice k, run BKZ-(k-s) on the block if $k > k_{min}$ (otherwise, do as in original BKZ, i.e. only LLL preprocessing of the local block lattice).

TABLE II
HIGHEST INDIVIDUAL RANKING IN DIFFERENT LATTICE-CHALLENGE SITES

Challenge	Lattice Type	Dim. (n)	Hermite Factor	Algorithm Used	Contestant
Latticechallenge	SIS	825	1.0049^n	BKZ 2.0	Chen, Nguyen
SVP challenge	Random	126	1.0085^n	Enum, BKZ	Chen, Nguyen
Ideal lattice challenge	Ideal	128	1.0083^n	–	Ishiguro et al.

TABLE III
SOME SVP CHALLENGE DIMENSIONS FOR WHICH WE SOLVE THE BOUND AND REACH THE CHALLENGE HALL OF FAME.

Dim. (n)	BKZ block	Seed	$\|\mathbf{b}_1\|$	Approx. of GH	Hermite Factor
87	35	1112	~ 2408	1.0115	1.0099^n
83	30	5123	~ 2384	1.0257	1.0103^n
77	30	190	~ 2271	1.0091	1.0104^n
75	30	1000	~ 2220	1.0030	1.0104^n
71	30	1000	~ 2195	1.0197	1.0109^n

We first give the compact RBKZ algorithm in the form of Algorithm 1 in this text. We used an optimized version of this Algorithm in the later experiments for Lattice Challenge and for the cryptanalysis of SWIFFT hash function.

Algorithm 1 The RBKZ(n, k) basis reduction algorithm

Input: a basis $B = (\mathbf{b}_1, \ldots, \mathbf{b}_n)$ of a lattice L with blocksize $k \in (2, n)$, minimum blocksize k_{min}, step size s, the GS triangular matrix μ and a vector $\mathbf{c}$ to hold all $\|\mathbf{b}_i^*\|^2_{(1 \le i \le n)}$
Output: a BKZ-k reduced basis $(\mathbf{b}_1, \ldots, \mathbf{b}_n)$ with updated μ and $\mathbf{c}$

if $k < k_{min}$ **then**
  return the input basis
else
  LLL(B, c, μ, δ)
  $z \leftarrow 0$, $i \leftarrow 0$
  compute $\tau(n, k)$
  while $z < \tau(n, k) \cdot (n - 1)$ **do**
    $i \leftarrow i + 1$, $j \leftarrow \min(i + k - 1, n)$
    if $(i = n)$ **then**
      $i \leftarrow 1$, $j \leftarrow n$
    end if
    compute the local projected block basis M_i of dim. $d \leftarrow \min(k, n - i + 1)$
    for $(\frac{1}{p_{succ}})$ times **do**
      apply randomization on M_i $\Rightarrow$ output is a randomized basis Z_i
      $n \leftarrow d$, $k \leftarrow (d - s)$
      call RBKZ(n, k) on Z_i $\Rightarrow$ output is a preprocessed basis P_i
      apply pruned enumeration on P_i
    end for
    compute $\mathbf{b}_{new}$ as a shortest vector found among all iterations of M_i
    $h = \min(j + 1, n)$
    $B_h = (\mathbf{b}_1, \ldots, \mathbf{b}_{i-1}, \mathbf{b}_{new}, \mathbf{b}_i, \ldots, \mathbf{b}_h)$
    LLL(B_h, c, μ, δ); $z \leftarrow z + 1$
  end while
end if

IV. LATTICE CHALLENGE

The goal of the lattice challenge sites is to assess and compare lattice reduction algorithms. The cited results give an indication of what modern lattice reduction can achieve in practice. The first lattice challenge has been introduced by the TU Darmstadt team. The type of lattice used in this challenge is based on the hard lattice instances reported in [11]. These hard lattices related to the SIS problem are generated by some parameters: lattice dimension m, reference dimension n and a modulus q. The target of all participants is to test their lattice algorithm by running them on these lattices of different higher dimensions. If one can find a short vector $\|\mathbf{b}_1\|$ such that it is less than the reference dimension n for some unique higher dimension or some dimension with shorter vector yet to be listed, then they will be able to be ranked in the challenge hall of fame. One can have the flexibility to generate a random instance from a given generator codes or pick from a list of challenge dimensions given in the site home.

The next challenge introduced by Schneider and Gama is called the SVP challenge. The challenge lattice type is called the random or regular lattice due to Goldstein and Meyer. Here the target is to find a nonzero vector of length shorter than the bound $1.05 \cdot GH(L)$, where $GH(L) = \frac{\Gamma(n/2+1)^{1/n}}{\sqrt{\pi}}$ is the Gaussian Heuristic estimate for the length of a shortest nonzero vector in L.

The most recent challenge namely the ideal lattice challenge has been introduced by Plantard and Schneider. It is for testing lattice algorithms' performance on ideal lattices. A summary of the each challenge site is given in Table II with the highest dimensional lattice and the corresponding Hermite Factor achieved by the contestants.

Table III shows some challenge dimensions that we are able to tackle in the SVP challenge using RBKZ. We can reach a root-Hermite factor of ~ 1.0099 at best using blocksize 35 for dimension 87. The fourth column gives the approximation factor of GH (should be < 1.05)) that we achieved for each particular dimension. For dimension 87, the required complexity is approximately 31.5 (in $\log_2$ number of nodes) with the number of BKZ tours equivalent to 1587 out of ~ 2361 tours. After this many tours (~ 1587), BKZ does not improve the Hermite factor required for the norm of short vector $\|\mathbf{b}_1\|$ any longer. That justifies the use of aborted-BKZ [17] in RBKZ reduction.

V. PSEUDO-COLLISION IN SWIFFT

In this section we run an experiment to improve the current attack time (reported in [16]) on the SWIFFT hash function. We use the RBKZ reduction utilizing the aborted-BKZ reduction [17] with so-called *sublattice attack*.

A. SWIFFT Hash Function

The SWIFFT hash function is defined by the following compression function:

$$\sum_{i=1}^{m} \mathbf{a}_i \cdot \mathbf{x}_i \in R$$

where $R = \mathbb{Z}_p[x]/(x^n + 1)$ is the ring of polynomials, $\mathbf{a}_i \in R$ $(\forall\, i)$ are m fixed multipliers and $\mathbf{x}_i \in R$ $(\forall\, i)$ with coefficients

TABLE IV
CHOICE OF PARAMETERS FOR FINDING *pseudo-collision* IN SWIFFT.

m	n	p	δ	d
16	64	45	1.0124	141
16	64	49	1.0121	144
16	64	53	1.0119	147
16	64	57	1.0117	150
16	64	61	1.0115	152

$\in \{0,1\}$ are the input of length mn. The two basic parameters are n and p, where n is a power of 2 and $p > 0$ is a prime modulus. The algebraic formulation of SWIFFT is equivalent to a lattice of dimension mn and the security of such function depends on the infeasibility of finding relatively short vectors in such a lattice. Finding a collision in this function means looking for a nonzero vector $\mathbf{x}_i \in R$ with coefficients in $\{-1,0,1\}$ such that $\sum_{i=1}^{m} \mathbf{a}_i \cdot \mathbf{x}_i = 0 \bmod p$. In other words, if we can find a vector by reducing the lattice of Euclidean length $\leq \sqrt{mn}$, then it is a *pseudo-collision*. We call it pseudo-collision because we consider a sublattice of dimension $m'n' \leq mn$ of the full dimensional lattice.

B. Better Attack Time

The experiment by Micciancio and Regev [13] suggests that a shortest vector of length $l = 2^{2\sqrt{n \log p \log \delta}}$ could be found in an optimal dimension $d = \sqrt{n \log p / \log \delta}$, where mn is the dimension of the lattice with modulus p and δ is the root-Hermite factor. Again, finding a sub-lattice collision[3] in the mn dimensional lattice is equivalent to finding a vector of length $l = \sqrt{mn}$. In [16], Buchmann and Lindner use the above idea to find pseudo-collision for the SWIFFT compression function. They introduced a parameter generator algorithm that generates minimal possible parameters for SWIFFT required to satisfy the pseudo-collision condition. The smallest parameter set (in Table 1 of [16]) was $m = 16$, $n = 64$, $p = 257$, compression ratio ≈ 2 with root-Hermite factor $\delta \simeq 1.0084$ in sub-dimension $d = 206$. As this amount of the Hermite factor is hard for current reduction algorithms, they come up with this less hard problem with smaller p and δ and successfully break 9 instances of this problem with the NTL implementation of BKZ, and RSR algorithm [18]. We use aborted-BKZ to break the harder 5 of these 9 instances. See the Table IV for the scale-down parameters of these 5 instances.

We search for the δ (root-HF) required from the table to break a particular instance by increasing the number of tours within a BKZ blocksize. To get average results, we use 10 random SWIFFT seeds/instances for each of these 5 instances. As soon as we found a required δ (after some tours) we stop and record time otherwise we move to the next blocksize. In Figure 1 we plot the average runtime required for this approach comparing the original BKZ and RSR algorithms. It shows that aborted-BKZ can save a considerable amount of time comparing to BKZ and RSR.

VI. CONCLUSIONS

We identified some open problems from the above study. First, we require to evaluate the performance of other type of lattices important to the cryptosystem such as SIS, NTRU, LWE etc along with random lattices. Another question is to verify if lattice reduction for ideal lattices is as hard as for random lattices. Plantard-Schneider's experiment in [14] roughly answer this question. They also point out the limitation of the theoretical analysis of the BKZ. Another problem is to make available recent improvements of the BKZ algorithm and its variants (such as RBKZ), going beyond the NTL implementation.

[3]The same idea also used in latticechallenge to allow reduced dimensional lattice

***Abstract*—Grid computing is the most popular infrastructure in many emerging field of science and engineering where extensive data driven experiments are conducted by thousands of scientists all over the world. Efficient transfer and replication of these peta-byte scale data sets are the fundamental challenges in Scientific Grid. Data grid technology is developed to permit data sharing across many organizations in geographically disperse locations. Replication of data helps thousands of researchers all over the world to access those data sets more efficiently. Data replication is essential to ensure data reliability and availability across the grid. Replication ensures above mentioned criteria by creating more copies of same data sets across the grid. In this paper, we proposed a data mining based replication to accelerate the data access time. Our proposed algorithm mines the hidden rules of association among different files for replica optimization which proves highly efficient for different access patterns. The algorithm is simulated using data grid simulator, OptorSim, developed by European Data Grid project. Then our algorithm is compared with the existing approaches where it outperforms others.**

Keywords—Scientific Data Grid; Replica Optimization; Dynamic Replication; Association rule mining

I. INTRODUCTION

The term scientific data grid [1] refers to the massive network of computational infrastructure used by a wide range of researchers who use petabytes of data for experimentation all over the world. It is used for large scale data sharing and simulation based experimentation in wide range of scientific and engineering domains – such as *Large Hadron Collider (LHC)*[8], *Earth System Grid (ESG)*[6], *Laser Interferometer Gravitational Wave Observatory (LIGO)* [7] *etc*. All these grids use massively distributed heterogeneous computing platform where reliable and fast access of huge data sets is a challenging task. To ensure data access requirements same data sets need to be replicated in several regions of the grid. An efficient replication strategy is required to make data sets available so that it can be accessed efficiently by all the users and to reduce the number of replicas in an optimal level. There are many techniques those are described in literature which address the problem. But they have their own problems. Least Frequently Use (LFU) approach decides about replica by deleting the least frequent item extracted from the access history. However, another popular approach is Least Recently Used Optimizer, which makes decision based on temporal information. It deletes the least recent files to make room for the new files and assumes that new files are more important than the old ones. Many economy based approaches are described in literature. To address the problem we have used data mining based history mining [9] to capture the hidden structure of files. We structured the grid using Bandwidth Hierarchy Replication (BHR) standard to simulate our Grid. It ensures file locality in the regional sites. Our algorithm collects site access history to optimize the files regionally. This process ensures locality based optimization for most efficient use of local network and storage elements. We compared our algorithm with all other existing approaches. To make comparison we have used some statistical measures- such as Mean Job Execution Time (MJET), Total number of replication, number of local file access, number of remote file access, Average Storage Usage (ASU), Network Usages (NU). Our proposed model successfully reduces the mean job execution time. It also reduces the overall local network usage to only 20% and simultaneously maximizes the local file access.

This paper is organized as follows: Section II explains our proposed model with algorithms. Experimental evaluation is described in Section III. Results and discussion is explained in Section IV.

II. PROPOSED ALGORITHM

Grid computing contains a massive collection of computing and network resources dedicated to perform complex computing and simulation on large scale data sets. Whole Grid architecture is a collection of numerous sites responsible for computing and data storage. Computational and Data storage resources are called *Computing Element (CE) and Storage Element (SE)* respectively. The grid site that has Computing Element is called Computing Site. Computing sites are used to run jobs that use data sets stored in Storage Elements. When user issues a job to be performed in Grid, the request is first handled by resource Broker. Resource broker is responsible for scheduling the job into a computing site to ensure proper load balancing. It is also responsible for analyzing the user requirements to make appropriate decision. When a particular job is scheduled in a computing site, it tries to get the required data sets and contacts the Replica manager. Replica manager is responsible for administering the replication process. It manages the replica copy, deletion, replacements etc. Replication can be both static and dynamic. In Static replication the location of data is predefined, however, in dynamic replication the decision is made in real time to cope with the changing access pattern and data distribution. Replica Optimizer is responsible for optimizing the number of replicas

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

of a file. The main goal of an optimizer is to make minimum number of replicas in such a way that can provide maximal data access facility among the Grid sites.

The computing elements need to access numerous numbers of files with different access patterns. To ensure the data locality it is essential to make available all the files in regional repositories called Regional Header. Regional headers are chosen based on bandwidth and storage efficiency, so that it can work as a pseudo-master repository for that region.

Algorithm 1.1 Data Mining Based Replica Optimization (DMRO)

$P = Number\ of\ jobs,$
$N = Number\ of\ sites$
$S_i = Replica\ sites\ [i = 1, \dots, N]$

Input : *Grid Topology,*
Jobs, $J_K\ (K = 1, \dots\dots\dots, P)$,
Bandwidth details, $BW_{i,j}\ [i = 1, \dots, N; j = 1 \dots, N]$

Output: *Mean Job Execution Time,* $MJET_j\ [j = 1, \dots, N]$
Average Storage Used, $ASU_j\ [j = 1, \dots, N]$
Networ Usage, $NU_j\ [j = 1, \dots, N]$
Number of Replications, $NR_j\ [j = 1, \dots, N]$
Local File Access $LFA_j\ [j = 1, \dots, N]$
Remote File Access $RFA_j\ [j = 1, \dots, N]$

Method:

1. *Master Repository replicates data to regional Header.*
2. *Regional Header has all info about Regional Sites.*
3. *User execute a job,* J_K
4. *Job* J_K *scheduled to site* S_i *by the Job Scheduler*
5. *Replica optimizer decides to get best replica and remove the least important replica;*
6. *Execute the job* J_K
7. *Compute statistical measures -* $MJET_j, ASU_j, NU_j, NR_j, LFA_j, RFA_j$ *for all site* S_j

An overview of the proposed model is depicted in Algorithm 1.1. After producing the raw data from the experiments, these are stored in the master repository *(Step1)*. Then the master repository replicates all those files to Regional Header *(Step 2)*. When a user requests to execute a job, J_K (*k* is the number of jobs), Job scheduler reserves an appropriate CE to execute the job *(Step-3)*. Replica optimizer is used when data file is not available in local site and replication of a specific file is required. The goal of replica optimizer is to reduce the replication of file and concurrently ensures best access time for the file *(Step-5)*. When file becomes available in local site CE starts to execute the job *(Step-6)*. Then the algorithm computes some statistical measures shown in Step-7. The replica optimizer is detailed below:

A. Replica Optimizer

At first, Replica optimizer checks whether it is available in local storage *(Step-1)*. When the file exists in local storage, optimizer simply executes a *getFile* command to make it available for the job *(Step-2)*. Then the TTL (Time to Live) values of all other files are reduced by one and proceeded to perform the *job (Step-3-4)*. However, in case when file does not exist in local storage, Replica optimizer starts querying the local storage whether it has enough available space to replicate the requested file *(step-6-7)*. In case of storage availability a replica selection method is used to replicate the file from Regional header and other regional sites *(Step-8-9)*. The file replacement becomes mandatory in situations when file is not found in local storage which does not have enough space to replicate the file *(Step-10)*. Here we have used a data mining based approach to capture the hidden access pattern of files in local storage. We have used apriori association mining discover the high confidence rules contained in *Frequent File Set (FFS)* and (Step-12). Then files are ranked based on their confidence value (Step-13). At step-14, Non Frequent File set, *NFS* is computed by set difference between *Files in Local Set (FLS) and Frequent File Set (FFS)*. This NFS file set is sorted according to their TTL value (Step-15). Finally, replica selection procedure is executed to get the replica file. The concept of Apriori rule mining is described in Algorithm 1.2

Algorithm 1.2 Data Mining Based Replica Optimizer

$F_i\ where\ i = 1, \dots, m$
$FFS = Frequent\ File\ Set$
$FLS = Files\ in\ local\ Site$

1:If (F_i *is available in local site* S_j *) {*
2: getFile(F_i*);*
3: reduce TTL value of all other files
4: proceed job J_K *execution*
}
5: else {
6: query local site S_j *for storage availability12;*
7: if (S_j *storage available) {*
8: replicaSelection(BW_{ij}*,latency,sites,* S_i*)*
9: *getFile(*F_i*);*
}
10: else {
11. Accumulate (accessHistory, AH_j*,* S_j*);*
12: $FFS = Apriori\ (AH_j, minSup, minConf)$
13: Rank files based on confidence
14: $NFS = \{FLS - FFS\}$
15: Sort based on NFS, TTL *value*
16: Remove files from NFS *with lowest* TTL *value*
17: $replicaSeceltion(BW_{ij}, latency, sites, S_i)$
18: getFile(F_i*);*
}
}

B. Association Rule Mining

At first, **In Algorithm 1.1** minsup is provided as input to find out the k-frequent item set. At step-1, k is initialized as 1. Step-2, initial frequent item set is prepared by taking one item. From step-3 loop is started to find out all (k+1)-frequent item set, considering k-frequent item set as input. At step-5, *apriori-gen* function gives the candidate item set of k-frequent item set. At step-7, for each transaction, candidate items of that transaction are determined and at step-9, support count is measured. After going through all the transactions, at step-12, items having minsup as support count are identified. For all possible combination the algorithm is run and all frequent item set are stored together at F_s.

***Algorithm 1.3: Frequent-item set generation Apriori Algortithm* [9]**

Input: minsup
Output: F_s *Frequent-item-set*

1) $k=1$
2) $F_k = \{i \mid i \in I \wedge \sigma(\{i\}) \geq N * minsup\}$
3) $Repeat$
4) $k = k + 1$
5) $C_k = apriori - gen(F_{k=1})$
6) ***For*** *each transaction* $t \in T$ ***do***
7) $C_t = subset(C_k, t)$
8) ***For*** *each candidate itemset* $c \in C_t$ ***do***
9) $\sigma(c) = \sigma(c) + 1$
10) *End* ***for***
11) *End* ***for***
12) $F_k = \{c \mid c \in C_k \wedge \sigma(c) \geq N * minsup\}$
13) $until\ F_k = \phi$
14) $F_s = \cup\ \phi$

In Algorithm 1.2, frequent items set and minconf are given as input. At step-1, loop is started for each k-frequent item set where k is greater than 2. One item consequent is taken from the frequent item set and *ap-genrule()* is called. **Algorithm 1.3** describes the *ap-genrule()*function. As input, minconf and frequent item set is given and support count of all frequent item set are given. At step-1 and 2, size of frequent item set and rule consequent is determined. At step-4, *apriori-gen()* generates candidates sets from H_m. For each rule, at step-6, confidence is measured from. A rule is stored if it meets the minconf threshold and deleted if threshold is not met. These are done in step-7, 8, 9 and 10. Then *ap-genrule()* is called for next set of rule consequents at step-13.

***Algorithm 1.4: Rule generation of Apriori Algorithm* [9]**

---

1) ***For*** *each* $frequent\ k - itemset\ f_k, k \geq 2$ ***do***
2) $H_1 = \{i \mid i \in f_k\}$

13) *call ap-genrules*(f_k, H_{m+1})
14) *End* ***if***

III. EXPERIMENTAL EVALUATION

OptorSim [2] serves as a framework to simulate the grid environment. Inputs to OptorSim can be controlled by using four configuration files, namely the parameter configuration file, grid configuration file, job configuration file and bandwidth configuration file. We also have used the CMS topology shown in Fig.1.We have used CMS Data Challenge 2004 [4] to simulate our proposed model. It submits jobs according to a Gaussian distribution of jobs entered around 3 pm. Here total number of job submitted each day is under 700. The basic simulation parameters are set up by means of the parameter configuration file. The most important parameters includes the number of jobs, the choice of scheduling algorithms, the choice of replication algorithms, access patterns for the job, initial file distribution job delay and the job submission pattern by which the user submit jobs to the resource broker. The job configuration file contains information for the simulated jobs. It also specifies the job each site will accept, the probability each job runs and the files needed by each job. There are six job types, with no overlap between the set of files each job accessed.

TABLE I. OPTORSIM RESULTS

	No Replication	LRU	LFU	EMO Zipf-like	EMO Replicates	Proposed Model
Number of Jobs Remaining	0	0	0	0	0	0
MJET of all Jobs on Grid	105237	27682	32190	34910	16547	13320
Total number of Replications	0	1984	2341	931	735	754
Total Number of Local File Accesses	0	8901	9421	7812	8125	10536

ASU	15.37%	40.91%	40.91%	40.91%	40.91%	56.23%
Effective Network Usage	1.0	0.25	0.27	0.28	0.29	0.20

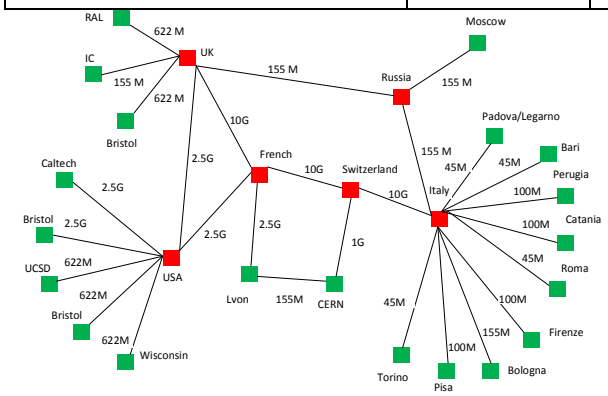

Fig. 1. CMS Data Grid Testbed

IV. RESULT AND DISCUSSION

After the simulation, we have compared different optimizers – such as LRU, LFU, EMO-Zipf-like, EMO Replicates with our novel algorithm. We have used several statistical measures, for example Mean Job Execution Time (MJET), Average Storage Used (ASU), Effective Network Usage (ENU) MJET is defined as the total time to execute all the jobs divided by the number of jobs completed. The total time includes the time that elapses from when a job enters the queue in a site to await execution until the time when the job finishes its processing and leaves the site. It is computed as shown in Eq. (1)

$$MJET = \sum_{i=1}^{n} \frac{Job\ Arrival\ time - Job\ departure\ time}{No\ of\ jobs\ completed} \quad (1)$$

ASU is the storage used specifies the amount of space used by files in MB. Monitoring the use of storage resources in the grid sites can also be a valuable source of information. Storage usage can be calculated for each site as a percentage of the capacity reserved by files out of the total capacity of the underlying storage. The average of all the storage elements in the grid can reflect the total system storage cost, which is computed as shown in Eq. (2)

$$ASU = \sum_{i=1}^{n} \frac{\frac{u}{c}(Site\ i)}{n} * 100\% \quad (2)$$

Replicating a file takes time and uses network bandwidth. This cost is effectively the ratio of files transferred to files requested, so a low value indicates that the optimization strategy used is better at placing files in the right places. It can be measured by using Eq. (3)

$$ENU = (Nremote\ file\ accesses + Nfile\ replication)/(Nremote\ file\ accesses + Nlocal\ file\ accesses) \quad (3)$$

Summary of all those optimizers are recorded in Table I. Our proposed model makes replication decision based on the local request pattern and the bandwidth between the source and destination of the file. It can be seen that the no replication policy takes the highest mean job execution time as it has to rely completely on the network bandwidth when it tries to access a file that is not available locally. However, local mining and hierarchical information sharing about popular data file proved efficient against other approaches. According to our approach, corresponding files of a popular file are replicated in a hierarchical order to the upper level storages and reduces the mean job execution time to 13320 s. It also reduces the network usage to only 20%. Total number of replication is also decreased due to the hierarchical order of file replication and it is approximately same as EMO Replicates Algorithm. Remote file access is highest for no replication as it has to request every file that is not locally available. LRU and LFU policy does not have remote file access option they just copy the file that is needed in the local site. However, our algorithm reduces the remote file access to only 1053 where EMO based approaches needs 3 or 4 times higher remote access.

Abstract— **The complexity of data requirement increasing day by day; therefore minimization of schema becomes an important role for equi distribution or equalization of two or more problems. Schema complexity is measured by transmitting schema to a graph with weight or weighted graph. Selected special fundamentals from schema for weight the schema graph are described as major part. Minimization of schema ensures easy to measure the schema complexity. Some consideration for this approaches are normalization and de-normalization. We also find the effect of normalization and de-normalization on minimization of schema of real life data model as well as synthetic data model. The purpose of this research is to examine the effectiveness of schema complexity based on schema minimization with weighted graph.**

I. Introduction

The definitive goal of minimization of schema is to build a good relational schema for database system. There are a number of design approaches for relational and object relational databases [2]: ER [4], Extended ER [4], Object Oriented [3] and Spatial ER [3]. Relational database can be formed by the following design approach: ER → Relational schema → normalization →denormalization. At the core of modern information, object / relational database management systems (ORDMSs) improve new object storage capabilities to the relational systems [3]. A relational schema, at the logical level of database design and describes how real world entities are modeled in the database. Schema complexity is measured by transforming it to direct weighted graph and minimization of schema ensures easy to measure the schema complexity. Normalization is good for optimization method of relational schema and reduces large table into smaller tables but time consuming for accessing data. Whether denormalization improve query performance with reducing number of table and speed up data retrieval but slow data modification process. Graph theory is an established field where users represent data as a series of nodes and edges [10]. A node represents an object of interest and an edge indicates a relationship between two nodes. A graph is one of the vital data concepts in computer science. Now a days graph theory also use in Graph databases model. Graph database models are useful in fields where facts about data interconnectivity or topology is more significant as, or as important as the data itself [11]. Graph theoretical ideas are highly utilized by computer science applications. On the basis of our research measurement, we are using the weighted graph for our measurement purposes of schema in database field.

II. Trade off Normalization and Denormalization:

To minimize redundancy, database normalization is the procedure of establishing the fields and tables of a relational database. The originator of the model, Edgar, presented the perception of normalization; 1NF in 1970. Codd also define the 2NF and 3NF in 1971. Codd and Raymond F. Boyce defined the Boyce-Codd Normal Form (BCNF) in 1974. The theoretical system contains a total of 6 paradigms (That is Normalization Function, referred to as NF) [5]: 1NF, 2NF, 3NF, BCNF, 4NF and 5NF. These are the elementary approaches of schema optimization based on normalization theory, 5NF is the ultimate pattern. An example:

Table I: Unnormalized Form

SID	Name	Instructor ID	Subject	Grade	Grade point
1	Ram	101 102 103	C C++ DS	A+ A A+	10 9 10
2	Shy	101 104 105	C DM EM	B+ A A	8 9 9
3	Mahe	101 102 103	C C++ DS	A+ A+ A+	10 10 10

With 1NF, there's really no reason for duplicate columns and non-unique entries and remove repeating groups of data. 2NF is a good idea for all but the smallest and most casual of databases and removes partial dependency.

Table II: 3NF -3rd Normalized Form

SID	Name
1	Ram
2	Shy
3	Mahe

Grade	Grade point
A+	10

3	102	C++	A+
3	103	DS	A+

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

Normal 3 is necessary, at least in the extended term, for any business task or any other task where the data is acute and removes transitive dependency. While higher level normal forms are available, normalization up to BCNF is often found to be adequate for business data and removes multiple overlapping candidate keys.

4NF isn't always necessary [9] but is required to remove non trivial multivalued dependency. 5NF is needed to remove join dependency. At least 2NF is for tiny organizations and at least 4NF is for any operation where the data's critical [9]. Most 3NF tables are permitted of insertion, update, and deletion anomalies. A relational DB table is regularly described as "normalized" as it is in the 3NF [8]. In 3NF database most of the business rule and the real world description can be implemented, where BCNF or 4NF is only used in some rare cases that are not mostly needed all intervals [2]. Again for database storage analysis, insert data in the three normal from and get a table and a bar chart. The space gain as of 1NF to 2NF and 2NF to 3NF is not same and linear. The increment of database size varies with the increment of record in the database.

Table IV: Database Size with Varied Number of Records

SL No.	No.of records	Table size in MB		
		1NF	2NF	3NF
1	10000	15	8	8
2	100000	120	57	56
3	200000	229	110	82
4	500000	493	272	264

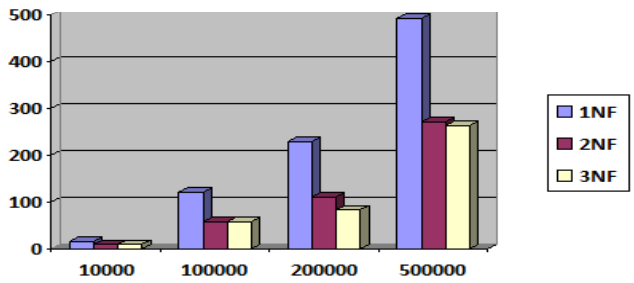

Fig. 1. Database Size vs Numbers of Record

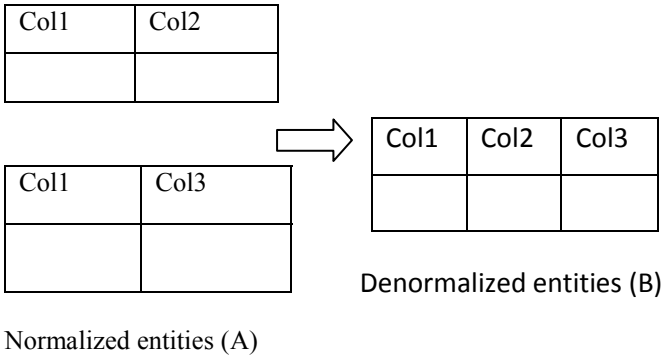
A standard design management is that the designer should first construct an entirely normalized design; then selective denormalization can be achieved for performance reasons by terminating join. A denormalized data model is not the identical as a data model that has not been normalized [9]. Denormalization should only apply after a reasonable level of normalization has been established because Denormalizing can progress database access speed. Collapsing of One- to- One relationships are one of the most common and important techniques. This situation arises while each row of entity A, there is only one related row in entity B. To see Col 1, Col 2 and Col 3 at the similar time, collapse the two tables into one shown in figure.

Table V: Collapsing Table for Denormalization



We can apply this in BCNF table 3. Again the response time for point query is described in the following tables for fully normalized database and tuned database schema [2].

Table VI : Response Time for Point Query

Number of records	Query Type	Response time in second	
		Fully Normalized	Tuned Data base
44296	Point Query	3.57	1.95
221480	Point Query	14.67	1o.17
487256	Point Query	67.6	16.96

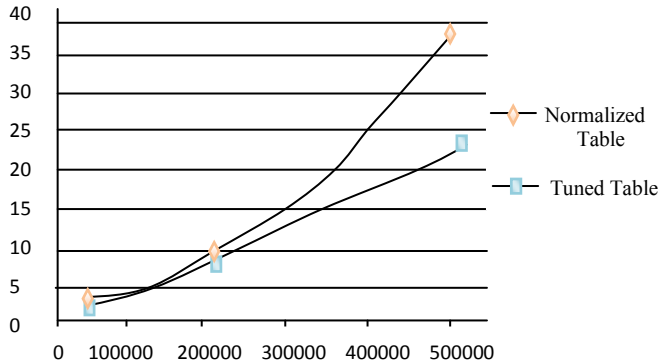


Fig. 2.Response time for point query

The response time gain by denormalization process is shown in above figure. Whether for large number records, exclusive joining processes make delay in the normalized database. The representation of data in the form of a graph lends itself well to structured data with a dynamic schema [12]. Relational database is losing its importance due to its dependence on a rigid schema which makes it difficult to add new relationships between the objects. The available data is growing manifolds; it is becoming

difficult to work with relational model as joining large number of tables is not working efficiently [13].

III. RESULT AND DISCUSSION:

Students only gather knowledge on weighted graph from mathematical fields. At present weighted graph are used in data structure section and many other section of engineering. On the basis of our research measurement, we can say that the weighted graph can also be used for schema in database field. Schema complexity is measured by transforming it to directed weighted graph and minimization of schema ensures easy to measure the schema complexity. Those minimized schema whose process discused before plays a vital role for transforming schema to weighted graph .

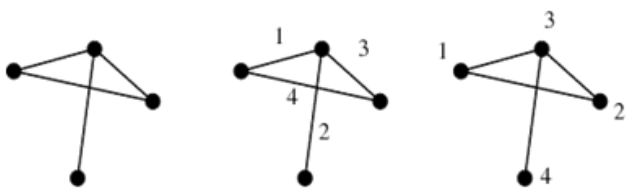
A. *Graph:*

Representations of a set of several pairs of objects are connected by links known as graph. A graph [6] is an object consisting of two sets called its vertex set and its edge set. The connected objects are denoted by mathematical notions called vertices, and the links that attach several pairs of vertices are called edges. A weighted graph is *a* graph in which each branch is given a numerical weight. Usually, the edge weights are nonnegative integers. Weighted graphs may be either directed or undirected. Such weights might represent, for example, costs, lengths or capacities, etc.

B. *Weighted graph:*

A weighted graph [7] is a graph in which a number w, called its weight, is assigned to each edge e or vertex v. A weighted graph is:

- A graph where vertices have some weights or values.
- A graph where edges have some weights or values.
- A graph where both edges and vertices have some weights or values.
- A graph where neither edges nor vertices have any weights or values.



Unlabeled graph edge-labeled graph vertex- labeled graph

Fig. 3. Labeled and unlabeled graph

C. *Graph for schema:*

Weights are usually real numbers or numerical values. Weighted graphs may be either directed or undirected.

For transforming schema to graph we choose directed weighted graph. We consider four fundamentals to weight the directed weighted graph of schema.

1. PK (primary key)
2. Fields
3. Tables
4. FK (foreign key)

We consider following schema:

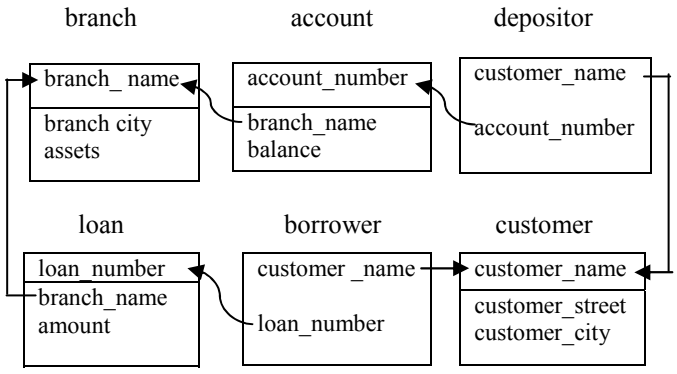


Fig. 4. A schema diagram

We represent the above schema through directed weighted graph. In our analysis representation of graph where vertices have some weights or values. Consider primary key as value for weight, the weight value is always one or zero because in every table there is only one primary key, value one or only foreign key, value zero. Consider field as value for weight, where value always more than zero because of containing enormous fields. Due to fragile performance multiply with .1 to form less weight. Tables are joined through foreign keys. Because of rare necessity, omit the consideration of table as weight value. Consideration of foreign key signifies the join between tables and present reasonable weight. A primary key of a table joined with one or more tables as a FK. So weight is based on this joined of FK. For calculating vertex weight use the concept of probability distribution. After combining above weight of all fundamentals the directed weighted graph is given below:

Vertex weight = (.7)*PK + (.2)*FK + (.1)* Fields

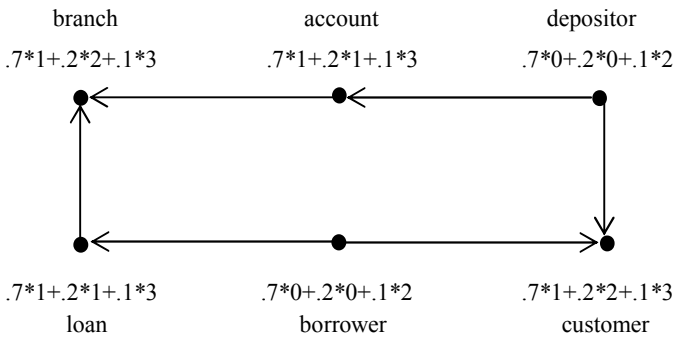

Fig. 5. Directed Weighted Graph with Value for Vertices

For schema representation vertices are denoted tables name and edges are denoted the connection between tables. The following equations are to determine total weight and the weight of each vertex of the weighted graph:

Total weight:

$$V = \sum_{W=1}^{n} v_w$$

Weight of each vertex:

V_w= (.7) * fields no. of PK + (.2)* total fields involved as FK + (.1)*no. of fields of particular table

Now the weight value for total weight and for each vertex is given by the following table:

Table VII: Weight value for vertices in table

Problem No.	Vertices Name	Fundamentals			Total weight on each vertex
		PK	FK	Field	
1	branch	.7*1	.2*2	3*(. 1)	1.4
	account	.7*1	.2*1	3*(. 1)	1.2
	depositor	.7*0	.2*0	2*(. 1)	0.2
	customer	.7*1	.2*2	3*(. 1)	1.4
	borrower	.7*0	.2*0	2*(. 1)	0.2
	loan	.7*1	.2*1	3*(. 1)	1.2
				Total weight = 5.6	

Through this paper we assure that the graph can be also used in database system efficiently. But we represent total schema to a weighted graph from which we are able to understand the number of FK in a table, connections between tables, number of fields in a table. We can't measure the complexity of schema through individual fundamental. For this reason we combine all fundamentals and find a perfect weight value. For schema minimization, is it necessary to add other fundamentals or not, is not verified. Here this is our method to measure the schema complexity on the basis of weight value. Based on this weight, our process will measure the complexity of schema manually which is time consuming.

IV. CONCLUSION

Based on the analysis presented in this paper, this study introduces the measurement of complexity and improves performance of database schema. To minimize the schema use normalization which produces minimal redundancy with larger number of smaller tables, minimized update anomalies and de-normalization which reduces join between tables, speed up data retrieval. This paper also provides concepts when not to normalize or should stop normalization in the database. Using those minimized schema, we are capable of transforming schema to directed weighted graph. Selected special fundamentals from schema are described in our research as major part for measuring complexity of schema. There may be some other considerations for complexity measurement which are not fully defined or understood. Complexity measurement of schema is partially implemented in our analysis though working on it is still going on. The significant properties of this analysis are that it is easy to understand, simple to measure and less time consuming. It fulfills most of the properties of a decent measurement of complexity. We are pretty sure that upcoming progress on this section will produce a great complexity measurement.

***Abstract*— The guard zone computation problem finds immense applications in the field of VLSI physical design automation and design of embedded systems, where one of the major purposes is to find an optimized way to place a set of two-dimensional blocks on a chip floor. In VLSI layout design, the circuit components (or the functional units / modules or groups / blocks of different sub-circuits) that may be viewed as a set of polygonal regions on a two-dimensional plane, are not supposed to be placed much closer to each other in order to avoid electrical (parasitic) effects among them [12]. Each (group of) circuit component(s) C_i is associated with a parameter δ_i such that a minimum clearance zone of width δ_i is to be maintained around C_i. If the guard zonal regions overlap, we have to remove the overlapped regions in order to compute the resultant outer guard zone (sometimes inner guard zones are also an issue to be considered). The location of the guard zone (of specified width) for a simple polygon is a very important problem for resizing the (group of) circuit components. In this paper, we have developed an algorithm to compute the guard zone of a simple polygon as well as to exclude the overlapped regions among the guard zonal segments (if any) in O(*n* log *n*) time, where *n* is the number of vertices of the given simple polygon.**

Keywords: Simple polygon; Safety zone; Notch; Convex hull; False hull edge; Convolution; Minkowski sum.

I. Introduction

The guard zone computation problem occupies vast place of interest in the field of VLSI physical design automation and design of embedded systems, as resizing is an important problem in VLSI layout design as well as in embedded system design. This motivates us to compute a guard zone of a simple polygon. Given a simple polygon P, its guard zone G (of width r) is a closed region consisting of straight line segments and circular arcs (of radius r) bounding the polygon P such that there exists no pair of points p (on the boundary of P) and q (on the boundary of G) having their Euclidean distance $d(p,q)$ less than r. If more than one polygonal regions are closed enough, their safety zones may overlap, violating the minimum separation constraint among them as shown in Fig. 1.

In computing the guard zone of a simple polygon [7], we have at most O(n) straight line segments and O(n) circular arcs for a polygon of n vertices. So, to find out all the intersection points and exclude the overlapped region(s) accordingly (in order to get the desired guard zone only, including holes, if any), we may execute an O(n^2) algorithm for each pair of such segments, among all straight line segments and circular arcs. Indeed, this algorithm is greatly expensive.

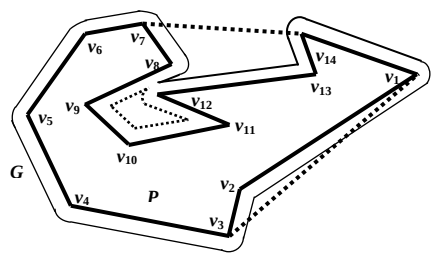

Fig. 1: A guard zone G of a simple polygon P.

In this paper, we have developed an algorithm to find and exclude that overlapped regions using coordinate as well as computational geometry, which reduces the time complexity of the algorithm to O(n log n).

II. Literature Survey

In the context of guard zone computation, several different algorithms have been proposed so far. The most discussed tool for guard zone computation is the Minkowski Sum [3]. Apart from Minkowski sum, convolution can also be used as a tool for guard zone computation. Essentially, Minkowski sum between a line (as polygonal segment) and a point (perpendicularly at a distance r apart) with the same x- and y-coordinates gives a line parallel to the given one. But the question arises is whether the parallel line is inside or outside the polygon. Here the definition of Minkowski sum [3] can be extended as below.

If A and B are subsets of R^n, and $\lambda \in R$, then $A+B = \{x+y \mid x \in A, y \in B\}$, $A–B = \{x–y \mid x \in A, y \in B\}$, and $\lambda A\ \{\lambda x \mid x \in A\}$. Note that $A+A$ does not equal $2A$, and $A–A$ does not equal 'zero' in any sense.

The convolution between a polygon and a circle of radius r may give us the desired solution of a guard zone. But the circles need to be drawn in every possible point of the polygon and thus the time complexity of the algorithm increases. The complexity of computing Minkowski sum of two arbitrary simple polygons P and Q is O(m^2n^2) [3], where m and n are the number of vertices of these two polygons, respectively. In particular, if one of the two polygons is convex, the

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

complexity of Minkowski sum reduces to O(mn). In [5], a number of results are proposed on the Minkowski sum problem when one of the polygons is monotone.

In this context, a linear time algorithm is devised for finding the boundary of the minimum area guard zone of an arbitrarily shaped simple polygon in [11]. This algorithm uses the idea of Chazelle's linear time triangulation algorithm and requires space complexity of O(n) as well [2], where n is the number of vertices of the polygon. After having the triangulation step, this algorithm uses only dynamic linear and binary tree data structures. Again, a time-optimal sequential algorithm for computing a boundary of guard zone has been developed in [7, 8, 9] that uses simple analytical and coordinate geometric concepts. The algorithm can easily be modified to compute the regions of width r outside the polygon as guard zone, and also inside the polygon.

III. Problem Formulation and the Algorithm

In this section, we formulate and develop a comprehensive algorithm to compute guard zone of a simple polygon while detecting and excluding the overlapped regions (if any) of the guard zone. The case becomes most simple, if the polygon is convex as there is no overlapping among the guard zonal regions. Thus, the guard zone for a convex polygon can be computed in linear time [7]. But the problem arises when the polygon has one or more notches in it.

A *notch* is a polygonal region outside the polygon that is starting and terminating between two consecutive convex vertices of the polygon that are not adjacent. That means a notch starts with a convex vertex, goes through one or more concave vertices, and terminates with a convex vertex, along the edges (and vertices) of the polygon (in one particular direction). But for some cases a simple polygon may contain a notch (or more) and guard zonal overlapping may also occur. Figs. 2(a) and 2(b) show two different cases of overlapping.

We can assume another case where a part of a polygon is shown Fig. 2(c), where B is a convex vertex but A is concave, and the guard zones of these two regions may overlap. Again the guard zones of two linear portions BD and BE of a simple polygon may also overlap with the linear portions of the guard zones AC and AF, respectively. All the above cases may occur for a simple polygonal guard zone. Now, as our objective is to compute the intersection points and exclude the overlapped regions (if any), we first compute the guard zone G (without excluding overlapped portions) of the given simple polygon P in linear time [7, 9].

Instead of checking all pairs of segments to detect the intersection points (if any), we apply the line sweep algorithm to reduce the time complexity to O(n log n) from O(n^2) [10]. But the line sweep algorithm can only be applied to a set of line segments as input, while a guard zone of a polygon is not only a set of line segments, but there are circular arcs as well. In case of guard zonal line segments we can compute the intersections of the guard zones (if any) by using the line sweep algorithm [10]. But in case of circular arc it cannot be applied directly. So, we have to do some pre-processing to make the algorithm run in time O(n log n).

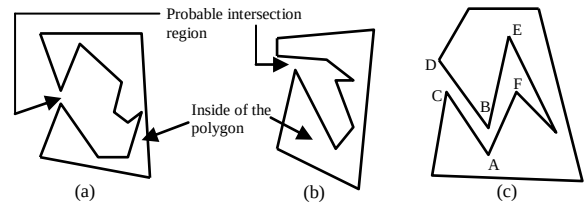

Fig. 2: Different kinds of probable intersections between overlapping of guard zonal regions. (a) Probable overlapping of guard zone of two convex regions. (b) Probable overlapping of guard zone of one convex region with a straight line segment. (c) A polygon consisting of a number of convex (e.g., B, C, D, F) and concave (e.g., A and E) vertices whose guard zonal regions are probable to overlap.

We know that a circular arc can be assumed to be the aggregation of a number of infinitesimally small ordered line segments. Thus if we can subdivide the arc into line segments, we can then apply the line sweep algorithm for detecting the intersection points between these derived line segments (instead of the circular arcs) with others. Though to break an arc into line segments, we have to take some precision, but that does not affect the output of the algorithm as it definitely reports all the intersections existing among the guard zonal segments [10].

Let us consider a simple polygon P and its related guard zone G [7, 8, 9]. To exclude the intersecting regions we have to find the intersections among the guard zonal segments. This application of the line sweep algorithm replaces each circular arc with its corresponding set of line segments and hereby converting the guard zone of P into a collection of line segments only. To convert the computed guard zone of P into a set of line segments, we only focus on each convex vertex of the given polygon P, as only here the consequent guard zone is a circular arc of radius (say) r. In Fig. 3, v is a convex polygonal vertex, also uv and vw are the adjacent edges of v, whose guard zonal segments are two straight line segments $u'v'$ and $v''w'$, where $u'v' \parallel uv$ and also $v''w' \parallel vw$, and the perpendicular distance between the parallel lines for both the pairs is same as r.

In order to obtain the smallest possible line segments, we follow a binary recursive procedure. First of all, we bisect $\angle v'vv''$ (or $\angle uvw$) by a bisector bs_1 whereon $vp_1 = r$. We join $v'p_1$ and p_1v''; so, $v'p_1v''$ is an approximated guard zone (for $p = 1$) of the circular arc. Next to make this approximation finer, we further bisect $\angle v'vp_1$ by bs_2, such that $vp_2 = r$ and bisect $\angle p_1vv''$ by bs_3 whereon $vp_3 = r$. Then we join $v'p_2$, p_2p_1, p_1p_3, and p_3v''; so, $v'p_2p_1p_3v''$ is an even finer approximation of the guard zone (for $p = 2$) than the previous one (i.e., $v'p_1v''$) of the

circular arc we usually draw. Now it is easy to realize that for $p = 3$, we get even smaller line segments $v'p_4 = p_4p_2 = p_2p_5 = p_5p_1 = p_1p_6 = p_6p_3 = p_3p_7 = p_7v''$, which is closer to the circular arc we usually draw as a part of guard zone for a convex polygonal vertex.

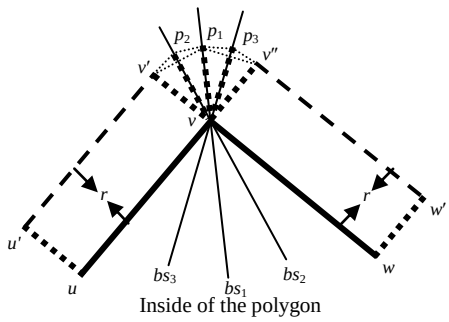

Fig. 3: Recursive division of a convex polygonal angle formed at vertex v wherefrom equal length smallest possible chords are computed that in a group replaces the circular arc that is computed as a part of guard zone outside the polygon up to a desired level of precision of an angle that is formed at the convex vertex for each such smallest possible chord.

This process of bisection is continued till the value of each bisectional angle becomes 0.50° or 0.25°, or up to some precision of angle that makes the straight line segments as chords of the circular arc reasonably very small. Needless to mention that all the points p_i over the bisections outside the polygon are the points on the circular arc as part of G, and each small line segment (whose length tends to zero for a smaller value of r) is an approximation of its associated arc for which it is the largest chord. So, further bisection of each of the bisected angles in subsequent levels of recursion and spotting a point p_i on each of the bisections at distance r from v outside the polygon helps to achieve more points on the said circular arc that are consecutively equidistant and closer to each other. Hence, up to some desired level of precision, we may obtain a set of equal length straight line segments collectively that replaces the circular arc we liked to draw as a part of G for vertex v.

Now, the line sweep algorithm is applied where the input is a set of line segments associated with their starting and ending coordinates as event points. The sweep line is traversed through the sorted list of event points depending on x- or y-coordinates. Here starting point, ending point, and point of intersection (if any) are the three types of event points at which insertion, deletion, and update of neighbouring operations are performed, respectively, during the sweep line traversal.

Here the data structures used are of the highest importance to accomplish it in $O(n \log n)$ time. This algorithm maintains two binary search trees, one for storing the event points and another for the line segments to keep track of their neighbouring information, which is known as the query tree. All the three operations are performed on the query tree. As an intersection occurs only between the neighbours, this data structure reduces the search space for intersection checking to the set of neighbours of a line segment. In addition, it is proved that line sweep algorithm reports all the intersection points [10]. After getting all these intersection points, we traverse the original guard zone and depending on the intersection points we exclude the intersected or overlapped region(s), and report the outer and inner guard zone [6], if they occur.

IV. Experimental Results

In this section, we cite a relative study based on the polygon shown in Fig. 1, in terms of time and detecting intersections, between the naive algorithm where the intersections are identified by checking each pair of segments and our proposed method on line sweep algorithm after repetitive bisecting the circular arcs.

Table 1: A study of comparison of detecting intersection(s).

Variables to be considered	Naïve algorithm	Repetitive bisection and line sweep algorithm
Number of edges of the polygon	14	14
Number of convex vertices of the polygon	9	9
Segments to be considered for checking intersections	14 (line segments) + 9 (circular arcs)	14 (original guard zonal line segments) + $9 \times p$ (derived line segments from the circular arcs), where p is a constant
Computation required	$(14+9)^2 = 529$	$(23+I)(\log_2 23) \approx 104.042 + 4.524 \times I$, where I is the number of intersections
Time complexity	$O(n^2)$	$O(n \log n + I \log n)$

V. Computational Complexity

If the number of edges in the original polygon is n, then the number of edges after the preprocessing of the polygon by replacing all the circular arcs by a set of (smaller) line segments is also $O(n)$ as we require a constant number of operations for each of the convex vertices. The next step is to apply the line sweep algorithm taking the set of all line segments, original as well as derived segments by preprocessing. The algorithm starts by creating the event queue by sorting the starting and ending points of the line segments, which takes $O(n \log n)$ time using any standard sorting algorithm. Initializing the status structure takes constant time. The handling of status structure consists of three operations, insertion, deletion, and interchange of positions that takes $O(\log n)$ time each. Now $m = n+I$, where I is the number of intersection points. Hence, the complexity of line sweep algorithm is $O(m \log_2 n)$ [10].

Lemma 1: If $p \geq 1$ be the number of times a circular arc is divided to replace the arc by a set of equal (smaller) line segments, then p must be a constant.

Proof: To prove the lemma we consider two extreme cases, i.e., the circular arcs for the convex vertices with two extreme values of the angles. If we can prove that p is a constant for these two cases, it is true for all the intermediate values. As circular arcs are introduced in the guard zones for convex vertices and the convex angle to be subdivided is minimum when it tends to 180° and maximum when it tends to 360°. Figs. 4(a) and

4(b) show these two cases. If the internal angle tends to 180º, the external angle also tends to 180º. Hence, we draw perpendiculars to the two adjacent line segments at the convex vertex O of the given polygon, where $OA = OB = r$ (see Fig. 4(a)). So, $\angle AOB$ is very close to 0º, and we get the line segment corresponding to the circular arc by connecting points A and B that may not be bisected further.

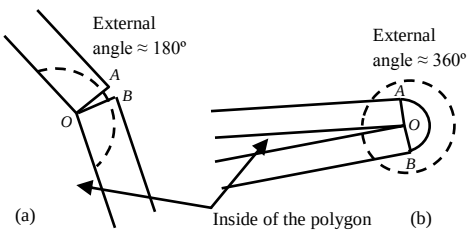

Fig. 4: (a) The external angle tends to 180º, when the angle associated with the circular arc to be subdivided tends to 0º. (b) The external angle tends to 360º, when the angle associated with the circular arc to be subdivided tends to 180º.

On the other hand, if the external angle tends to 360º (see Fig. 4(b)), the angle $\angle AOB$ to be subdivided tends to 180º. When an arc makes an angle less than or equal to 4º, we may consider it to be a line segment. So, if we apply a recursive algorithm to subdivide $\angle AOB$ up to a level of height six (or any constant number more than six), we may get a collection of straight line segments that may replace the circular arc up to a level of desired precision; hence the value of p is proved as constant. □

VI. Applications of the Problem

Now in brief we like to point out the importance and motivation of the problem as follows. In case of VLSI physical automation design, given a set of isothetic non-overlapping polygonal regions and a common resizing parameter δ, the objective is to compute another set of closed regions resizing each polygon by an amount of δ. If two or more polygons are closed enough so that their guard zones overlap, indicating the violation of least separation constraint among them, then the polygons have to move relatively to overcome this breach [12].

The guard zone problem finds another important application in the automatic monitoring of metal cutting tools. Here a metal sheet is given and the problem is to cut a polygonal region of some specified shape from that sheet. The cutter is like a ballpoint pen whose tip is a small ball of radius δ, and it is monitored by a software program. If the holes inside the notch also need to be cut, our algorithm can easily be tailored to satisfy that requirement too.

The Minkowski sum is an essential tool for computing the free configuration space of translating a polygonal robot [1]. It also finds application in the polygon containment problem and in computing the buffer zone in geographical information systems [4], to name only a few.

VII. Conclusion

As we have discussed earlier, resizing of electrical circuits is an important problem in VLSI layout design as well as in embedded system design, while accommodating the (groups of) circuit components on a chip floor, this problem motivates us to compute a guard zone of a simple polygon. In this paper we have considered the problem of computing a guard zone of a (2D) simple polygon, and developed a sequential algorithm for computing the same that uses the concepts of analytical and coordinate geometry to detect overlapped region(s) within the guard zone (if any) and accordingly exclude that region to report the resulting outer guard zone. Our algorithm can easily be modified to compute the regions of width r (as guard zonal distance) outside the polygon, and also inside the polygon (if necessary), which may find several applications in practice. This work can also be extended for computing a guard zone of a three-dimensional simple solid object as a problem of probable future work.

***Abstract*—Nuclear Magnetic Resonance (NMR) Spectroscopy is a widely used technique to predict the native structure of proteins. However, NMR machines are only able to report approximate and partial distances between pair of atoms. To build the protein structure one has to solve the Euclidean distance geometry problem given the incomplete interval distance data produced by NMR machines. In this paper, we propose a new genetic algorithm for solving the Euclidean distance geometry problem for protein structure prediction given sparse NMR data. Our genetic algorithm uses a greedy mutation operator to intensify the search, a twin removal technique for diversification in the population and a random restart method to recover stagnation. On a standard set of benchmark dataset, our algorithm significantly outperforms standard genetic algorithms.**

***Index Terms*—Genetic Algorithms, Protein Structures, NMR, Euclidean Distance Geometry, Greedy Mutation**

I. Introduction

The function of a protein depends on its *native conformation* or the stable three dimensional structure with minimum free energy in a particular environment. Knowledge about this native structure is of paramount importance and can have an enormous impact on the field of rational drug discovery. Nuclear magnetic resonance (NMR) spectroscopy is one of the most widely used techniques to predict native structure of proteins. NMR machines provide inter-atomic distance data for a given protein. Thus, the molecular distance geometry problem (MDGP) arises in this context: given the set of Euclidean distances between the atoms in a protein, MDGP asks to find the Cartesian coordinates of the atoms.

However, in practice, NMR machines are able to produce the inter-atomic distances of only a subset of the pairs of atoms that are spatially close and this data too lacks accuracy. As a result, we are given the upper and lower bounds of only a subset of the Euclidean distances. Thus we are left to solve a variant of the MDGP problem with incomplete and inaccurate data. Many computational approaches have been applied to solve MDGP problem with sparse and inaccurate data on real instances [1], [2], [3], [4], [5], [6]. However, complete search methods like spatial branch and bound (sBB) and stochastic methods like variable neighborhood search (VNS) have been able to solve the problem for proteins with only upto 50 atoms [7] and fail to converge quickly for larger number of atoms.

In this paper, we present GreMuTRRR (pronounced grey matter), which is a scalable genetic algorithm to solve the MDGP problem for sparse and inaccurate NMR data. Much of the success of our approach comes from a greedy mutation operator, sude to intensify the search, a twin removal technique to diversify the population and a random restart method to recover from stagnation. Experimental results on proteins with number of atoms ranging from 50–2147 shows that our algorithm outperforms standard genetic algorithms and thus obtains state-of-the-art results.

II. Preliminaries

In this section, we provide a formal definition of the MDGP problem and a brief description of genetic algorithms.

A. Distance Geometry Problem

Molecular distance geometry problem can formally be defined as followed [8]: find a set of Cartesian coordinates $c_1, c_2, \cdots, c_n \in \mathbb{R}^3$ of atoms of a molecule such that $l_{ij} \leq d_{ij} \leq u_{ij}, \forall (i,j) \in E$, where l_{ij} and u_{ij} are the lower and upper bounds of the Euclidean distance $d_{ij} \equiv ||c_i - c_j||$ between a pair of atoms $(i,j) \in E$. Notably, in the context of NMR data, E is sparse. Here, Cartesian coordinate c_i of an atom i corresponds to a three dimensional point (x_i, y_i, z_i) in the Euclidean space.

B. Genetic Algorithm

Genetic Algorithms are population-based search methods that resemble the natural phenomena of biological evolution. Genetic Algorithms are widely used for different search optimization problems in different fraternity. It basically starts with a pool of initial random solutions which is called the initial population. Each individual in the population are encoded by a set of properties which are called chromosome or genotype which can be altered for attaining diversification in the population. It then follows an iterative process in which each of these iteration is called a generation. In each generation, the population are then allowed to evolve using different operators which also mimics the natural process of biological evolution like mutation, recombination or survival of the fittest. In each generation, the fitness of each individual is evaluated. Generally the fitness is the value of the optimization function being considered to be solved. The more fit individuals are usually selected to breed and generate new fitter individuals in the population. Thus a new generation of population is 'breeded' and are used in the next generation. This process of evolution are continues until a sufficient number of generations has been produced or a satisfactory level of fitness value has been attained.

III. Related Works

Euclidean distance geometry problem and its variants are applied to many problems in various fields including wireless sensor network localization [9], inverse kinematic problem [10], multi dimensional scaling [11], protein structure determination [6] etc. The variant of the MDGP problem, when we know distances for all pairs $(i, j) \in E = \{1, 2, \cdots\}^2$ and $d_{ij} = l_{ij} = u_{ij}$ has a polynomial algorithm to produce exact solution [8]. Even when some of the pairwise distances are unknown, the problem is solvable by a linear time algorithm [3]. However, the variant of MDGP with sparse and inaccurate data is shown to be NP-hard by More and Wu [12]. A recent survey of computational methods applied to solve this variant of MDGP can be found in [2].

Among the general purpose methods, spatial branch and bound [13] and variable neighborhood search (VNS) [14] methods are not scalable [7]. Smoothing based methods like DGSOL [6], [12] also fail for large instances of the problem. In [15], VNS was combined with DGSOL approaches which provided better results for larger instances but resulted into a slow algorithm. A combinatorial build up algorithm was proposed in [16]. It is important to note that all these methods were tested on dense instances only. Among other methods applied to this problem graph decomposition methods [1] and NLP formulations [17] are notable.

IV. Our Method

GreMuTRRR is formally presented in Algorithm 1. It starts with a population initialized randomly and terminates at convergence. Convergence is achieved if the search does not improve the quality of the global solutions for a given period of time. In each generation, individuals are selected from the population for cross-over to produce new individuals. Mutation operations are performed probabilistically on the newly found individuals. Global best solutions are updated in each iteration and are kept in the new populations to maintain elitism. Periodical twin removal and random restart operations are activated to ensure diversification and recover stagnation. Rest of this section describes the various components of GreMuTRRR.

A. Search Space

A Protein structure is formed by the interaction among different amino acids tied with each other by chemical bonds. A pair of these amino acid cannot reside closer than 3.8Å to each other to avoid steric clash. If all the amino acids in a certain protein structure align in a straight line, we have a chain of amino acids of length $3.8 \times V$ in each directions, where V is the number of amino acids in the protein structure. Hence, we have taken the upper bound of our 3-D search space to $3.8 \times V$.

B. Encoding

In our method, we have encoded every individual in a population by $3 \times V$ number of genes. Here, V is the number of atoms in a protein structure. Each of these genes in an individual is initialized randomly from an uniform distribution of the range $[0, 3.8 \times V]$. So, an individual X can be represented as the ordered list of $3V$ number of genes:

$$X = \left\{ \underbrace{x_1, y_1, z_1}_{1^{st} Atom}, \underbrace{x_2, y_2, z_2}_{2^{nd} Atom}, \ldots, \underbrace{x_i, y_i, z_i}_{i^{th} Atom}, \ldots, \underbrace{x_V, y_V, z_V}_{V^{th} Atom} \right\}$$

Algorithm 1: GreMuTRRR()

```
nonDiverseSteps = 0
nonImprovingSteps = 0
GreedyMutationRate = 0.8
Intialize the population, P randomly
while Termination criterion are met do
    P_new = {globalBest}
    for each Individual X ∈ P do
        ⟨X_1, X_2⟩ = tournamentSelection(P)
        X_new = crossOver(X_1, X_2)
        add X_new to P_new
    end
    for each Individual X in P_new do
        if rand(0,1) ≤ GreedyMutationRate then
            greedyMutate(X)
        else
            randomMutate(X)
        end
    end
    find the individual X_best ∈ P_new with best fitness
    if fitness(globalBest) < fitness(X_best) then
        globalBest = X_best
        nonImprovingSteps = 0
    else
        nonImprovingSteps++
    end
    if nonDiverseSteps ≥ twinRemovalInterval then
        activate twinRemoval(P_new) procedure
        nonDiverseSteps = 0
    else
        nonDiverseSteps++
    end
    if nonImprovingSteps ≥ randomRestartInterval then
        activate randomRestart(P_new) procedure
        nonImprovingSteps = 0
    end
    P = P_new
end
return globalBest
```

C. Fitness Evaluation

We have calculated the euclidean distance between each pair of points present in the individual's chromosome where each non-overlapping consecutive subsequence of length three in the chromosome represents the position of an atom in the protein structure in a 3-D space. We have assumed an upper bound, u_{ij} and lower bound, l_{ij} of the distances between pair of amino acids. The fitness of an individual X is defined by as Equation 1 below:

$$Fitness(X) = \left(\frac{1}{|E|} \sum_{(i,j) \in E} e_{ij}^2 \right)^{1/2} \tag{1}$$

where, $e_{ij} = max\{l_{ij} - \|c_i - c_j\|, \|c_i - c_j\| - u_{ij}, 0\}$ is the error associated to the constraints $l_{ij} \leq \|c_i - c_j\| \leq u_{ij}$ and $|E|$ denotes the number of distance pairs given. This is known as the *Largest Distance Error (LDE)* in the literature [2].

D. Genetic Operators

Genetic algorithms are guided by different genetic operators to help in keeping a balance of the exploitation and exploration of the search process. We use three types of genetic operators in our search: random mutation, greedy mutation and cross-over.

1) Random Mutation: Genetic diversity is a necessity for the process of evolution which is generally attained by mutation operator. Mutation helps the evolutionary process to guide through and look for different avenues and solutions in the search space. It also helps to avoid local optima by preventing the individuals from becoming too similar to one another. We have used uniform mutation in our method. We have mutated the value of each gene into a new value within the pre-specified bound of the search space($[0, 3.8 \times V]$). Whether an individual will be mutated or not depends on a mutation rate which is kept to a lower value of 0.015 to avoid primitive random search. A sketch of the pseudo-code is given in Algorithm 2.

Algorithm 2: Random Mutation (individual X)

$mutationRate = 0.015$
for *each gene X(i) in the genotype of* X **do**
  if $rand(0,1) \leq mutationRate$ **then**
    $X(i) = U(0,1) * (3 * V)$;
  end
end
return X

2) Greedy Mutation: In our proposed method, we have also used a greedy mutation where we greedily choose the new value of a particular gene in an individual. We randomly alter a certain gene and try r different random values for the gene temporarily. The value of gene that gives the best fitness of that individual is retained and used as the final new value of the gene. As, greedy mutation is computationally expensive, we make selection between the random mutation and greedy mutation with a probability, $GreedyMutationRate(= 0.8)$. The algorithm for greedy mutation is given in Algorithm 3.

Algorithm 3: Greedy Mutation (individual X)

set $r = 20$
for *each gene* $X(i)$ *in the genotype of* X **do**
  S = set of r random values for gene $X(i)$ from the range $[0, 3.8 * V]$
  find $v \in S$ for which fitness(X) is minimum
  set, $X(i) = v$
end
return X

3) Cross-over: Cross-over operators help genetic process to exploit the better solutions found thus far along the evolution process and regenerate new individuals by combining the genetic information of the individuals with better fitness value. It uses the better historical genetic information to guide the search into the search space regions with solutions having better fitness. By recombining the fitter individuals to generate new offspring, this operator is likely to produce more fitter individuals. We have used tournament selection with tournament size being equal to 5 to select two individual parents to take part in the cross-over operation. We then have recombined genes of the two parents and have generated a new set of genes for each of the offsprings with equal probability for each gene of being selected from any of the parents. The algorithm is outlined in Algorithm 4.

E. Twin Removal

We have removed and reinitialized individuals with identical genetic information. We have defined the similarity measure

Algorithm 4: Cross-Over (individual X_1, individual X_2)

X_{new} be a new offspring
$uniformRate = 0.5$
for *each gene X(i) in the genotype of* X_{new} **do**
  if $rand(0,1) \geq uniformRate$ **then**
    $X_{new}(i) = X_1(i)$
  else
    $X_{new}(i) = X_2(i)$
  end
end
return X_{new}

between two individuals as follows:

$$Similarity(X_1, X_2) = e^{-\frac{\|X_1 - X_2\|^2}{2\sigma^2}} \quad (2)$$

Here, the value of σ has been chosen to be 75. The $Similarity(X_1, X_2)$ function will return a value in the range [0,1]. The more the value of the similarity function is closer to 1, the more genetically similar are X_1 and X_2. We have chosen 0.8 as the threshold to define similarity between two individual. If $Similarity(X_1, X_2) >= 0.8$, we declare that X_1 and X_2 are twins and reinitialize randomly one of them. We have run the this Twin Removal procedure after every 100 generations of evolution.

Algorithm 5: Twin Removal

$similarityThreshold = 0.8$
for *each pair of individuals* (X_i, X_j) *in the population* **do**
  if $Similarity(X_i, X_j) \geq similarityThreshold$ **then**
    declare X_i and X_j as Twins
    reinitialize X_j
  end
end

F. Random Restart

If the algorithm does not show enough improvement within a significant number of generations, we reinitialize some individuals of the population with random values within the search space. We have evaluated the improvement over the immediate past 50 generations. If the improvement in the last 50 generations is less than or equal to a threshold, $t = 0.001$, we initiate the random restart procedure.

V. Experimental Results

We have implemented GreMuTRRR in Java programming language using JDK 1.6 and have run our experiments on an Intel 3.3GHz core $i3$ machine with 2GB RAM. We compared the performance of GreMuTRRR with a basic genetic algorithm without considering the greedy mutation, twin removal and random restart. We denote this algorithm as 'Basic GA' henceforth. Basic GA differs with GreMuTRRR given in Algorithm 1 in Lines 27–36 since it does not contain twin removal and random restart and in Line 3, as the parameter $greedyMutationRate = 0.0$ for Basic GA. All other parameters were kept same for the sake of fair comparison.

A. Benchmark

We have considered two sets of protein instances for our experiments: one considering only the backbone atoms (backbone only) and another containing all atoms (full atomic).

These are larger protein benchmarks introduced in [18]. We extracted the structures from PDB website [19] and have calculated the distance among pair of atoms. Lower and upper bounds of the distances are calculated using the following equation:

$$l_{ij} = (1-\epsilon)\hat{d}_{ij}, u_{ij} = (1+\epsilon)\hat{d}_{ij} \quad (3)$$

Here, $\hat{d}_{ij}$ is the real distance between point c_i and point c_j in the known structure of the protein sequence and $\epsilon = 0.8$. To make the dataset sparse, we took only 30% of the distances that are less or equal to $6\mathring{A}$.

B. Results

The largest distance error (LDE) values for our algorithm and Basic GA for backbone only instances and full atomic instances are given in Table I and Table II respectively. Each protein is reported with its corresponding PDB id and number of atoms in the structure considered.

TABLE I
BEST FITNESS FOR POPULATION SIZE 50 WITH RUN OF 2000 GENERATIONS(WITH BACKBONE ATOMS ONLY)

Protein Id	V	Basic GA	GreMuTRRR
1PTQ	50	0.49546	0.44977
1LFB	77	0.18060	0.13360
1F39	101	0.06595	0.02051
1AX8	130	0.06064	0.00253
1RGS	264	0.12380	0.00297
1TOA	277	0.12993	0.00156
1KDH	356	0.19119	0.00458
1BPM	481	0.34434	0.00441
1MQQ	679	0.58863	0.00894

TABLE II
BEST FITNESS FOR POPULATION SIZE 50 WITH RUN OF 1500 GENERATIONS(INCLUDING ALL ATOMS)

Protein Id	V	Basic GA	GreMuTRRR
1PTQ	402	0.71000	0.17224
1LFB	641	0.97121	0.31463
1F39	767	1.81091	0.16805
1AX8	1003	2.52303	0.43211

C. Analysis

From the results presented in the tables it is evident that for both of the instances GreMuTRRR achieves better solutions compared to the Basic GA algorithm for the proteins. However, the improvement is more clearly shown in Figure 1. GreMuTRRR significantly lowers the objective function LDE before both algorithms gets stuck and can not improve further. Its interesting to note thatGreMuTRRR is able to converge very early ($\leq$ 50 generation) compared to the Basic GA.

VI. CONCLUSION

In this paper, we presented a new genetic algorithm to solve the molecular distance geometry for protein structure determination problem using NMR data. We use a greedy mutation operator to intensify the search, a twin removal technique for diversification in the population and a random restart method to recover stagnation. On a standard set of benchmark dataset, our algorithm significantly outperforms standard genetic algorithms. In future, we want to implement a web service based on our method and make it public to be used by biologists.

Abstract—**In this work, a quick and effective method to calculate the second and third optical transition energies of metallic armchair single wall carbon nanotubes (SWCNT) is presented. In this proposed method, the transition energy of any armchair SWCNT can be predicted directly just by knowing one of its chiral index. The predicted results are compared with recent experimental data and found to be accurate over a wide diameter range. The empirical equation proposed here is also compared with that proposed in earlier works. The proposed way may help the research works or applications where information of optical transitions of armchair metallic nanotubes is needed.**

Index Terms—**SWCNT, chiral index, metallic, optical transition energy.**

I. Introduction

Electronic and optical properties of single-wall carbon nanotubes (SWCNT) are directly associated with their geometrical structures [1, 2] which are uniquely specified by a pair of chiral index (n, m). A SWCNT (n, m) will be metallic if its n-m = 3k (k is integer), i.e. mod(n-m, 3) = 0 and it will be semiconducting if its n-m ≠ 3k, i.e. mod(n-m, 3) = 1 or 2 [3]. This relation is always found true except for SWCNT with very small diameter, where curvature effect dominates its properties [4]. This relation indicates that theoretically two third of the total SWCNTs are semiconducting and one third are metallic. Metallic nanotubes are a potential choice for nanoscale electrodes and 1-D quantum wires [5], transparent conductors and semi-transperant conductive coating [6, 7] and many similar nano device applications.

The one-dimensionality of the nanotubes gives rise to a discrete set of singularities (splitting into 1D subbands instead of one wide electronic energy band), the so called *van Hove singularities* (vHS) in the nanotube Density of States (DOS) [2,8,9]. Each SWCNT (*n*, *m*) has a unique set of interband energies E_{ii} denoting the energy differences between the *i*th van Hove singularities in the conduction and valence bands and optical transitions associated with the vHSs can only occur between these mirror subbands [2]. This vHS is an unique feature of nanotubes and also primarily responsible for many distinguished optical and electronic properties of SWCNTs.

According to the electronic band theory, the vertical interband transition energy (E_{ii}) between the *i*-th pair of VHSs in both the valence and the conduction bands of a semiconducting (S) or metallic (M) nanotube is represented by E_{ii} which is inversely proportional to nanotube diameter and corresponds to the first, second, third,…… interband transitions (E_{11}^S, E_{22}^S, E_{44}^S, ….) of semiconducting SWCNTs when *i* = 1, 2, 4,… and to the first, second, third interband transitions (E_{33}^M, E_{66}^M, E_{99}^M…) of metallic SWCNTs when *i* = 3, 6, 9,… respectively [2]. This inverse proportional trend of transition energy with SWCNTs diameter is also observed from well known Kataura plot [10].

Theoretical model derived from electronic band theory fails quantitatively to predict experimentally observed values of optical transitions for both semiconducting and metallic SWCNTs. Nanotube's 'curvature effect' [4, 11-13] and 'trigonal warping effect' [14] cause deviations in the electronic properties of nanotubes derived from the simple π-orbital graphene picture. Curvature causes π and σ states of nanotube's chemical bond to mix. This leads to hybridization between σ and π orbitals. The degree of hybridization becomes larger as the diameter of a SWCNT gets smaller [12]. The σ–π hybridization effect has been considered and calculated in the literature [11-13]. The main result is that nanotubes satisfying |n−m| = 3k (k=0, 1, 2….) develop a small curvature-induced bandgap, and hence become quasi-metallic or small gap semiconductor [15]. Armchair nanotubes (n, n) are an exception because of their special symmetry, and only they remain truly metallic for all diameters [15]. Saito *et al* [14] investigated the 'trigonal warping effect' analytically and derived expressions to estimate the corresponding deviation in optical transitions of metallic and semiconducting SWCNTs. They showed that trigonal warping causes splitting of the density of State (DOS) peaks of metallic SWCNTs except for armchair tubes. Thus only armchair SWCNTs are unaffected due to curvature and trigonal warping and remain truly metallic.

As armchair nanotubes are the most pure kind of metallic SWCNTs, the concentration of this work will be only on armchair tubes. Sometimes, researchers need to find or measure the optical transitions in metallic nanotubes. Many authors [16-19] studied the properties of metallic SWCNTs and discussed first, second and third optical transition energies of metallic SWCNTs. From these Liu *et al* [19] studied the matter more recently and more extensively than anyone before. They carried a series of optical experiments and measured optical transition energies of numerous semiconducting and metallic SWCNTs. The experimental data of optical transitions of metallic armchair SWCNTs used in this work is primarily based on the work of Liu *et al* [19]. Though sometimes researchers need the value of optical transitions in metallic nanotubes, but there is no easy way to calculate or predict those transitions except experimental procedure. Some complex empirical relations are proposed by some authors

[16,18,19] but they are not simple to calculate and involve lot of parameters. Here, in this work, a concise empirical relation is devised to predict the second and third optical transitions in armchair metallic nanotubes which directly relates the optical transition value with any of the chiral index of armchair tubes. The proposed relation can give a quick as well as highly accurate prediction of second and third optical transitions in armchair metallic SWCNTs.

II. Method and Results

Optical transition energies for metallic armchair (n, n) SWCNTs with chiral index (15,15) to (35,35) were closely studied here. There are total 21 armchair SWCNTs within these two chiral index range having diameter from 2 nm to 4.8 nm. Values of optical transition energies of these tubes were recorded from various experimental reports [16-19] with a special focus on the work of Liu *et al* [19] which is most recent and provides most comprehensive data. From these experimental reports, second optical transition energy of 16 armchair tubes ranging from chiral index (15,15) to (30,30) and third optical transition energy of 13 armchair tubes ranging from chiral index (23,23) to (35,35) were found.

In their work, Liu *et al* [19] proposed following empirical equation to fit their experimental values of different optical transitions of a number of semiconducting and metallic nanotubes:

$$E_p(k) = 2\hbar v_F(p)\times k + \beta\times k^2 + \eta(p)\times k^2\cos(3\theta)$$

Here, p is the transition index, k is the magnitude of wave vector in the grapheme Brillouin zone that varies with nanotube chirality (n, m) and transition index p. Magnitude of k is given by p× 2/(3d), where d is the nanotube diameter. $E_p(k)$ is the effective dispersion for transition p, $\hbar$ is the reduced Planck constant = 6.582×10^{-16} ev.s and β=-0.173 ev. nm^2. Rest two parameters v_F and η have different values for different transition index p.

For second optical transition energy (E_{66}) of metallic tubes, p=6, so, k= 4/d. Liu *et al* [19] proposed v_F (p) =1.236×10^6 m/s and η(p) = 0.058 ev.nm^2 for p=6. Using their proposed values and using the fact that Θ=30° for armchair tubes, the expression for second optical transition energy (E_{66}) of metallic armchair tubes reduces to,

$$E_{66} = \frac{6.5083}{d} - \frac{2.768}{d^2} \qquad (1)$$

For third optical transition energy (E_{99}) of metallic tubes, p=9, so, k= 6/d. Liu *et al* [19] proposed v_F (p) =1.248×10^6 m/s and η(p) = 0.047 ev.nm^2 for p=9. Using their proposed values and using the fact that Θ=30° for armchair tubes, the expression for third optical transition energy (E_{99}) of metallic armchair tubes reduces to,

$$E_{99} = \frac{9.8572}{d} - \frac{6.228}{d^2} \qquad (2)$$

So, these are the empirical expression of E_{66} and E_{99}, simplified from the work of Liu *et al* [19]. One can easily note that lot of parameters are involved in the overall calculation of empirical values of E_{66} and E_{99} from their prarent equation which increases computational efforts. Hence, an attempt will be made here to devise a simple empirical relation between the chirality and optical transition of armchair metallic tubes so that the value of second or third optical transition of these tubes can be predicted directly from just one of their chiral index n (for armchair tubes, n=m, so, knowing one index will be enough).

After a careful study of the symmetry in the structure of armchair tubes, their optical transitions and their relation with corresponding chiral index, we devised following empirical formula to predict the optical transitions from corresponding chiral index **n** of any armchair nanotube (n, n).

For second optical transition energy (E_{66}) of armchair SWCNTs:

$$E_{66} = \frac{50}{n\exp(4.3/n)} \qquad (3)$$

For third optical transition energy (E_{99}) of armchair SWCNTs:

$$E_{99} = \frac{75}{n\exp(6/n)} \qquad (4)$$

Empirical values of second and third optical transition energies of these armchair SWCNTs with chiral index (15,15) to (35,35) were calculated using empirical equations (1) and (2) as well as using empirical equations (3) and (4). Both results agree well with experimental values of second and third optical transitions of corresponding metallic armchair SWCNTs. Nevertheless, it was observed that the overall prediction accuracy of equations (3) and (4) as proposed in this work is much better than that of equations (1) and (2) as simplified from the parent equation proposed by Liu *et al* [19]. Besides, equations (3) and (4) gives quite simpler expressions to calculate the value of optical transitions directly from one chiral index in compared to the expression of equations (1) and (2) that requires additional calculation to know the value of diameter of corresponding armchair tube. Moreover, it has to be noted that the simplified expression of equations (1) and (2) results from its parent equation only after knowing the values of a number of parameters. Hence, empirical equations (3) and (4) as proposed in this work is better than simplified empirical equations (1) and (2) from the work of Liu *et al* [19].

Experimental [19] and empirical values of optical transition energies along with chiral index (n, n) and diameter of these armchair tubes are shown in Table I and Table II. In Table I, empirical result for second optical transition (E_{66}) from this work using Eqn. (3) and the empirical result from the work of Liu *et al* [19] using Eqn. (1), both are provided so as to compare them. Similarly, in Table II, empirical result for third optical transition (E_{99}) from this work using Eqn. (4) and the empirical result from the work of Liu *et al* [19] using Eqn. (2), both are provided so as to compare them. From these two tables it can be observed clearly that the predicted values from Eqn. (3) and (4) are much closer to the experimental values than those predicted by Eqn. (1) and (2). For second optical transition (E_{66}) the average absolute error in prediction using Eqn. (3) was found to be only 0.009 ev and corresponding % average absolute error is only 0.53%. Similarly, for third optical transition (E_{99}) the average absolute error in prediction using Eqn. (4) was found to be only 0.006 ev and corresponding % average absolute error is only 0.27%. Thus, the empirical equations proposed here can predict the value of

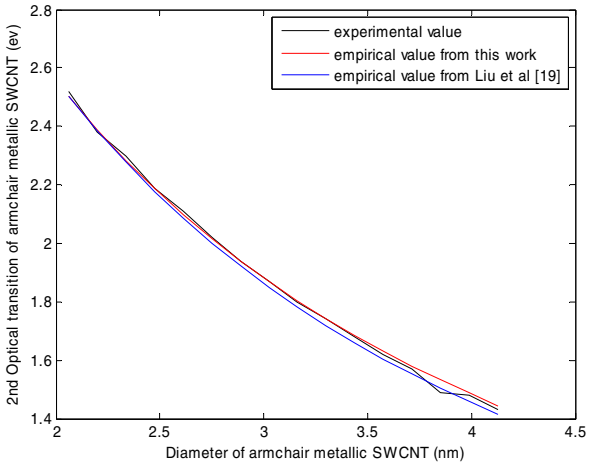
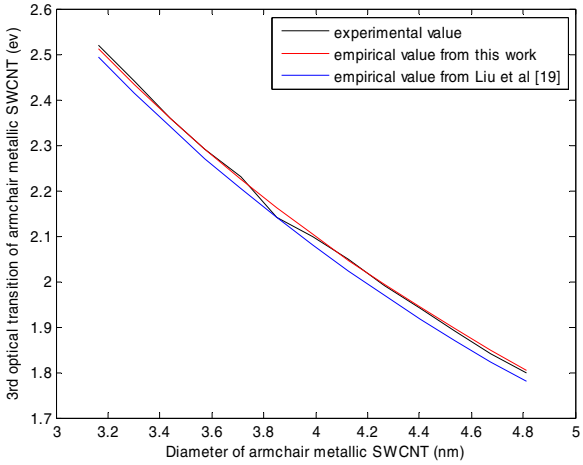
optical transition energies of armchair tubes with higher accuracy.

Figure 1 (a) and (b) shows the plot of experimental and empirical values of second and third optical transition energies, respectively, of metallic armchair SWCNTs with respect to their diameters. Here also, empirical results for second and third optical transition (E_{66} and E_{99}) from this work using Eqn. (3) and (4) and the empirical result from the work of Liu *et al* [19] using Eqn. (1) and (2), both are plotted so as to compare them. Again it can be observed from these two plots that, for both optical transitions, empirical values predicted by Eqn. (3) and (4) are closer to the experimental values in compared to those predicted by Eqn. (1) and (2) over the full diameter range under consideration. This curve can be extrapolated using above two empirical relations to predict other armchair



(a)



(b)

Fig. 1 Experimental value(black), empirical value from this work(red) and empirical value from earlier work (blue) of optical transition vs diameter of armchair SWCNTs, a) second optical transition b) third optical transition.

tubes beyond this diameter range.

Another interesting observation from the second and third optical transition energies of armchair SWCNTs is, the ratio of third transition to second transition of same armchair tubes are equal to a constant whose value is around 1.4. This observation further facilitate the calculation of higher optical transitions in metallic armchair tubes as one can know the third transition energy value of a tube by knowing the value of second transition multiplied by that constant. This relation also indicates the built in high symmetry in armchair SWCNTs which causes their higher optical transition energy values to grow in a systematic order. This relation may also help to study the behaviour of metallic armchair tubes in a more systematic way.

III. Conclusions

In this work, an effective method to calculate the second and third optical transition energies of metallic armchair single wall carbon nanotubes (SWCNTs) is presented. Second and third optical transitions of metallic armchair (n, n) SWCNTs are expressed through a concise empirical formula that directly relates the transition energy with chiral index **n**. Thus, in this method, the transition energy of any armchair SWCNT can be predicted quickly and directly just by

knowing one of its chiral index. The predicted or calculated results are compared with recent experimental data and found to be accurate over a wide diameter range. The empirical equations and corresponding result found in this work are also compared with empirical works proposed by others. It was found that the empirical expression proposed here is much simpler than earlier works and corresponding result provides better accuracy for armchair metallic SWCNTs than earlier works. The proposed way may help the research works or applications where information of optical transitions of armchair metallic nanotubes is needed.

Abstract—**The dynamics of fullerene self-insertion into carbon nanotubes in water are studied by molecular dynamics simulations. It is revealed that the van der Waals interaction between the nanotube and fullerene introduces a spontaneous insertion of fullerene molecule inside the nanotube in the presence of water molecules when the initial separation between the nanotube and the fullerene is less than a critical distance. It is also demonstrated that the insertion process is strongly dependent upon the radius of the nanotubes and does not show a significant dependence upon the temperature or the length of the nanotubes. The study suggests possible bottom–up self-assembly of novel nanostructures like peapod (one or more fullerene molecules inside a carbon nanotube), which has great potential in the fields of nano-oscillator and futuristic quantum information processor.**

Index Terms— **Carbon nanotube, fullerene, molecular dynamics, water.**

I. Introduction

In the past few decades, carbon nanotubes (CNTs) have drawn a great deal of attention as a model system for studying many important physical phenomena because of its extraordinary mechanical and electronic properties [1, 2]. These properties along with the rigid structure make it ideal for an integrated chip design [3], biosensors [4, 5] and fuel storage [6]. Besides, these nonpolar rigid structures can be used as unique molecular channels for water and protons, with tunable conductivity by changing the local channel polarity and solvent conditions [7, 8]. Recently, CNT in water system has drawn a lot of interest because of its emerging applications in superfast water transport [9] and water supply [8]. The possibility of tuning the properties of CNTs by inserting molecules of different sizes and doping has improved the scope of using CNTs in nanoelectronics [3]. Dynamics of different molecules like CNTs, DNA, fullerene translocating through CNTs as nanofluidic channels both in vacuum and in different media have been reported [10, 11]. Recently, fullerene peapod (i.e. an array of fullerene molecules in a CNT) has got extensive attention for its potential use in nano-oscillator [12]. Peapod is also considered as a possible candidate for quantum information processor [13, 12]. Xue *et al.* [11] has presented that molecules translocating through CNTs in vacuum are encapsulated by the nanotubes in an oscillating manner whereas in the presence of aqueous media, the oscillation is strongly impeded. Khlobystov *et al.* [10] has also reported the possibility of assembling fullerene arrays inside CNTs in supercritical fluids at low temperatures. However, a detail analysis on the interaction of CNTs and fullerene in water has not been reported yet. A comprehensive study is required to fully understand the physics and dynamics of these nanostructures and to explore their usage for novel applications.

In the present study, the dynamics of self-insertion of fullerene through single-walled carbon nanotube (SWCNT) is investigated in water using molecular dynamics (MD) simulation [14, 15]. The influence of van der Waals (vdW) interaction between the CNT and the fullerene has been studied. In addition, effect of the CNT chiralities and length on the self-insertion time has been investigated. We have also varied the initial center of mass (COM) distance between the CNT and the fullerene to observe its impact on the insertion time and mechanism. The effect of temperature on the insertion process has been studied as well.

II. Model and Simulation Methods

CNTs are characterized by two indices (n, m) corresponding to two unit vectors ($\boldsymbol{a_1}$ and $\boldsymbol{a_2}$) in the crystal lattice of graphene. The structures with n = m are known as armchair and the structures with m = 0 are known as zigzag. Throughout this study, armchair CNTs (with chiral indices (10, 10), (12, 12) and (15, 15)) have been used along with the buckyball (C_{60}) fullerene molecule. For molecular dynamics simulation [14, 15], CNTs and the fullerene molecules can be described by a Morse bond potential, a harmonic cosine potential, a twofold cosine potential for torsion and a Lennard-Jones (LJ) 12-6 potential for nonbonding interaction [16]:

$$U\left(r_{ij},\theta_{ijk},\varphi_{ijkl}\right)=K_{Cr}\left[\exp\left(-\gamma\left(r_{ij}-r_C\right)\right)-1\right]^2$$
$$+\frac{1}{2}K_{C\theta}\left(cos\theta_{ijk}-cos\theta_C\right)^2+\frac{1}{2}K_{C\varphi}\left(1+\cos\left(2\varphi_{ijkl}-\varphi_C\right)\right)$$
$$+4\varepsilon_{CC}\left[\left(\frac{\sigma_{CC}}{r_{ij}}\right)^{12}-\left(\frac{\sigma_{CC}}{r_{ij}}\right)^{6}\right] \quad (1)$$

where, the bonding parameters K_{Cr}, r_C and γ are the parameters for the Morse bond potential; $K_{C\theta}$ and θ_C are the parameters for the bending angle potential; $K_{C\phi}$ and ϕ_C are the torsion parameter [16]. The nonbonded parameters ϵ_{CC} and σ_{CC} are the Lennard-Jones interaction for carbon-carbon interactions and ϵ_{CO} and σ_{CO} are Lennard-Jones interaction for carbon-water interactions [17]. The values of the interaction potential parameters for carbon atoms are given in Table I.

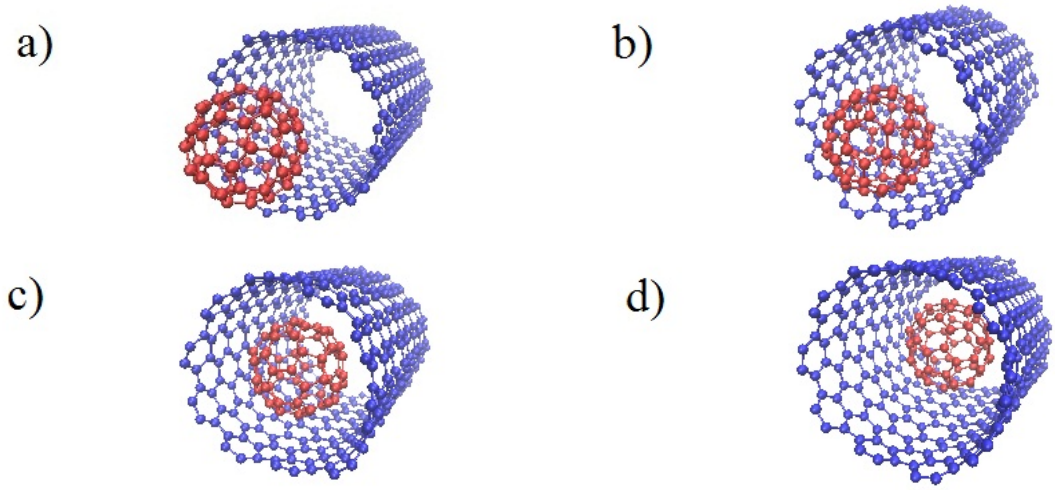

Fig. 1. Simulation snapshots of the self-insertion process of a fullerene inside a (10, 10) nanotube at (a) $t = 0$ ps, (b) $t = 2$ ps, (c) $t = 5$ ps and (d) $t = 100$ ps (water molecules omitted for clarity). The molecular dynamic simulation showing the movement of the molecules up to 20 ps can be found in the video files uploaded on – http://teacher.buet.ac.bd/kawsaralam/res.html.

TABLE I
PARAMETERS FOR INTERACTION POTENTIALS USED IN THE SIMULATIONS

Interaction Potential Parameters	
K_{Cr} = 478.9 kJ mol^{-1}	r_C = 0.1418 nm
$K_{C\varphi}$ = 25.12 kJ mol^{-1}	γ = 21.867 nm^{-1}
$K_{C\theta}$ = 562.2 kJ mol^{-1}	θ_C = 120°
ε_{CC} = 0.3601 kJ mol^{-1}	φ_C = 180°
ε_{CO} = 0.4787 kJ mol^{-1}	σ_{CC} = 0.3400 nm
	σ_{CO} = 0.3275 nm

The CNT-water and fullerene-water interactions have been described by a Carbon-Oxygen LJ potential [17]:

$$U\left(r_{ij},\theta_{ijk}\right)=\frac{1}{2}K_{Wr}\left(r_{ij}-r_W\right)^2+\frac{1}{2}K_{W\theta}(cos\theta_{ijk}-cos\theta_W)^2 \qquad (2)$$

where, r_W and θ_W are the reference O-H bond length and H-O-H angle, and the K_{Wr} and $K_{W\theta}$ are the corresponding force constants. The well-known TIP3P water model [18] has been used to represent water molecules. The values of the interaction potential parameters for water are given in Table II.

TABLE III
PARAMETERS FOR THE TIP3P WATER MODEL [19]

Interaction Potential Parameters	
K_{Wr} = 502416 kJ mol^{-1}	r_W = 0.09572 nm
$K_{W\theta}$ = 628.02 kJ mol^{-1}	θ_W = 104.52°
ε_{OO} = 0.6367 kJ mol^{-1}	σ_{OO} = 0.3151 nm
q_O = -0.834e	q_H = 0.417e

All simulations were performed at a constant pressure of 1 bar and the Berendsen thermostat [20] was used to keep the temperature constant with a coupling time of 0.1 ps. The cut-off radius for the Lennard-Jones interaction as well as Born electrostatics was 1.2 nm. The electrostatic interaction was evaluated using the particle-mesh-Ewald (PME) method [21]. To achieve a structure with a natural orientation, energy minimization was performed. Periodic boundary condition was applied in all directions to avoid problems with boundary effects caused by finite size of the system and no position restraint was applied in the simulation.

III. RESULTS AND DISCUSSION

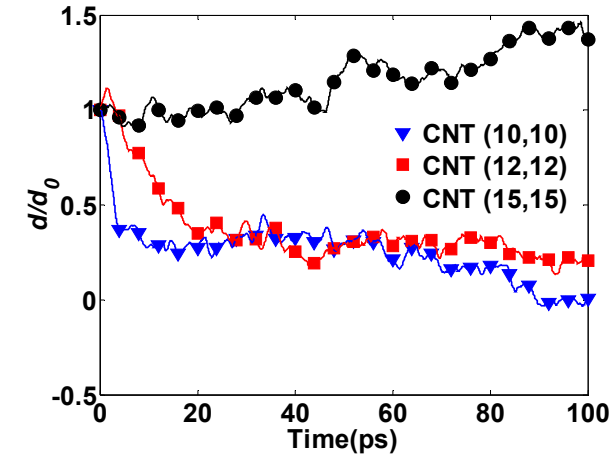
To explore the self-insertion process, we have performed a series of MD simulations with different CNT chirality, length, temperature and initial COM separation between the CNT and the fullerene. Fig. 1 shows the snapshots of the self-insertion process of a fullerene inside a (10, 10) nanotube at $t = 0$, 2, 5, 10 ps. For a better understanding of the simulation results, an illustration video of the MD simulation for 20ps is uploaded on http://teacher.buet.ac.bd/kawsaralam/res.html.

We start with the simulation of an armchair CNT having chirality (10, 10) and a fullerene molecule separated by a distance of 0.1 nm. The length and radius of the CNT is 1.95 nm and 0.678 nm. Blue triangle marker in Fig. 2(a) shows the time vs. normalized COM distance (d/d_0) of this simulation (where d_0 is the initial COM distance between the CNT and the fullerene, and d is the COM distance at different time). It shows an extremely fast insertion process of the fullerene into the CNT within 4 ps. After the insertion process is completed, the fullerene buckyball oscillates slightly inside the nanotube due to the inertia effect. By bringing together more fullerene molecules close to this structure, it is possible to create a peapod (one or more fullerene molecules inside a carbon nanotube).

The physical mechanisms of the insertion process lies within the CNT-fullerene vdW energy which is plotted in Fig 2(b) [blue triangle marker] against time. The CNT-fullerene vdW energy decreases rapidly as a function of the insertion time and reaches a stable value after a while. If we change the chirality of the CNT to (12, 12) [corresponding radius of the nanotube is 0.814 nm], the insertion process takes longer time which is shown in Fig.

2(a) (red square marker). This indicates the dependence of insertion time with the radius of CNT. If the chirality of the CNT is further changed to (15, 15) [corresponding radius of the nanotube is 1.017 nm], the fullerene does not enter into the nanotube [Fig. 2(a) black circle marker]. This is because of the fact that the presence of the carbon atoms (of CNT molecule) too far away from the fullerene results in lower vdW force. To support this argument, another simulation was done (not shown here) with the fullerene initially placed close to the edge of the (15, 15) tube with the same separation of 0.1 nm. This time the fullerene gets into the CNT, confirming the essence of our argument. It is important to mention that there exists a lower limit for the radius of the CNT for a successful self-insertion too. The radius of the fullerene must be smaller than the radius of the CNT added to the interaction parameter σ_{CC}. This is caused by the repulsive short-range interactions between the CNT and the fullerene carbon atoms [15].

a)



b)

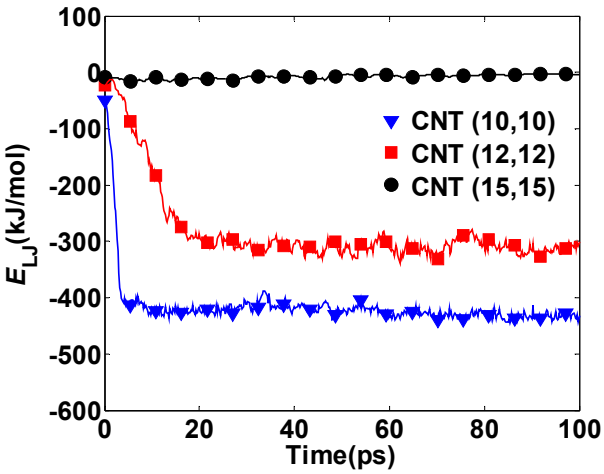


Fig. 2. The dynamic assembly process of fullerene and (10, 10), (12, 12) and (15, 15) CNTs. (a) Normalized COM distances between the fullerene and the CNTs as a function of time. (b) The Lennard-Jones potential for the CNT-fullerene interaction as a function of time.

If the initial separation between the CNT (10, 10) and the fullerene is changed from 0.1 to 0.2 nm the normalized COM distance vs. time does not show significant change (Fig. 3 red square marker). However, when it is increased to 0.3 nm, it shows a slow insertion (black circle marker). The fullerene shows a slower insertion with the initial separation further increased to 0.4 nm (magenta diamond marker). Interestingly, if the separation is further increased to 0.5 nm, the insertion process is stopped completely (green asterisk marker). At this critical distance, the fullerene is too far away from the CNT to feel the vdW force and hence fail to perform the self-insertion mechanism.

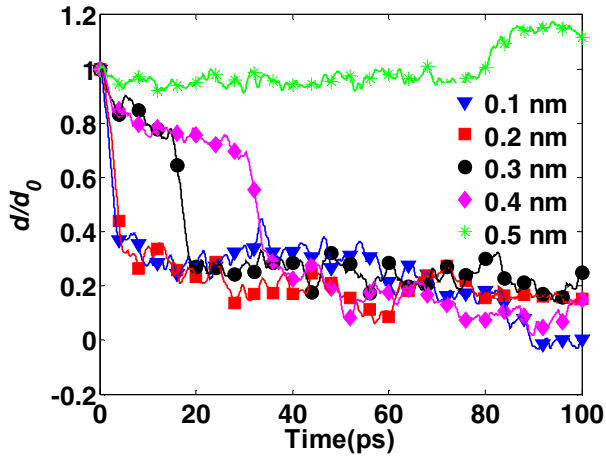

Fig. 3. The effect of initial position variation (between the CNT (10,10) and the fullerene) in the self-insertion process. The self-insertion process is stopped if the separation between the CNT and the fullerene is above 0.4 nm.

We have also examined the effect of temperature on the insertion process (for an initial separation of 0.1 nm between the (10, 10) CNT and the fullerene). It has been found that the insertion time has a very little dependence on the temperature from 200 K to 500 K (Fig. 4). However, at increased temperature of 500 K (green asterisk marker) after getting inserted into the CNT, the fullerene moves back and forth inside the nanotube due to the increased molecular mobility.

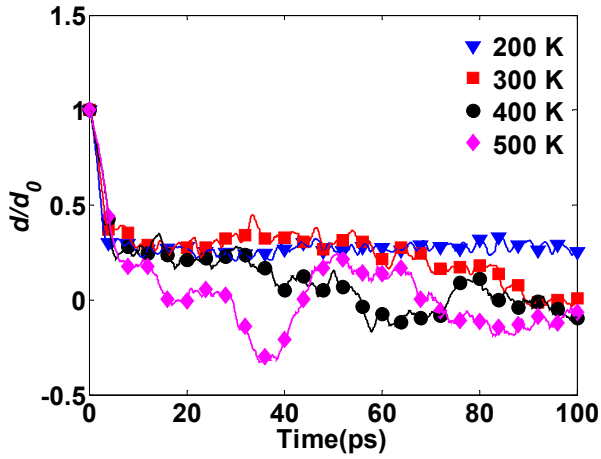

Fig. 4. The effect of temperature on the self-insertion process.

It has also been found that the length of the CNT does not play a significant role in the insertion time (Fig. 5a). This can be easily understood by looking at the change in the Lennard-Jones potential for the CNT and the fullerene (Fig. 5b). For an initial separation of 0.1 nm, the Lennard-Jones CNT-Fullerene interaction goes to a stable value at almost the same time for the CNT lengths of 1.47, 1.95 and 2.44 nm. If we increase the tube length, the carbon

atoms far away (e.g. atoms at the right side of the CNT in Fig. 1) from the fullerene molecule do not have a significant influence on the insertion process. The atoms (of the nanotube) which are near to the fullerene play the major role here. Therefore, the tube length does not affect the fullerene insertion time considerably (Fig. 5).

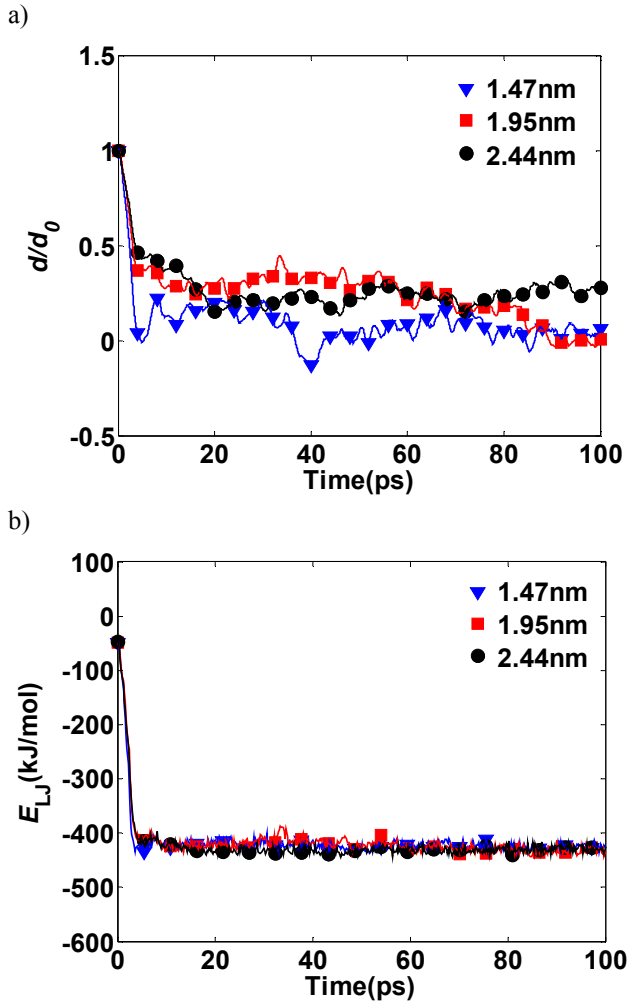

Fig. 5. The effect of variation in the length of the CNT. (a) The normalized COM distance between the CNTs and the fullerene as a function of time for CNT lengths of 1.47, 1.95 and 2.44 nm. (b) The Lennard-Jones potentials for the corresponding CNT-fullerene interaction as a function of time.

IV. Conclusions

In summary, we have conducted molecular dynamic simulation of the self-insertion of fullerene into carbon nanotubes in water. It has been observed that the insertion time of the fullerene is dependent upon the radius of the CNT as well as the initial separation between the fullerene and the CNT. However, after a critical distance the self-insertion process has been found to be completely stopped. It has also been observed that the insertion time does not show a significant dependence upon the temperature as well as the length of the CNT. To investigate further with more accuracy and precision, a combined quantum mechanics/molecular dynamics or the *ab initio* study could be performed.

Abstract—**Recently nanomaterial have gained a great interest due to their unique electrical and optical properties. The area of carbon materials have since been dominated by studies of carbon nanotubes. So far numerous methods have been developed for the synthesis of CNTs; in this work we have synthesized CNTs via a simple chemical route. Carbon nanotubes (CNTs) are successfully synthesized by heating a mixture of ferrocene and ammonium chloride at temperature as low as 250 ^{0}C. Carbon nanospheres are also observed here. Carbon spheres (CSs) of different sizes and shapes are present randomly in the sample. Field emission scanning electron microscopy is performed to examine the morphology of the sample and Energy Dispersive X-ray Spectroscopy (EDX) is performed to examine the composition.**

Index Terms—**nanotube; nanosphere; ferrocene; ammonium chloride.**

I. Introduction

The discovery of fullerenes in the mid-1980s has led to an upsurge in interest in the structures and shapes of carbon containing materials, in particular when the carbons are in the 'nano' regime. In the past two decades many differently shaped carbon materials (SCMs) have been synthesized and characterized and their properties in a range of different environments studied. These shaped materials include tubes and fibers, onions, spheres, horns, calabashes, flasks, etc [1]. Carbon nanotubes (CNTs) took a great interest among the carbon materials due to their various physical and chemical properties. CNTs were discovered by Iijima [2] in 1991. CNTs can be viewed as sheets of graphite rolled into seamless cylinders.Carbon Nanotubes can be categorized by their bonding i.e. c-CNTs and α-CNTs. CNTs can be divided also based on number of walls i.e. Single-wall nanotubes (SWNTs) and Multi-wall Nanotubes (MWNTs). The multi walled carbon nanotubes can be considered as an assembly of concentric SWNTs of different diameters. Various methods were developed such as arc discharge method, chemical vapor deposition method, laser vaporization method, pyrolysis, plasma-enhanced deposition method, template assisted method, solvothermal method, etc. High synthesis temperature and pressure, complicated processing steps, catalyst supports, longer synthesis period or expensive costs are the major drawbacks from the above-mentioned techniques [3]. Defects in CNTs give outstanding electrical properties which are used in field-emission display devices. Rakitin et al. [4] investigated both theoretically and experimentally the nanotubes comprised mainly of disordered graphene and found that this type of nanotube displayed a semiconductor band gap that is inversely proportional to the diameter.

Carbon nanospheres (CSs) have inspired great interest due to their special structure among carbon materials. Spherically shaped carbon materials have been given many names. These include carbon balls, carbon nanospheres, carbon microbeads, carbon blacks, onions, mesoporous microbeads, etc [1].

The synthesis methods used to produce carbon spheres include chemical vapor deposition, the catalytic-reduction route, the sol-gel method, the solid template approach, and the solvothermal method [5]. For example, Bao et al. have used hexachlorobenzene and sodium to prepare porous carbon materials; after an annealing process in N_2 flowing atmospheres above 1400^{0}C, carbon spheres were finally obtained [6]. Liu et al. synthesized carbon spheres via the reactions between ferrocene and ammonium chloride in a graphite crucible at 700^{0}C under an Ar atmosphere of 2.8 MPa[7]. A co-pyrolysis method was also developed to prepare high yield and proportion of carbon spheres (composed of solid and hollow one) by pyrolyzing a C_2C_{l4}/Fe-$(C_2H_5)_2$ mixture at 550^{0}C [8].

In this paper, CNTs and carbon nanospheres are synthesized simultaneously via a simple chemical route i.e. reaction of ferrocene and ammonium chloride. Carbon nanotubes synthesis from this reaction were previously reported by many authors [3,10].The low temperature synthesis is capable of eliminating the potential disadvantages associated with the aforementioned growth techniques[3]. Characterization is done by Field emission scanning electron microscopy to examine the morphology of the sample. EDX is also done to analysis the composition of the CNTs and carbon nanospheres.

II. Experimental Procedure

A. Mixing

1g ferrocene and .5g ammonium chloride was taken in a mortar and mixed thoroughly for 30 min. Mixture was taken in alumina boat and covered using alumina foil to prevent the sublimation of ferrocene.

B. Heating

Temperature was set to 250 ^{0}C in air furnace. After attaining the equilibrium temperature the boat was inserted carefully into the furnace and heated for 30 min. After 30 min of heating sample was removed and allowed to cool naturally.

C. Remixing

The content of sample was taken in a mortar again and mixed homogenously for 30 min .

D. Reheating

The mixed sample was heated again in air furnace for 30 min. After 30 min heating sample was removed for cooling.

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

E. Purification

After second time natural cooling black powder was washed consecutively by dilute HCl and distilled water to remove the presence of trace iron .Sample was filtered and dried for 24 hr at 80c.

F. Characterization

Then sample was taken for Field emission scanning electron microscopy (FESEM) and EDX for characterization.

III. Results And Discussion

Field emission scanning electron microscopy (FESEM) was employed to observe the structure and morphology of the samples. The FESEM was operated at an accelerating voltage of 15 kV and 5 KV, with a working distance of 8.5 mm and 8.1 mm.

Fig. 1,2 presents both low and high magnification FESEM images of nanotubes after the treatment with hydrochloric acid. Nanotubes are agglomerated heterogeneously and different sizes of Nano-tubes were produced.

The full understanding of the growth mechanism of this kind of structure is still under investigation. It is interesting to mention that Liu et al. [9,11] reported the formation of carbon nanotubes following similar kind of experiments. According to them, ferrocene was first oxidized to ferrocenium cation which in turn acted as electron acceptor and ultimately produced $(C_5H_5)_2FeCl$, which further oxidized by dehydrogenation and reacted with ammonium chloride. The following chemical reaction equations have been proposed to explain how the CNTs were synthesized

$$4(C_5H_5)_2Fe + O_2 + 4NH_4Cl \rightarrow 4\,(C_5H_5)_2FeCl + 4NH_3 + 2H_2O \quad (1)$$

$$(C_5H_5)_2FeCl + 3O_2 + 2NH_4Cl \rightarrow 10C + FeCl_3 + 2NH_3 + 6H_2O \quad (2)$$

During this process pentagon unit of carbon in ferrocene constitute the tube structure. Also the diameter determining factor is not known, as according to them the iron particles do not act as a catalyst but only act a reducing agent. Obviously, further research is necessary for clearly understanding the growth mechanism [10, 11].

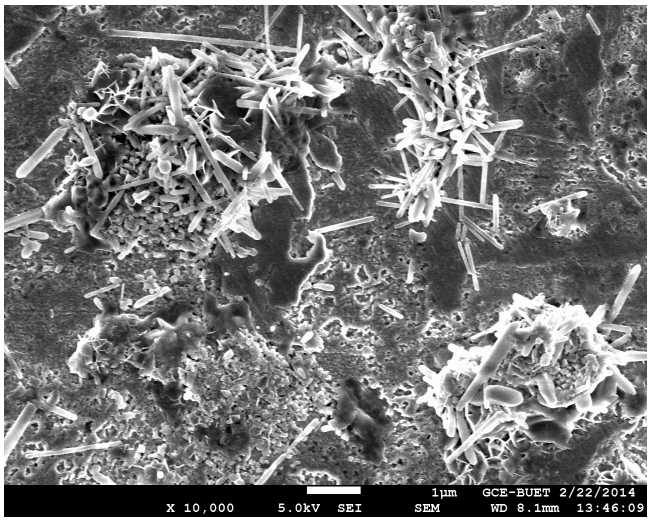

Fig. 1 FESEM of the obtained CNTs after 1g ferrocene and .5g ammonium chloride reaction at 250^0C (10000X)

Fig. 2 FESEM of the obtained CNTs after 1g ferrocene and .5g ammonium chloride reaction at 250^0C(20000X).

Fig. 3 represents the carbon nanospheres. Spheres are dispersed randomly in the sample .They are in different sizes and irregular in shape. It is observed in fig. 4 that nano spheres are growing and some nanofibres as well.

Liu at al. [7] reported the formation mechanism of carbon nanospheres. According to this author the reaction rate between ferrocene and ammonium chloride is slow for the formation of carbon spheres.

The chemical reactions took place in this temperature range are proposed as follows

$$(C_5H_5)_2Fe \rightarrow C + Fe + H_2 + CH_4 + C_5H_6 + \text{other hydrocarbon} \quad (3)$$

$$Fe + 2NH_4Cl \rightarrow Fe(NH_3)_2Cl_2 + 2H_2 \quad (4)$$

$$Fe(NH_3)_2Cl_2 + 3NH_4Cl \leftrightarrow (NH_4)_3FeCl_5 + 3NH_3 \quad (5)$$

$$Fe(NH_3)_2Cl_2 + 4NH_3 \leftrightarrow Fe(NH_3)_6Cl_2 \quad (6)$$

ferrocene will decompose to form carbon and iron which will react with ammonium chloride to form $Fe(NH_3)_2Cl_2$ .Thus the reaction rate should be dominated by the decomposition of ferrocene. In this experiment, as the decomposition of ferrocene is a slow process, excessive NH_4Cl will further react

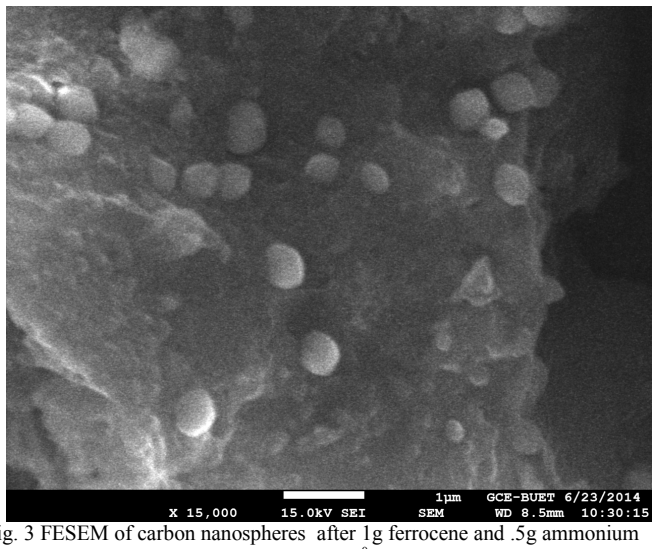

Fig. 3 FESEM of carbon nanospheres after 1g ferrocene and .5g ammonium chloride reaction at 250^0C(15000X)

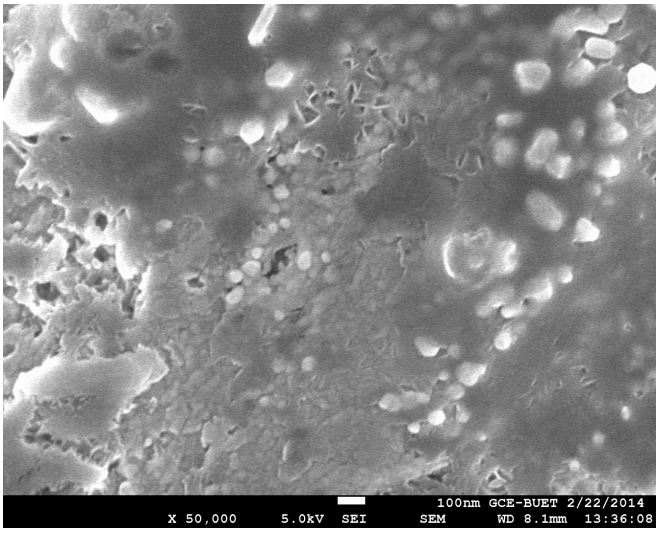

Fig. 4 FESEM of the growing process of carbon fibres and carbon spheres simultaneously after 1g ferrocene and .5g ammonium chloride reaction at 250^0C(50000X)

with $Fe(NH_3)_2Cl_2$ to form $(NH_4)_3FeCl_5$ and ammonia. Moreover, the atmosphere in the boat is a quasi-static atmosphere, so the ammonia generated by Eq. (5) could not quickly diffuse out of the alumina boat to the muffle furnace. Therefore, the generated ammonia will simultaneously react with $Fe(NH_3)_2Cl_2$ to form $Fe(NH_3)_6Cl_2$.

The EDX results of CNTs and carbon nanospheres are shown in fig. 5, 6. The peak represents the higher percentage of carbon but some N, Cl are present also in CNTs and carbon spheres. N and Cl came from ammonium chloride .Some traces of iron came from ferrocene. Oxygen in carbon nanospheres came from air due to the long time exposure in air.

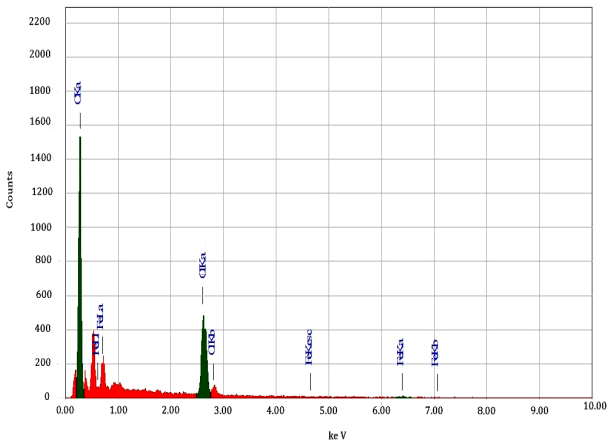

Fig. 5 EDX spectra for CNTs

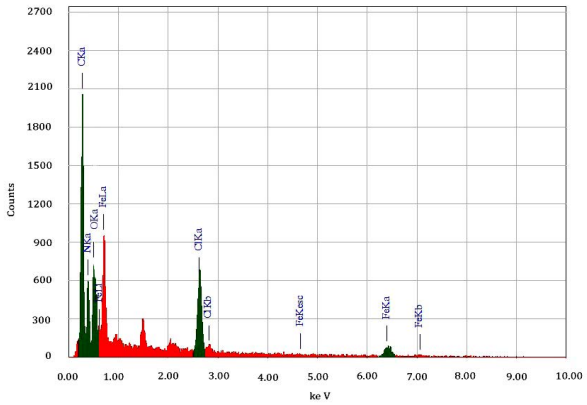

Fig. 6 EDX spectra for carbon nanospheres

IV. Conclusions

CNTs and carbon nanospheres were produced successfully after the reaction of 1g ferrocene and .5g ammonium chloride at 250^0C. FESEM and EDX confirm that the produced samples are CNTs and carbon nanospheres. Yield of CNTs were small in this procedure. Details of controllable preparation and mechanism studies are in progress for the large scale production of carbon nanotubes. This chemical synthesis for carbon spheres is very cost effective and simple for mass production.

Acknowledgment

The authors would like to thank the Glass and Ceramics Engineering department (GCE), BUET for giving the opportunity to perform FESEM and EDX analysis.

Abstract—**Multiwall Carbon Nanotube (MWCNT) films were deposited on Silicon (Si) substrate. The effect of 0.1% and 0.2% solutions of MWCNT incorporation with methanol were investigated. pH of various solutions before and after deposition has been analyzed. pH of the solutions was increased after deposition. Change in the variation of current density as a function of applied potential was observed. Current density was increased as the percentage of MWCNT was increased. The electrodeposited MWCNT films were characterized by SEM, UV-VIS-IR and Raman spectroscopy. In SEM micrographs, changes were observed in the electrodeposited films compared to pure Si substrates. Raman measurement proved the amorphous nature of MWCNT in these thin films. From the UV-VIS-IR measurement it was observed that the absorption of light has been increased by the increase of MWCNT. So the optoelectronic properties of the electrodeposited films are tunable by electrodeposition using MWCNT on Si substrates.**

***Keywords*— Thin Film, Electrodeposition, Multiwall Carbon Nanotube.**

I. Introduction

There have recently been important advances in the science of crystalline carbon, once considered exotic— fullerenes are now commonly synthesized and used in research. They include buckyballs (C_{60}), single-walled carbon nanotubes (SWCNT), multi-walled carbon nanotubes (MWCNT), carbon nanofibers etc. Carbon nanotubes exhibit remarkable mechanical and electronic properties and are, therefore, being regarded as a new functional material for next generation electronics. Nevertheless, several obstacles still exist for an application in industry. The control of carriers in carbon nanotubes is of critical importance prior to an industrial application in transistors [1].

Within materials science, the optical properties of carbon nanotubes refer specifically to the absorption, photoluminescence, and Raman spectroscopy of carbon nanotubes. Spectroscopic methods offer the possibility of quick and non-destructive characterization of relatively large amounts of carbon nanotubes. There is a strong demand for such characterization from the industrial point of view: numerous parameters of the nanotube synthesis can be changed, intentionally or unintentionally, to alter the nanotube quality. Raman spectroscopy and optical absorption photoluminescence allow quick and reliable characterization of this "nanotube quality" in terms of non-tubular carbon content, structure (chirality) of the produced nanotubes, and structural defects. Those features determine nearly any other properties such as optical, mechanical, and electrical properties.

Carbon nanotubes are unique "one dimensional systems" which can be envisioned as rolled single sheets of graphite (or more precisely graphene). This rolling can be done at different angles and curvatures resulting in different nanotube properties. The diameter typically varies in the range 0.4–40 nm (i.e. "only" ~100 times), but the length can vary ~10,000 times reaching 18.5 cm. Thus the nanotube aspect ratio, or the length-to-diameter ratio, can be as high as 132,000,000:1, [2] which is unequalled by any other material. Consequently, all the properties of the carbon nanotubes relative to those of typical semiconductors are extremely anisotropic (directionally dependent) and tunable.

Whereas mechanical, electrical and electrochemical (supercapacitor) properties of the carbon nanotubes are well established and have immediate applications, the practical use of optical properties is yet unclear. The tunability of properties is potentially useful in optics and photonics. In particular, light-emitting diodes (LEDs) [3]- [4] and photo-detectors [5] based on a single nanotube have been produced in the lab. Their unique feature is not the efficiency, which is yet relatively low, but the narrow selectivity in the wavelength of emission and detection of light and the possibility of its fine tuning through the nanotube structure. In addition, bolometer [6] and optoelectronic memory [7] devices have been realized on ensembles of single-walled carbon nanotubes.

Precursors and method of deposition of carbon films are the two dominating factors that dictate the optical and electrical properties of the film. Therefore, researchers on finding alternative precursor materials and simple method of deposition have been getting priority all the time. In connection with this research, MWCNT has been used as an alternative precursor material.

There is experimental evidence that most materials that can be deposited from the vapour phase can also be deposited in the liquid phase using electroplating techniques and vice versa. Enlightened by this conclusion, Namba [8] first attempted to grow diamond phase carbon films in the liquid phase with the aid of an organic solution such as ethanol at a temperature less than 70°C. DLC films had been obtained there, but the choice of a suitable solution was limited. Then Suzuki et al. [9] made an attempt to deposit carbon films by electrolysis of a water-ethylene glycol solution. Nevertheless, ethylene glycol is a viscous solution, which will cause some difficulty in cleaning the substrate after deposition. Hao Wang

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

et al. [10] deposited film by using methanol solution. Methanol is selected because its polarizability and conductivity are stronger than those of ethanol and the structure of methanol is even closer to that of diamond. Mominuzaman *et al.* [11] reported semiconducting carbon films by pulsed laser ablation obtained from camphor ($C_{10}H_{16}O$), a natural source. In connection to this few electrodeposion works have been reported [12]-[15] where carbonic thin films were deposited on silicon (Si), cupper (Cu) and aluminium (Al) substrates by electrolysis of methanol with camphor incorporation. Teresa *et al.* deposited [16] CNTs on Si substrates by CVD where CNT growth rate was possible even at low pressure. Tomoya *et al.* electrodeposited [17] carbon nanotubes on Zinc Oxide where CNTs were embedded on ZnO films.

In the present article considering all these continuations from electrodeposition in methanol, deposition of CNT on Si substrate by CVD and electroplating of CNTs on ZnO an attempt has been made for electrodeposition of MWCNT on Si substrate. Varying concentration of MWCNT materials were mixed to prepare carbon nanotube-methanol solution. As per our knowledge this type of work has been reported first time.

II. Experimental Details

For the deposition of MWCNT films on Si substrate an experimental setup was prepared. Si substrate was mounted on the negative electrode. Prior to deposition the substrates were cleaned in electronic grade acetone (CH_3COCH_3) and methanol (CH_3OH) for 5 minutes at 55°C. The distance between the substrate and positive electrode was set to 1 cm. The pH measurements were done before and after deposition. MWCNT with varying amount (0.1% and 0.2%) was mixed in methanol solvent to prepare the electrolytes. Variations of current densities as a function of applied potentials were compared.

III. Results and Discussions

The experiment was performed for 0.1% and 0.2% of multiwall carbon nanotubes (MWCNT) in methanol solution. pH was measured before and after deposition. There was a sharp change in the pH which indicates variation of ionic concentration in the solution and reveals possibility of electrodeposition. Table-1 shows the changes in pH due to film deposition for the incorporation of MWCNT.

TABLE I
Change in pH Due to Film Deposition

Carbon Materials	pH Before Deposition	pH After Deposition
0.1% MWCNT	2.3	4.7
0.2% MWCNT	2.3	4.4

Current densities as a function of applied voltage for different percentage of MWCNT in methanol solution were compared. Higher current density indicates more ionized charge particles to move from solution to electrode, which indicates the effect on the growth rate of film. Current densities were measured in the voltage range of 100V~600V.

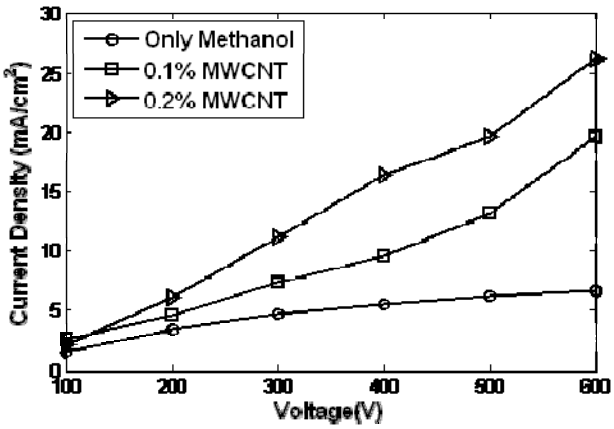

Fig. 1 Comparison of current densities as a function of applied potential for different percentage of MWCNT with methanol.

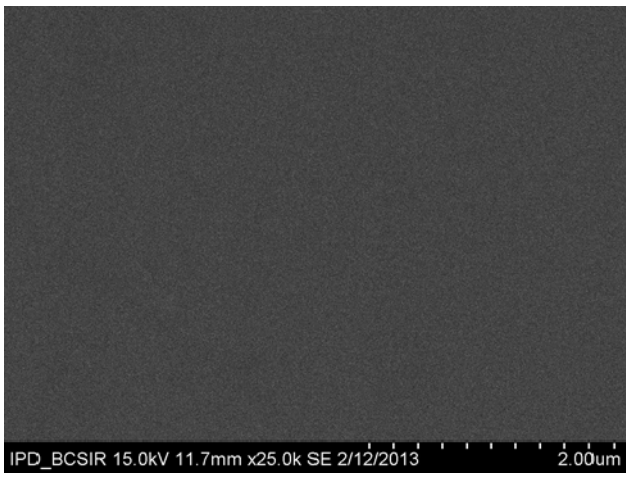

Fig. 2 Pure Si substrate observed in SEM.

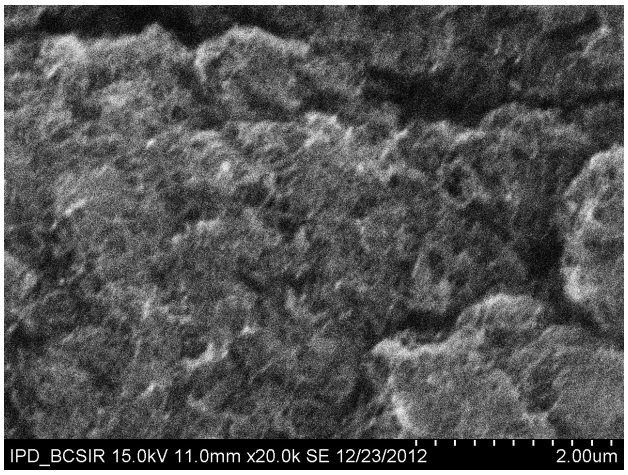

Fig. 3 Nanotube films deposited on Si using 0.1% MWCNT observed in SEM.

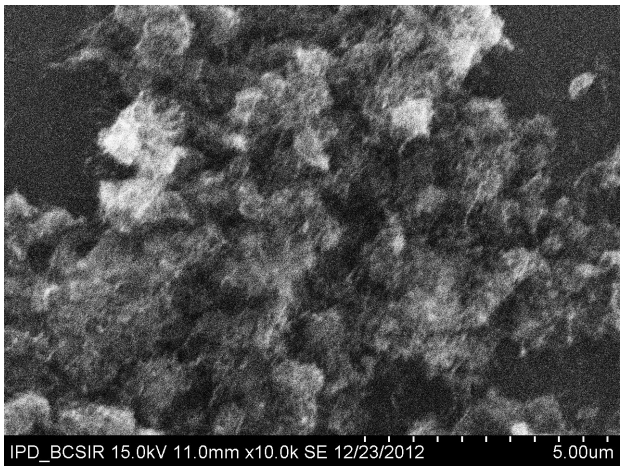

Fig. 4 Nanotube films deposited on Si using 0.2% MWCNT observed in SEM.

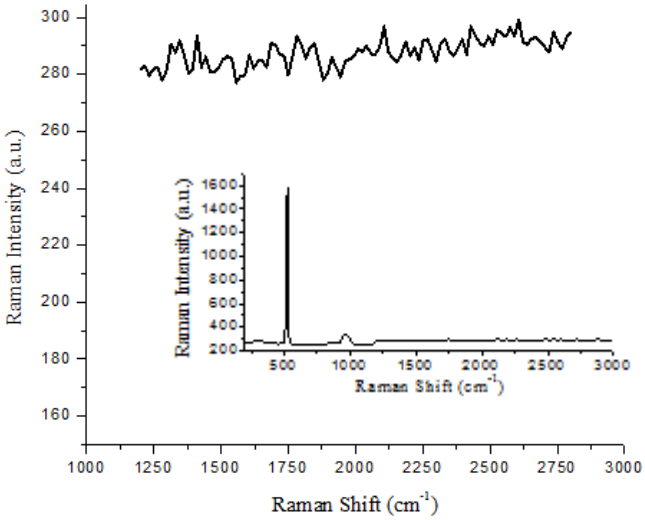

Fig. 5 Raman Spectra of Pure Si substrate

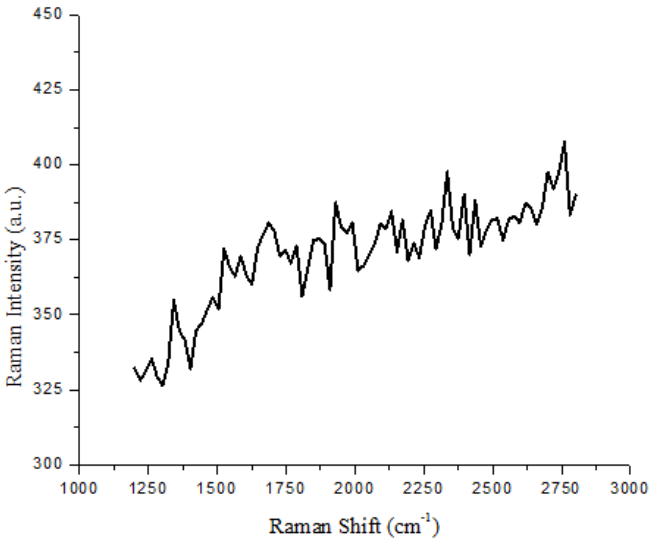

Fig. 6 Raman Spectra of Nanotube films deposited on Si using 0.1% MWCNT

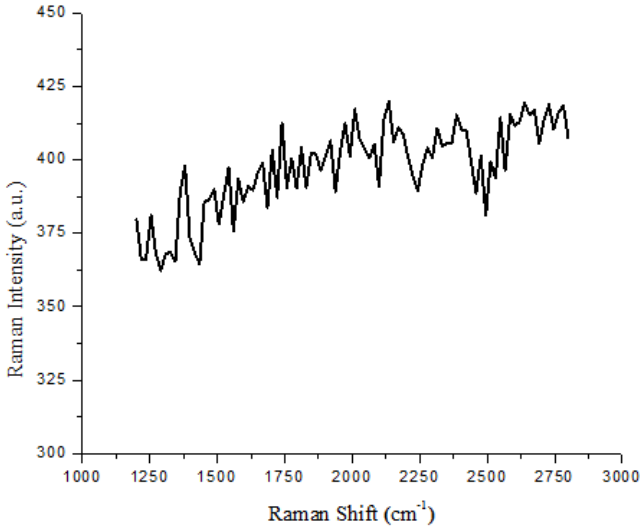

Fig. 7 Raman Spectra of Nanotube films deposited on Si using 0.2% MWCNT

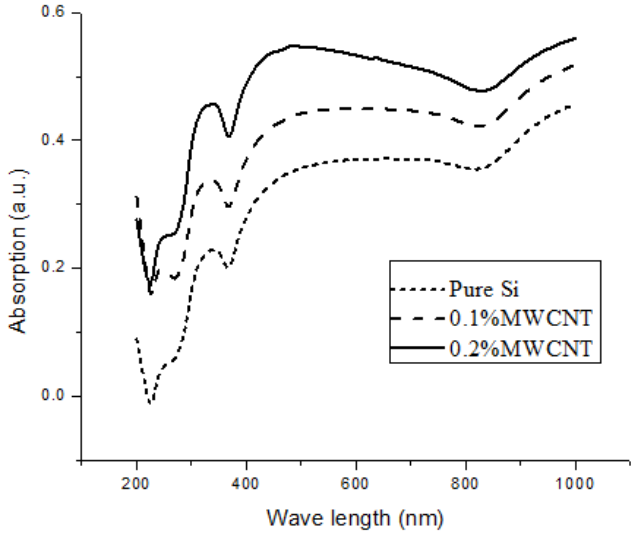

Fig. 8 Absorption of light as a function of wavelength for MWCNT films electrodeposited on silicon substrate.

Fig. 1 show the comparison of current densities of only methanol solution and that of 0.1% and 0.2% MWCNT in methanol solutions as a function of applied potential in the voltage range of 100V~600V. Fig. 2, 3 and 4 show the SEM micrographs of pure Si substrate, 0.1% MWCNT electrodeposited film and 0.2% MWCNT electrodeposited film respectively.

Raman measurements were performed using a He-Ne laser operating at a wavelength of 632.8nm (1.96 eV) and input power of ~300μW at the sample surface. A confocal microscope experimental setup [18] was used for Raman signal acquisition. Fig. 5, 6 and 7 show the Raman Spectra of pure Si substrate, 0.1% MWCNT electrodeposited film and 0.2% MWCNT electrodeposited film respectively.

Fig. 8 shows the comparative study of absorption of light as a function of wavelength in UV-VIS-IR region for pure Si substrate, 0.1% and 0.2% MWCNT electrodeposited films.

Current densities for MWCNT were higher than that of only methanol solution. Also the current densities were increased by the increase of MWCNT (from 0.1% to 0.2%).

Change in the variation of current density as a function of applied potential was observed with different percentage of carbon nano-materials. For example at 600V, the current densities for only methanol, 0.1% MWCNT and 0.2% MWCNT were 7mA/cm^2, 20mA/cm^2 and 27mA/cm^2 respectively. So higher conductivities were observed for MWCNT. It is possible to grow MWCNT films by electrodeposition at lower voltages compared to carbonic thin films with methanol [13].

In SEM images, changes were observed in the electrodeposited films compared to as-obtained Si substrates. The distinction could be ascertained by 0.1% and 0.2% MWCNT films. These images shows that MWCNT and amorphous carbon are exist in combined form.

In Raman spectroscopic images, only 1200 cm^{-1} to 2800 cm^{-1} Raman shift was considered as the peak at 300 cm^{-1} corresponds to the radial breathing mode (RBM) which is unique to CNTs, is not seen in case of MWCNT [19]. But there will be peaks explicitly appears at ~1360 cm^{-1} and ~1580 cm^{-1} for D band and G band respectively for MWCNT [20]. These peaks are not prominent as compared with SWCNT [19]. Furthermore MWCNT is combined with amorphous carbon (Fig. 3, 4) which makes the peak more broaden. So no prominent peaks for the samples were found.

From the comparative study of the spectrum of light absorption as a function of wavelength in UV-VIS-IR region in Fig. 8 it was observed that, absorption of light increased by the increase of MWCNT (from 0.1% to 0.2%). So the optoelectronic properties of the electrodeposited films are tunable by electrodeposition using MWCNT on Si substrates.

Existence of MWCNT combined with amorphous carbon in thin film certainly increases the electrical conductivity and optical absorption in comparison with only amorphous carbon based thin film [13], [15].

IV. Conclusions

MWCNT films were deposited on Si substrates. Effect of variation of MWCNT in methanol was observed. pH of the solutions was increased after deposition, thereby indicated variation of ionic concentration as well as formation of MWCNT on Si substrates. Current densities for MWCNT were higher with respect to methanol and increased as the percentage of MWCNT was increased. SEM micrographs shows the existence of MWCNT with amorphous carbon. Raman spectroscopy proved the amorphous nature of thin films. Absorption of light in UV-VIS-IR spectroscopy were increased by the increase of MWCNT. So the electrical and optoelectronic properties of the electrodeposited films are tunable by electrodeposition using MWCNT on Si substrates.

V. Acknowledgements

The authors would like to thank Dr. Abdul Gafur, for providing UV-VIS-IR spectroscopy and SEM facility at BCSIR and also thank to Professor Dr. B M Arora for Raman spectroscopy facility under Indian Nanoelectronics Users Program (INUP) at Indian Institute of Technology Bombay (IITB).

Abstract— **Electronic transport properties of Graphene nanoribbon (GNR) are explored by self-consistent numerical simulation. The effects of vapour (H_2O) adsorption in GNR sheets on its current-voltage (I-V) characteristics, conductivity, electrostatic difference potential and device density of states were studied with necessary physical insight. We found that conductivity of GNR sheet increases in some particular energy range with the increase in number of H_2O molecules adsorbed. Then we encounter the effects of metal-GNR contact to investigate the practical performance of GNR as a medium of humidity sensing. Later we propose a simple schematic model for GNR Humidity Sensor (GNRHS) to investigate its performance in applied regime.**

Index Terms— Humidity sensor; Graphene; NEGF; GNR; GNRHS.

I. Introduction

Flexible, highly sensitive and low cost humidity sensors are highly enviable in future generation sensor technology. As a result of recent year's research conducted concerning the applicability in gas and humidity sensors, graphene is reported to be an appropriate sensing material for this purpose [1-3]. The inimitable structural, mechanical and electronic properties of graphene has attracted extensive attention of scientists, therefore the successful synthesis of novel two-dimensional (2D) graphene and the experimental observation of Dirac fermions in unpatterned graphene devices has been increasing rapidly [4]. Gas and vapour adsorption on these devices could change their electronic properties which can be used as sensing parameter. The previous and recent researchers have concentrated to focus on the interaction of small gas molecule, such as CO, NO_2 and NH_3 with the pristine graphene in theory [5] and CO_2 sensing using graphene sheet in experiment [6].

The interaction between small molecules and graphene can be highly enhanced by introducing adsorption into 2D nanosheets of graphene. Again, it can be shown that water (H_2O) molecules adsorbed on graphene cause defects in it which facilitate to electron-tunnelling of the band gap and cause widening of graphene band gap to 0.206 eV [1]. However, the changes in resistance are directly influenced by the amount of water vapour adsorbed by the graphene [3].

Here we report a simulation based study of humidity sensing ability of patterned graphene adsorbing vapour (H_2O) and investigate electronic and quantum transport properties of these system such as Device Density of States (DDOS), Electrostatic Effective Potential (EDP), Conductivity (G) and Current-Voltage (I-V) characteristics. Transport simulation is based on Non-equilibrium Green's Function (NEGF) formalism. An unpatterned graphene sheet is a zero bandgap material with linear energy dispersion relation. Patterning graphene sheet can open up bandgap. In this paper we work on patterned graphene sheet called Graphene nanoribbon (GNR). We consider the edge atoms as hydrogen (H) passivated. Later we propose a simple schematic model to characterize device performance which incorporates the effect of metal contact resistance with GNR.

II. Device Geometry and Simulation

The electronic bandstructure of graphene was calculated very early on [7]. The valence electrons of carbon atoms in graphene are sp^2 hybridized with the remaining p_z carbon orbitals forming an extended π-electron system that is responsible for the low energy transport and optical properties of graphene. The bonding π-states form the valence band and the antibonding π*-states form the conduction band. These two bands touch at six points, the so called Dirac or neutrality points show zero bandgap semimetal characteristics. Whereas nano-patterning of graphene sheet can open up a bandgap upto ~1.4eV [8], depending on the chirality of nanoribbon it can be Armchair or Zigzag. Armchair GNR (A-GNR) and Zigzag GNR (Z-GNR) shows semiconducting or semimetallic behaviour depending on the number of carbon atoms, N along the width of the nanoribbon [9].

In general humidity sensing through GNR is a process of vapour (H_2O) adsorption in graphene surface where the interaction is limited to π-electrons of GNR and electrons of oxygen ion in H_2O. In this paper we investigate the change in electronic transport in GNR due to H_2O adsorption. Fig. 1 shows an A-GNR (N=10, E_g=~1.1eV) without H_2O adsorption (Fig. 1(a)) and with adsorption of four H_2O molecules (Fig. 1(b))

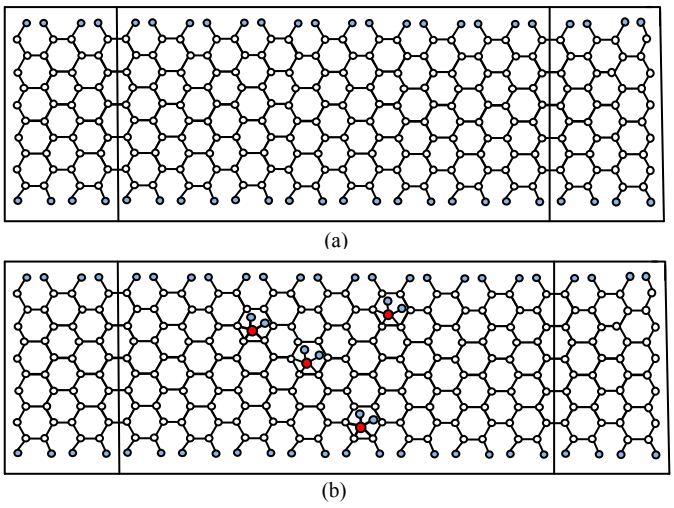

Fig. 1 A-GNR (N=10) surface (a) without H_2O adsorption (b) after H_2O adsorption. Middle portion is the sensing medium and side portions are extended electrodes.

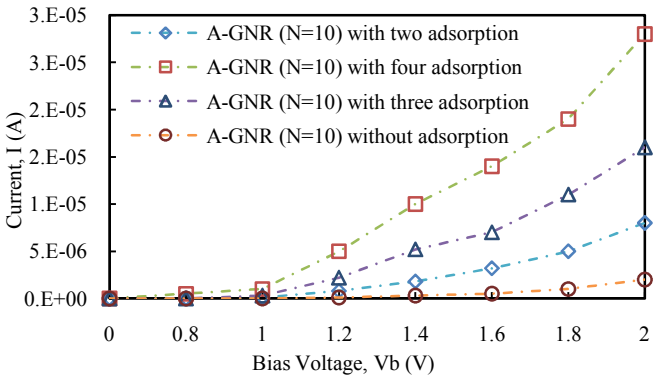

Fig. 2 I-V curves of semiconducting A-GNR (N=10) with and without H_2O adsorption.

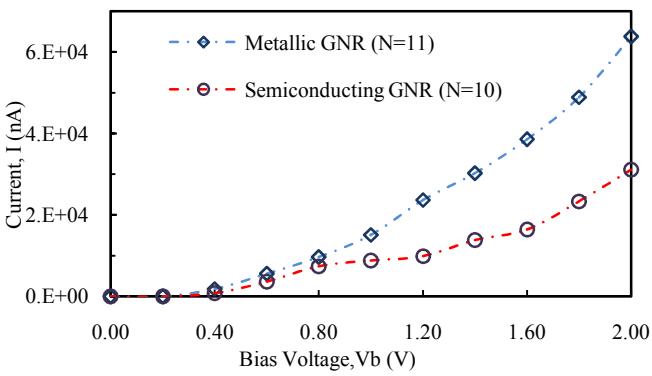

Fig. 3 I-V curves of metallic A-GNR (N=11) and semiconducting A-GNR (N=10) with metallic A-GNR electrodes with four H_2O molecules adsorbed.

The electronic transport calculations were performed by implementing non-equilibrium Green's function (NEGF) formalism [10, 11]. Ballistic current through GNR sheet considering self-consistent field imposed by H_2O molecules is calculated using Launder's equation.

$$I = \frac{2q^2}{h}\int_{-\infty}^{\infty} dE\, T(E)\,(f_L^+ - f_R^+)$$

Where, q=charge of electron and h=Plank's constant. f_L^+ is the Fermi function of left electrode and f_R^+ is the Fermi function for right electrode.

$$f_{L,R}^+ = \frac{1}{1 + e^{(E - E_F^{L,R})/K_B T}}$$

Where, K_B =Boltzmann's constant. $E_F^{L,R}$ is the electro-chemical potential at left or right contact and T(E) is the transmission spectrum.

$$T(E) = Tr[\Gamma^L G^R \Gamma^R G^A]$$

$$G^R(E) = [G^A(E)]^\dagger = [(E + i\delta_+)S - H - \Sigma^L(E) - \Sigma^R(E)]^{-1}$$

Here, $G^R(E)$ is Retarded Green's function where S and H are overlap integral matrix and device Hamiltonian matrix respectively. Self-energy terms are represented by $\Sigma^L(E)$ and $\Sigma^R(E)$ respectively for left electrode and right electrode. Here 'Tr' represents Trace of a matrix and $\Gamma^L = i[\Sigma_L - \Sigma_L^\dagger]$ and $\Gamma^R = i[\Sigma_R - \Sigma_R^\dagger]$. δ_+ is an infinitesimally positive number. Matrix S and H provides the atomistic description of GNR which is dependent on tight-binding P_Z orbital hopping parameter, previously calculated by Reich et al. [12]. In our simulation we have calculated Device Density of States (DDOS), conductance (G) and Electrostatic difference potential (EDP) using following equations.

$$DDOS(E) = \frac{1}{2\pi} Tr[G^R(\Gamma^L + \Gamma^R)G^A]$$

$$G(E) = \frac{2q^2}{h} Tr[\Gamma^L G^R \Gamma^R G^A]$$

$$EDP\left(\frac{r}{\max(r)}\right) = \frac{U(r) - \max(U(r))}{\max(U(r))}$$

Where, U(r) is the electrostatic potential calculated from Poisson's equation using finite difference algorithm and r represents two dimensional space coordinates (x, y, z). EDP is an unit less and normalized parameter.

III. Results and Discussion

At first, we have analysed homogenous semiconductive (N=10) A-GNR sheet as sensing medium. Then, we have analysed transport after the adsorption of two and four H_2O molecules on that GNR sheet. Fig. 2 shows the simulated I-V curves. Typically the GNR sheet doesn't show significant conduction at bias voltage of below 1V and then its conduction increase with the increment of bias voltage, Vb, whereas adsorption of H_2O increase the current more significantly depending on number of adsorbed H_2O molecule.

Later we have used two other GNR structures; homogeneous metallic A-GNR (N=11) and cascaded Hetero-GNR structure, where sensing medium is semiconducting A-GNR (N=10) which is connected to metallic A-GNR (N=11) electrodes. Fig. 3 shows I-V curves of these two types of structure. Here we found that the cascaded structure shows significant conduction even in lower bias voltage (Vb=0.4V) than a homogeneous semiconducting A-GNR (Vb=1V). Moreover, metallic A-GNR is less sensible in current increment adsorbing H_2O molecules at low bias voltage. To get the physical insight of such sensing phenomenon we have to investigate the change in device density of states (DDOS), conductance (G) and electrostatic difference potential (EDP) with the amount of H_2O adsorption.

Fig. 4 and Fig. 5 show DDOS and G respectively of a semiconducting A-GNR (N=10) for different H_2O adsorption conditions. Energy, E=0 signifies Fermi energy when GNR sheet is at equilibrium (without external bias voltage). For unadsorbed semiconducting A-GNR sheet bandgap region contains no energy states and so that conduction is zero within this energy range (Fig. 4(a) and Fig. 5(a)). Later due to adsorption of H_2O numbers of energy states are suppressed at higher energy level, whereas some electrons become localized due to heavy nuclei of oxygen atom from H_2O molecules. Because of this electron localization some small potential barriers are generated within the GNR sheet. These locally generated potential barriers can be seen from EDP. Fig. 6(a) shows the difference in sheet potential in three different directions of the A-GNR. Along the length of A-GNR or in transport direction potential is zero everywhere. With the adsorption of two H_2O molecules Fig. 6(b) shows two peaks in potential profile working as potential barriers for electrons. These potential barriers give rise to quasi quantized energy states at lower energy range which is evident from Fig. 4(b). These low energy states increase conductance of the GNR sheet at lower energy (Fig. 5(b)) which in turns enable significant current increment even in lower bias voltage, Vb.

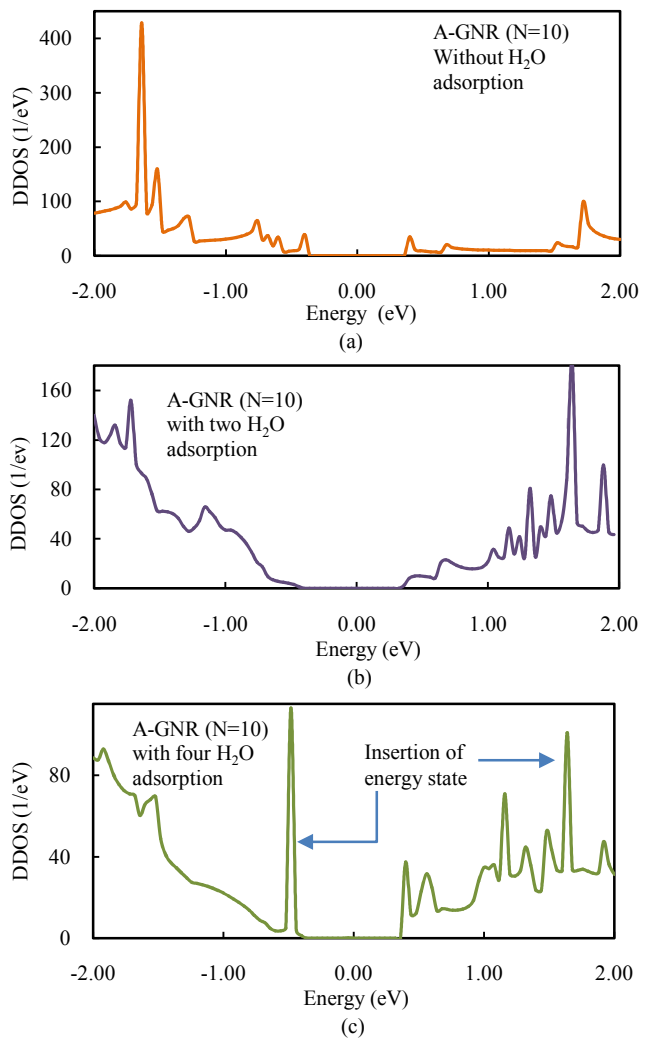

Fig. 4 Device Density of States (DDOS) (a) Without H_2O adsorption (b) Two H_2O adsorbed (c) Four H_2O adsorbed on GNR surface.

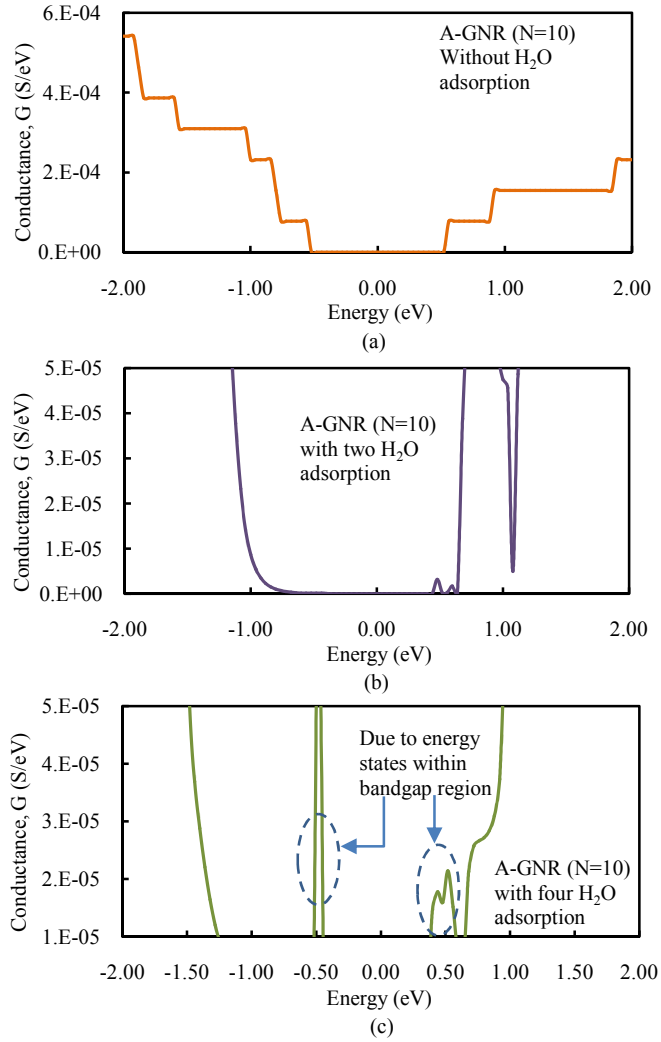

Fig. 5 Conductance of GNR sheet (a) Without H_2O adsorption (b) Two H_2O adsorbed (c) Four H_2O adsorbed.

With the increment of number of adsorbed H_2O molecules the number of potential barriers increased. At Fig. 6(c) there are four peaks in potential profile of GNR along the transmission direction because of the adsorption of four H_2O molecules. Because of such closely packed but relatively lower height of potential barriers the ground states of quantized energy states become lower and fall within the bandgap energy region, which enable electronic conduction within the bandgap energy region of the semiconducting A-GNR sheet shown at Fig. 4(c) and Fig. 5(c). For insertion of such inter-bandgap electronic conduction, current start to increase in GNR even at lower bias voltage, Vb.

On the other hand metallic A-GNR shows significant electronic conduction at very low energy because of the absence of bandgap, which enable current flow at very low bias voltage, Vb. So increment of current in metallic A-GNR is less significant than semiconducting A-GNR with adsorption of H_2O molecules.

Finally we can make a statement that the adsorption process actually has two impacts on conductivity of GNR sheet. Firstly, it lowers higher energy electronic conduction of the GNRs and secondly, it enables low energy conduction through quantized energy state (even through the bandgap region of the semiconducting A-GNR). So, for low voltage application semiconducting A-GNR will be a better choice over metallic A-GNR as the sensing medium though metallic GNR gives higher current but less sensitive to H_2O adsorption.

IV. Effect of Metal Contact

So far we have considered only the effects on electronic conduction of GNRs due to H_2O adsorption. Here we will discuss the effect of metal contact with the GNRs which is realistic to encounter the practical performance of such sensing device. The metal-GNR contact can be ohmic contact or schottky contact depending on the width of A-GNR and the difference in work functions, $\Delta\Phi$ of the metal and A-GNR. Recent works suggest that metal-GNR schottky barrier height (SBH) can be modulated through vertical potential which works as electrostatic doping in GNRs [13]. Their numerical simulation investigated that metal-GNR contact becomes ohmic with a steeper decrement in contact resistance, R_C with the decrement of GNR width, W_{GNR}. For semiconducting A-GNR of width, W_{GNR}=1.1nm (N=10) the value of normalized contact resistance, (R_C/ W_{GNR}) is ~11Ω-µm or a resistance (R_C) of ~10kΩ for $\Delta\Phi$=460meV, whereas the international roadmap for semiconductor calls for a normalized contact resistance of 80Ω-µm [14], which can be achieved by contacts to GNR materials under the ideal conditions with ballistic transport. For Gold (Au) to A-GNR contact ($\Delta\Phi$=~440meV) assumption of a contact resistance of 10kΩ is reasonably realistic in low voltage range. Fig. 7(a) shows the effect of metal contact on the sensing performance of GNR through its decrement in current due to some voltage drop across the contact to GNRs potential barrier.

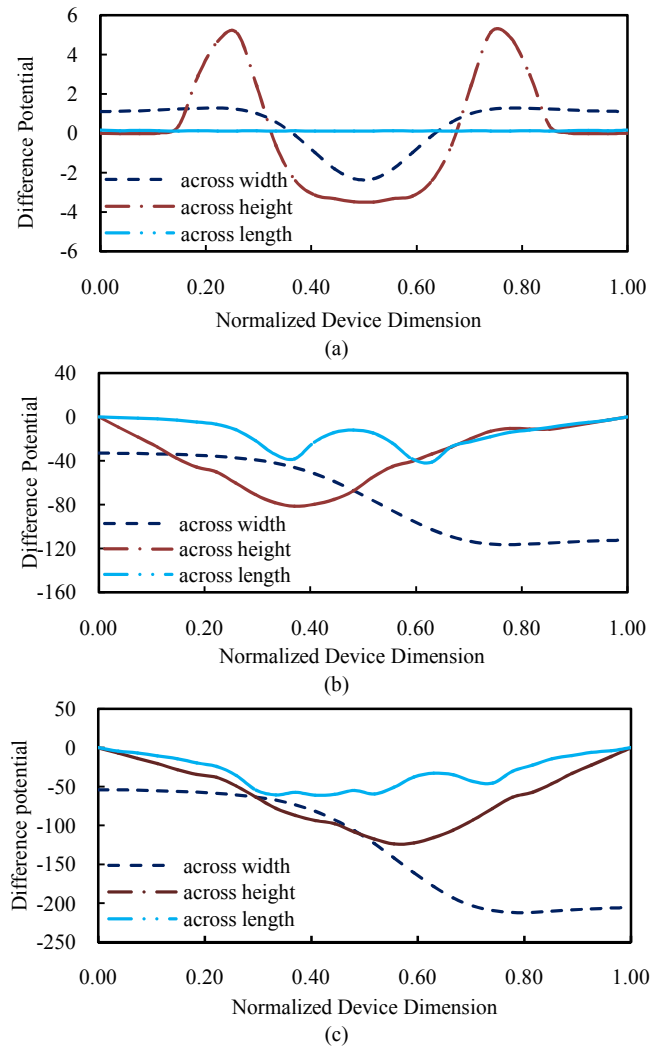

Fig. 6 Electrostatic difference potential of GNR sheet (a) Without H_2O adsorption (b) Two H_2O adsorbed (c) Four H_2O adsorbed.

Finally we have proposed a simple schematic model (Fig. 7(b)) for GNRHS approximated with linear operational range. Here the sensing medium is modelled by two parallel resistances named $R_{graphene}$ and R_{vapour}, where $R_{graphene}$ represent the GNR sheet without H_2O adsorption and R_{vapour} imposes the change in conductance due to H_2O adsorption. R_{vapour} decreases with the increment of number of adsorbed H_2O molecules.

$$I = \frac{V_b - 1}{\left[2R_c + \frac{R_{graphene}R_{vapour}}{R_{graphene}+R_{vapour}}\right]}, \quad R_{graphene} = 1M\Omega$$

Fig. 7(a) shows I-V curves for such schematic model which shows a good match with the I-V curves we get from NEGF simulation for different number of adsorbed H_2O.

V. Conclusions

In summary, we have investigated changes in electronic transport of A-GNR due to H_2O adsorption through self-consistent NEGF and electrostatics. Different transport properties show significant changes due to adsorption of H_2O on A-GNR surface, which become dominant in transport mechanism with increasing number of adsorbed H_2O molecules. Finally, we proposed a schematic model which incorporates this sensing phenomenon along with the effect of contact resistance. This work may provide useful guideline for future work in the field of GNR humidity sensor (GNRHS).

Abstract—**In this work, structural and electronic properties of a bilayer structure composed of one single layer of graphene on top of a two dimensional hexagonal boron nitride (h-BN) has been investigated using first principle calculations based on density functional theory (DFT). Three different configurations are possible for this bilayer system namely B1, B2 and B3. In this paper biaxial strain was applied to B2 configuration and structural and electrical properties were observed. A small band gap opens for this bilayer structure though graphene is a zero gap material. Some important material parameter such as band gap, effective mass and Fermi velocity were investigated with the variation of biaxial strain. It was observed that the material remains to be a direct band gap material for the applied strain range from -12% to +12%. Interestingly, with the application of compressive strain effective mass decreases and Fermi velocity increases which is very crucial for high frequency RF devices.**

Index Terms—**Graphene, Boron Nitride, 2-D Material, Biaxial Strain, Density Functional Theory, Fermi velocity**

I. Introduction

As the dimensions of modern silicon metal-oxide semiconductor field-effect transistors (MOSFETs) have been shrinking according to the prediction of Moore's law, the conventional planar structures face severe short-channel effects [1]. Scaling theory predicts that a FET with a thin channel material like graphene will be robust against short-channel effects [2]. But graphene is not suitable for logic applications as it lacks proper band gap. However, it is possible to open a band gap in three ways: i) constraining large-area graphene in one dimension to form graphene nano ribbons (GNRs) [3]-[5] ii) biasing bilayer graphene [6]-[7] and iii) applying strain to graphene [8]-[9].GNRs have rough edges that cause band gap difference with different edge geometries [4]. If an electric field is applied in bilayer graphene, a band gap of 200-250meV opens [6]-[7] which is not suitable for application of transistors in logic circuits. The effect of uniaxial strain on the band structure has been simulated [10]-[11].However, opening a gap in this way will require a global uniaxial strain exceeding 20%, which will be difficult to achieve practically. On the other hand, though experimentally biaxial strain has been applied on graphene [12] but little is known about the influence of this strain on the band structure of graphene. However, once the problem of creating band gap is resolved in graphene, there comes the issue of substrate related mobility degradation for SiO_2/Si substrate [13]. Recently, graphene on h-BN has shown enhanced mobility, reduced carrier inhomogeneity and reduced intrinsic doping than on SiO_2 [14]. So to reduce SiO_2/Si substrate induced performance degradation, graphene/h-BN hetero bilayer composite material can be a promising channel material for future logic FETs. Several methods for tailoring band gap in this composite material has been proposed in recent literature [15]-[16] which varies with (a) the stacking order, (b) the separation distance of graphene from the h-BN, and(c) the externally applied perpendicular electric field. Also variation of band gap with biaxial strain was reported for grapheme/h-BN bilayer structure [17]. But detailed analysis for all the possible configurations of this bilayer system is still missing in literature.

In this work, structural and electrical properties of B2 configuration of bilayer graphene/h-BN were studied using DFT. Using Hellmann-Feynman theorem with a Broyden–Fletcher–Goldfarb–Shanno(BFGS)quasi-Newton optimization algorithm, optimized crystal structure for bilayer graphene/h-BN is computed. Then, the band structure of this hetero bilayer material was computed. With the help of band structure some important material parameter such as band gap, effective mass and Fermi velocity were computed. Biaxial strain was applied to the material and its effect on these parameters was also investigated.

II. Computational Details

Three distinct structures for graphene/h-BN super lattice are discussed in literature in which they are usually referred as B1, B2 and B3 [17]. In Fig. 1 we have produced the geometry of B1 and B2 structures schematically with Xcrysden [18]. The B1 structure is thoroughly discussed in [17]. Here we have conducted a detailed treatment on the B2 structure.

The electronic properties of the proposed super lattice are investigated using density-functional theory (DFT) with a plane-wave basis set. Perdew-Zunger variant LDA (Local Density Approximation) was performed using the Ab inito code PWSCF package of Quantum Espresso [19]. To include the electron-ion interaction we have used norm conservative pseudo potentials for all the atoms.

Our calculation methodology started with structural optimization of the B2 super lattice structure and then a precise self consistent field (scf) analysis was done to

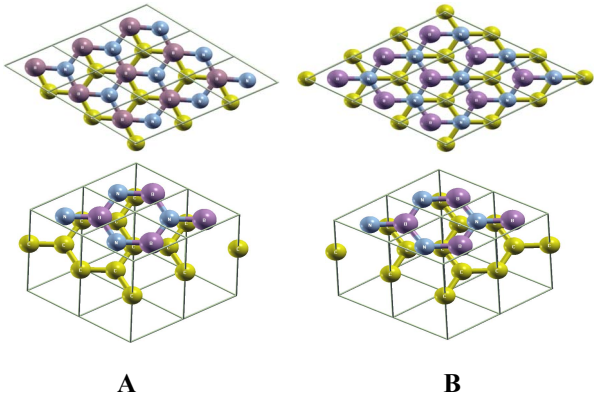

Fig. 1 Two structures of grapheme/h-BN super lattice. (A) B1, (B) B2. The blue ball represents Nitrogen, purple ball represents Boron and the yellow ball is carbon.

determine the band structure of the super lattice. For the structural optimization the plane wave basis cut off was set at 45 Ry and the convergence threshold on force was 10^{-3} Ry/a.u. A 15×15×1 Monkhorst-Pack k-point grid was used. To avoid the interaction between repeating unit cells a large vacuum space of 20 Å thickness was maintained throughout the optimization process. Then the lattice parameters were varied for different interlayer distances to determine the optimum unit cell for the B2 structure.

In the next part of scf calculation a 30×30×1 k-points Monkhorst-Pack grid was employed for better accuracy. The convergence threshold for self consistency energy was set at 10^{-8} Ry. All atomic position and unit cell parameters found as the final output of geometry optimization and relaxation process were used for scf and band-structure calculation. The band structure is plotted on the lines joining the high-symmetry points Γ, M, K and Γ.

III. ATOMIC STRUCTURE AND GEOMETRY OPTIMIZATION

At first the B1 structure was reviewed using PWSCF to compare the simulated results with the reported results published by G. Mukhopadhyay et al. to emphasize the accuracy and validity of our calculation. These results are summarized in Table 1 and Fig. 2. While Table 1 illustrates the optimized parameters obtained from both PWSCF and ELK code, Fig. 2 shows the band gap vs. percentage of biaxial strain applied to the super lattice. Both Table 1 and Fig. 2 indicate the accuracy of PWSCF package.

Having verified the compatibility of PWSCF package with the B1 structure we investigated the B2 structure. The optimization process was performed iteratively by varying both interlayer distance and lattice parameter and observing the minima of the potential energy surface. A built in variable cell relaxation function of PWSCF was run to verify the iterative process. The result is shown in Fig. 3, from which it is seen that the lattice parameter of the B2 is 2.48 Å and the inter layer distance is 3.4 Å.

A more precise relaxation process reveals that the optimized lattice parameter is 2.4805 Å and the interlayer distance is 3.44 Å, which agree with the lattice parameter of 2.47 Å and interlayer distance of 3.4 Å reported by [20] and [15] respectively.

TABLE I
LATTICE PARAMETER AND BAND GAP FOR B1 STRUCTURE

	Simulated Result	**Reported by G. Mukhopadhyay et.al. [17]**
Lattice parameter (a = b) (Å)	2.481	2.47
Interlayer Distance (Å)	3.241	3.217
Band gap (mev)	59	59

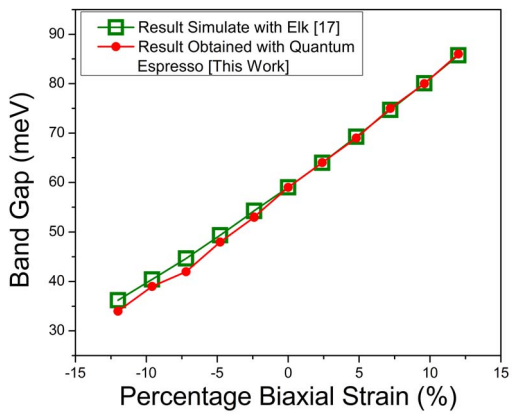

Fig. 2 The band gap of B1 structure as a function of biaxial strain applied to the super lattice. The red line shows the results obtained from PWSCF and the green line is obtained from the result published by G. Mukhopadhyay [17]

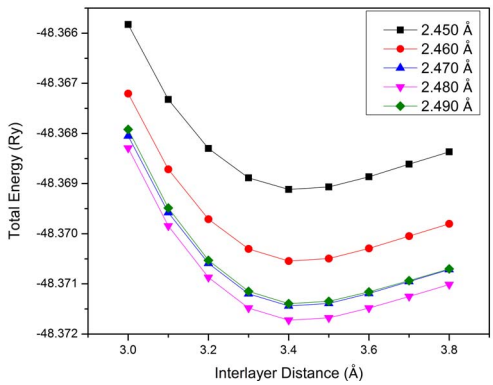

Fig. 3 The total energy of B2 structure as a function of lattice parameter and interlayer distance.

IV. ELECTRONIC STRUCTURE

The band structure of the super lattice was calculated along the line joining the points Γ, M, K and Γ in the Brillouine Zone. A total of 804 points was taken along the line using the Xcrysden. Care was taken to calculate the empty bands with the same accuracy as for the filled bands. The band structure for the optimized and relaxed super lattice is shown in Fig. 4 and a direct band gap of 54 meV was obtained for this case.

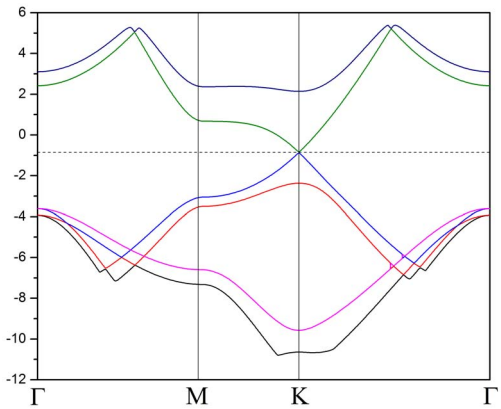

Fig. 4 Band structure of the B2 super lattice. The direct band gap of about 54 meV was found in the K symmetry point. The dashed horizontal line shows the Fermi energy.

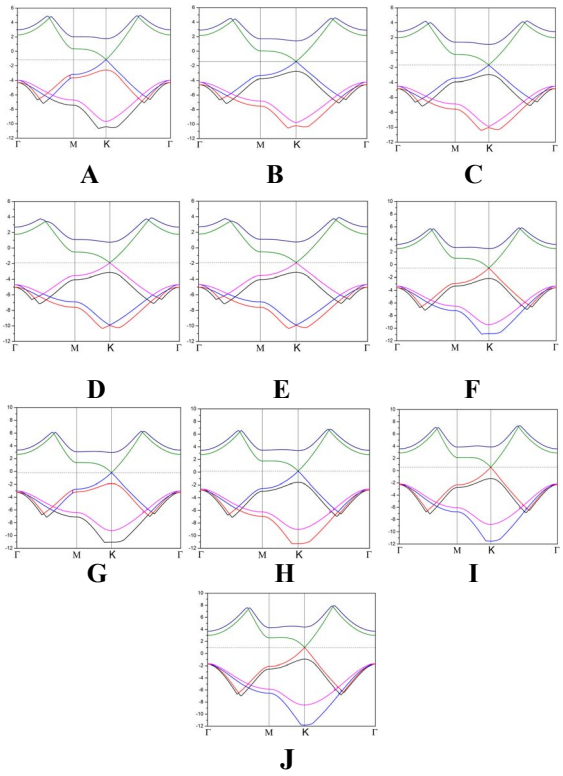

Fig. 5 The band structures of the strained super lattice. A to E shows the band structure of super lattice when +2.4%, +4.8%, +7.2%, +9.6% and +12% strain was applied. F to J shows the band structure when the super lattice was compressed to 2.4%, 4.8%, 7.2%, 9.6% and 12% respectively.

Furthermore biaxial strain was applied at the super lattice and each time the structure was relaxed before the scf analysis to conduct the band structure determination. The interlayer distance remained almost constant when expanded and slightly increased during compression. The band gap remained direct at the K point and during compression to expansion the band gap increased monotonically. Fig. 5 shows all the band structures of the strained super lattice.

From Fig. 5 it is observed that upon expansion the Fermi energy decreases gradually. Again when the structure is compressed, the Fermi energy increases and becomes positive.

The variation of band gap with the biaxial stress applied is shown in Fig. 6, which also compares the band gap between the B1 and B2 structures. This figure shows that with B2 structure offers less band gap than B1.

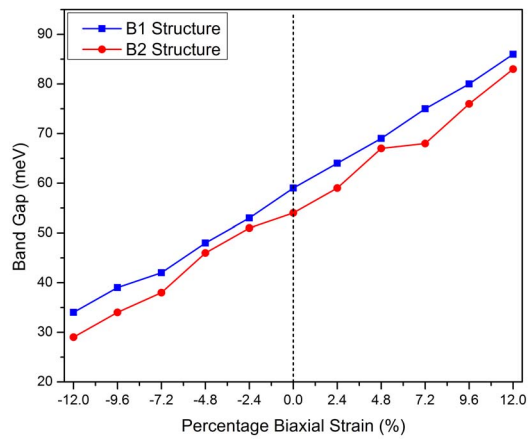

Fig. 6 The band gap of B2 (red line) and B1 (blue line) as a function of percentage biaxial strain applied to the super lattice.

In the next part we have calculated the longitudinal effective mass of both super lattices using the well-known formula: $m^* = \dfrac{\hbar^2}{\dfrac{\partial^2 E}{\partial k^2}}$ (1)

along the Γ to K path. The second derivative was evaluated on the lowest conduction band minima using five point stencil method [21], [22].The energy dispersion near the lowest conduction band minima is almost linear like graphene. Previous works [16], [17] have exploited this linearity to extract the electron effective mass using the formula

$$m^* \simeq \frac{E_g}{2 * v_f^2} \quad (2)$$

Where, E_g is the band gap and v_f is the Fermi velocity. But here we have tried to consider the meagre non-linearity present in the conduction band minima region and evaluate the effective mass from a more general formula (1). To appreciate our method we have presented a comparison between the effective mass calculated with equation (1) from Quantum Espresso results and the results published by G. Mukhopadhyay et al. with equation (2) [17] for B1 structure in Fig. 7. The results are in fine agreement. In Fig. 8 we have shown the electron effective mass for both B1 and B2.

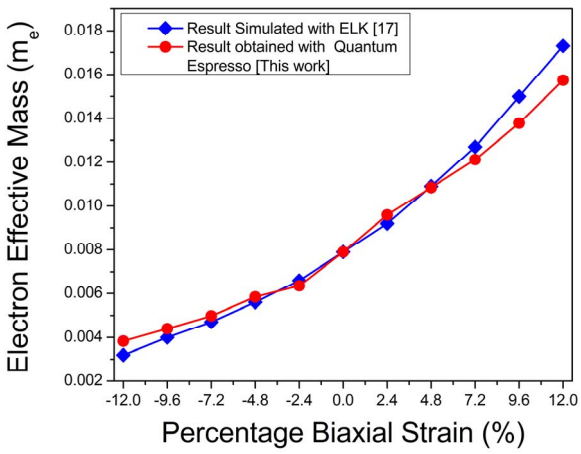

Fig.7 Longitudinal electron effective mass of B1 structure as a function of biaxial strain. Result obtained from equation (2) and with Elk simulation is shown in blue line. Electron effective mass calculated using equation (1) with Quantum Espresso is shown in red line.

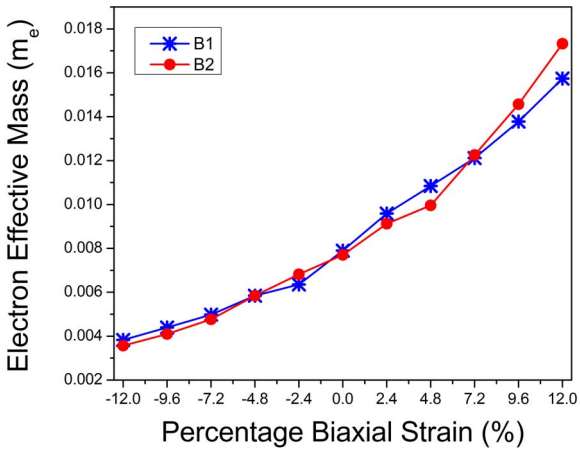

Fig. 8: Longitudinal electron effective mass of B1 structure (blue line) and B2 structure (red line) as a function of biaxial strain.

Fig. 8 indicates that the effective mass of the B1 and B2 structure is almost same except for the higher strain regions. At higher compression B2 structure prevails, while at higher expansion, B1 structure prevails.

Finally the Fermi velocity is calculated by fitting a straight line through the lowest conduction band minima and nearby almost linear points and then its slope was determined to calculate the group velocity using the equation:

$$v_g = \frac{\frac{\partial E}{\partial k}}{\hbar} \tag{3}$$

Using this formula the Fermi velocity for optimized B1 structure was found to be 0.864×10^6 m/s, closely matched with 0.8×10^6 m/s reported by [17]. For optimized B2 structure the value is 0.851×10^6 m/s almost equal to the value for B1.

The Fermi velocity for B1 and B2 is shown Fig. 9

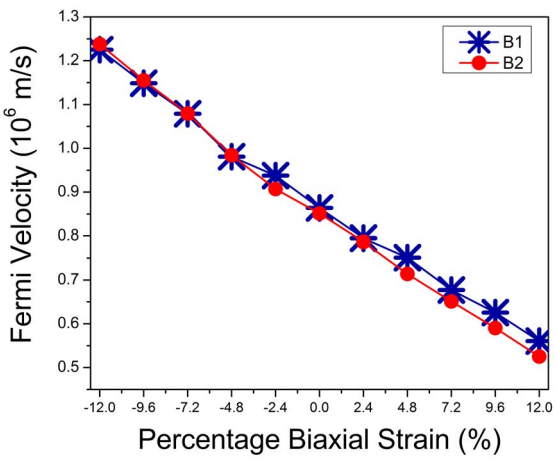

Fig. 9 Fermi velocity for B1 structure (blue line) and B2 structure (red line) as a function of biaxial strain

V. Conclusions

In this work, structural and electrical properties of B2 super lattice structure of graphene/h-BN hetero bilayer system were investigated. For optimized structure very high Fermi velocity (0.851×10^6 m/s) and extremely low effective mass ($0.0077m_e$) were observed. In addition, our study reveals that by applying compressive biaxial strain Fermi velocity can be increased and effective mass be decreased further which is the basic requirements of channel material for high frequency radio frequency (RF) applications. Moreover, the finding of non-zero band gap of the optimized structure (54 meV) that can be increased with tensile strain makes it also promising for channel material in logic transistors.

***Abstract*—In this paper, we propose a way of using the AudioVisual Description Profile (AVDP) of the MPEG-7 standard for stereo video and multichannel audio content description. Our aim is to provide means of using AVDP in such a way, that 3D video and audio content can be correctly and consistently described. Since AVDP semantics do not include ways for dealing with 3D audiovisual content, a new semantic framework within AVDP is proposed and examples of using AVDP to describe the results of analysis algorithms on stereo video and multichannel audio content are presented.**

***Index Terms*—AudioVisual Description Profile (AVDP), MPEG-7, stereo video, semantic content description**

I. Introduction

Automatic analysis of video and audio includes various tasks e.g., shot/scene boundary detection, person detection/tracking/recognition, facial expression recognition, music/speech segmentation, speaker diarization and music genre/mood characterization. The relevant algorithms are used in various applications, such as semantic description of video content for archival, indexing and retrieval, implementation of better audiovisual editing tools, intelligent content manipulation, etc. Recorded, broadcasted and webcasted data increase exponentially with time and research is focused on finding ways to analyse, describe and annotate video content in an efficient and automatic manner.

A rather new trend in multimedia is the use of stereoscopic video. Many of the recent film productions have their 3D versions [1]. Analysis of stereoscopic video has the advantage of benefiting from the additional available information, namely depth/disparity, which can boost the performance of analysis algorithms, such as the ones mentioned above. In addition, analysis of stereoscopic video can derive information that cannot be inferred from single-view video, such as 3D object position. Finally, the particularities of 3D video call for analysis algorithms that can characterize 3D video quality or its conformance to the rules of 3D cinematography [2].

For handling audiovisual content annotation and description, MPEG-7 standardizes a set of Descriptors (Ds), Description Schemes (DSs), a description definition language (DDL) and a description encoding [3]. A considerable amount of effort has been invested over the last years to improve MPEG-7 ability to deal with semantic content description. Nevertheless, 3D audiovisual content description has not yet been investigated in the MPEG-7 context. Although some description and description schemes have been proposed to model 3D information, they are only explicit descriptors for geometrical information and not for 3D video content.

The AudioVisual Description Profile (AVDP) has been recently adopted as a new profile of the MPEG-7 standard [4]. This profile consists of a subset of the original MPEG-7 standard and aims at describing the results of most of the known audiovisual analysis tasks (e.g., shot detection, face detection/tracking), in a normative manner. AVDP was designed to benefit both broadcasters and the digital media industry in order to create a normative layer between media content production and consumption. In this paper, we propose to store 3D video and multichannel audio content (e.g., 3DTV content) semantic analysis results to an XML file compatible to the specifications of the AVDP. Our aim is to show that AVDP can be used, by properly utilizing its descriptors and description schemes, for describing and storing the results of 3D audiovisual content analysis.

II. The Use of the AudioVisual Description Profile for 3D Content Description

The AudioVisual Description Profile (AVDP) provides a normative way to store high and low level information, extracted from the analysis of video and/or audio content. We have selected a subset of the decomposition types (namely TemporalDecomposition (TD), MediaSourceDecomposition (MSD), SpatioTemporalDecomposition (STD), SpatialDecomposition (SD)) available in the AVDP, in order to create various segment types (AudioVisualSegment (AVS), VideoSegment (VS), AudioSegment (AS), StillRegion (SR), MovingRegion (MR)) for representing the output of various analysis algorithms. In our approach, a content entity is used as the root of the description for a specific channel. Such a channel can be a color or disparity channel (left/right) of a stereo video segment or the audio content description, which unlike video is stored in a single content entity despite the fact that multichannel audio is present. All the relevant information of a channel obtained by various media analysis algorithms is stored within the content entity representing the corresponding channel by employing the above mentioned decomposition and segment types. Information that does not refer to a specific video channel (e.g., left or right), but to the 3D video as a whole, is stored to a reference channel, namely left channel. In the following sections, we will describe a number of 3D video and audio content analysis algorithms and the way their results can be stored using AVDP. Figure 1 illustrates the proposed AVDP usage for 3D content description.

III. Description of 3D Video Analysis Results

A. Scene/Shot Boundary Description

A scene/shot boundary detection algorithm can detect boundaries of scenes/shots in 2D or stereo video content, resulting in a temporal decomposition of a multimedia content into different scenes/shots [5], [6]. In terms of AVDP, a

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

TemporalDecomposition of an AudioVisualSegment describing the entire channel of a 3D video content is generated. Each resulting AudioVisualSegment represents a scene/shot. Moreover, with the same approach we can handle the case of shot transitions, such as fade-in, fade-out, dissolve etc. In all the cases, the type of the segment (e.g., scene, shot, transition of a certain type) is stored using the StructuralUnit element within the AudioVisualSegment. Additionally, semantic characterizations of scenes/shots, such as comfortable for 3D viewing, wide, close-up or popup, is provided using the How element of the StructuralAnnotation type. In the following partial XML example, a shot with its time and shot type information (medium shot) is described:

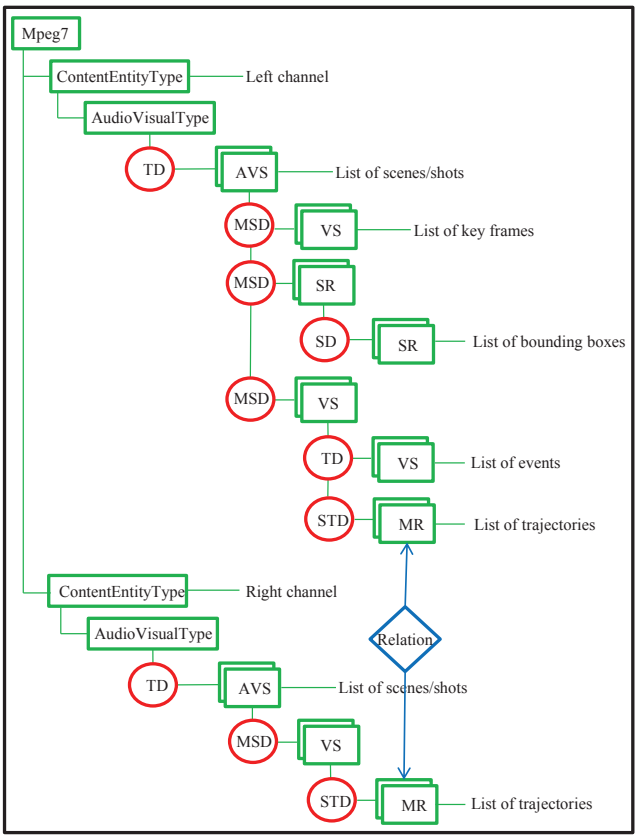

Fig. 1. Schematization of AVDP usage for 3D content description.

```
<AudioVisualSegment id="Shot_25">
 <StructuralUnit href="StructuralUnitCS#shot"/>
 <TextAnnotation>
  <StructuredAnnotation>
   <How href="SceneShotCharacterizationCS#medium"/>
  </StructuredAnnotation>
 </TextAnnotation>
 <MediaTime>
  <MediaRelIncrTimePoint>50</MediaRelIncrTimePoint>
  <MediaIncrDuration>192</MediaIncrDuration>
 </MediaTime>
</AudioVisualSegment>
```

B. Key Frame and Key Video Segment Description

Key frame or key video segment extraction algorithms produce characteristic video frames/segments summarizing a video segment [7]. Both color and depth information can be used for 3D video summarization. Key video frames and segments provide a video summary that can be used e.g., for fast browsing of query results in a 3D video asset management system. To describe such a summary, the MediaSourceDecomposition type is used within each respective shot, in order to generate a list of VideoSegment types representing each a key frame/video segment with the corresponding frame duration. Information regarding the respective multimedia data (e.g., image files for the key frames) can be stored using the MediaLocator type. A key frame example is given below:

```
<MediaSourceDecomposition
    criteria="DecompositionCS#key_segments">
 <VideoSegment id="KeyFrame_1">
  <MediaLocator>
   <MediaUri>/kf_4.jpg</MediaUri>
  </MediaLocator>
  <StructuralUnit href="StructuralUnitCS#key_frame"/>
   <MediaTime>
    <MediaRelIncrTimePoint>4</MediaRelIncrTimePoint>
    <MediaIncrDuration>1</MediaIncrDuration>
   </MediaTime>
  </VideoSegment>
</MediaSourceDecomposition>
```

C. Event Detection

An event is a semantically important concept having a certain duration in the audiovisual stream, such as a dialogue among people or a car accident. For describing events occuring within a shot, we use the TemporalDecomposition type of the VideoSegment, representing the visual information of the shot. The criteria attribute is set to “events”, to create a series of VideoSegments, each corresponding to a single event. The specific type of an event is stored within the StructuralUnit element of VideoSegment. An example of a dialogue occuring in the time interval [100, 50] is shown below:

```
<TemporalDecomposition
    criteria="DecompositionCS#events">
 <VideoSegment id="Event_1">
  <StructuralUnit href="StructuralUnitCS#event.dialogue"/>
  <MediaTime>
   <MediaRelIncrTimePoint>100</MediaRelIncrTimePoint>
   <MediaIncrDuration>41</MediaIncrDuration>
  </MediaTime>
 </VideoSegment>
</TemporalDecomposition>
```

D. Semantic 3D Video Quality Descriptions

3D video quality is highly related to the depth perception and the visual comfort while watching such a video [2], [8]. Semantic qualitative descriptions of 3D quality are more intuitive than quantitative descriptions and thus are preferred. Such descriptions can be at the shot level, pre frame or refer to a segment of the video. Shot level 3D quality semantic descriptions include information related to e.g., depth continuity, syncness, or depth stress. Annotation of the VideoSegment representing a shot is done by assigning the 3D quality semantic terms via the How element of StructuralAnnotation. Frame level 3D quality descriptions include information related to e.g., colorimetric or contrast mismatch, and are stored using the same approach as above within the StillRegion that corresponds to the frame. The semantic terms are defined in a respective Classification Scheme file. 3D video quality defects such as stereoscopic window violations, bent window effects or depth jump cuts refer to a segment of the video and the corresponding characterizations are stored as events (see Section III-C). An example of 3D quality description at shot level is given below:

```
<VideoSegment id="vis.shot_0">

   <How href="SemanticFeat3dCS#DepthBudget.medium"/>
   </StructuredAnnotation> </TextAnnotation>
 <MediaTime>
  <MediaRelIncrTimePoint>100</MediaRelIncrTimePoint>
  <MediaIncrDuration>199</MediaIncrDuration>
 </MediaTime>
</VideoSegment>
```

E. Person/Face/Object Description in Stereo Video

The description of an object (e.g., a person, a face, a car, a ball) is performed after object/person detection and tracking that provide the location of an object over time. In the case of humans, additional information can be included, such as depicted activity or facial expression. Semantic characterizations of object/person position and motion can also be stored.

In more detail, object detection is the process of finding the location of a predefined object (e.g. a face, a car, a ball etc) in a per-frame basis [9]. Since the object detector usually detects a specific object or a specific object category, this information can be used to semantically annotate the detected object type. To store the location of the detected object(s), usually in terms of a bounding box, as well as other relevant information, a StillRegion type is used for each detected object, where the specific type (e.g., face, car) is stored, within the StructuralUnit element, while the SpatialLocator type is used to hold the coordinates of the bounding box.

Object/person tracking produces the trajectory of a predefined object (e.g., a face) in a sequence of video frames [10], [11]. Usually, object tracking is initialized by an object detector and performed in a video segment in a frame-by-frame basis [12]. The spatial position of the tracked object (usually in the form of a bounding box) over time forms the object trajectory. The type e.g. face or ball, and the coordinates of the bounding boxes of a trajectory are stored within the StructuralUnit and SpatioTemporalLocator elements of a MovingRegion, respectively.

The resulting StillRegions (detection) and MovingRegions (tracking) are stored within the VideoSegment representing the visual information of the corresponding shot. As can be seen in Figure 1, we use a MediaSourceDecomposition type, to decompose this VideoSegment into a list of StillRegion elements, where each of them represents an entire frame of the video segment. Subsequently, we decompose each frame into further StillRegions representing detected objects through a SpatialDecomposition type. Similarly, we use a SpatioTemporalDecomposition type to decompose the VideoSegment, representing the visual information of the corresponding shot, into a list of MovingRegion elements where each of them represents an object trajectory. In 3D video content, correspondences between StillRegions (e.g. bounding boxes) or MovingRegions (e.g. trajectories), that correspond to the same depiction of the object in two channels, e.g. between the right and left video channel, should be established. To denote such a correspondence, we use the Relation type in order to connect two Segment types, namely StillRegions and MovingRegions across channels.

After object/person detection and tracking, various video analysis algorithms may be used for extracting semantic descriptions for these entities, e.g., information regarding person identity, facial expression or activity and/or object motion. More specifically, human activity recognition can be used to recognize specific predefined human activities, such as run or walk on a person trajectory. Such information can be stored using the WhatAction element of the StructuredAnnottion of the respective StillRegion or MovingRegion. Moreover, facial expression recognition labels, such as happiness, anger, fear etc., can be stored in the WhatAction element. The value “affect” is used within the StructuredAnnotation of the respective StillRegion or MovingRegion, whereas the How element holds the recognized expression.

By using geometrical reasoning algorithms, one can also annotate 3D video content with information related to the geometric or motion properties of objects or object ensembles [13]. Such properties may refer to the geometrical position of an actor or object in the 3D world, the size of an actor/object, the location of a displayed object with respect to the screen or the stereoscopic comfort zone, the direction of object motion etc. In the case of stereo video, object position and motion characterization in the depth domain can be obtained. Such geometric descriptions are stored using appropriate elements of the StructuralAnnotation type of StillRegions and MovingRegions. Specifically, the Where, WhatObject and How elements are used to store labels related to the position (e.g., “left”, “near”, “in front of screen”), size and movement (e.g., “forward”) of an object, respectively.

Image regions depicting faces (facial images) can be clustered into clusters of actors though a facial image clustering algorithm [14]. For storing the results of face/object clustering (i.e., labels such as Actor_1, Actor_2,...), we update appropriately the Who/WhatObject element, respectively, in the structured annotation of each involved segment type (StillRegion and MovingRegion).

It should be noted that in all above cases, the href attribute of the various elements (namely Who, WhatObject, How, Where) of StructuralAnnotation is updated by utilizing appropriate terms from corresponding Classification Schemes.

Relations between faces and real persons may be obtained through manual annotation or through a face recognition algorithm. For example, a face, that is automatically detected and is given an abstract face term (e.g., Actor_1) after face clustering, may be annotated as depicting a certain real person (e.g., Jack Smith). Hence, relations between abstract face terms and real names may be obtained. Each such relation is represented by a StructuredAnnotation which contains two ’Who’ elements: the first ’Who’ element holds the corresponding abstract face term and the second a term from a Classification Scheme containing real names of actors. The resulting StructuredAnnotations are stored in the top level structure for content description, namely the AudioVisual.

In the following XML example, a face trajectory, where the depicted person is sad and running, as well as the relation between Face_1 and John Smith is described:

```

F. Soccer Analysis in Stereo Video

3D Soccer analysis [15] extracts diverse semantic informations, such as camera view class, players positions and identities and interesting highlights [16]. More specifically, the goal of camera view classification for football videos is to recognize different camera views. Usually, four different camera view classes can be observed during a broadcast football match: (i) overview, which is the main camera placed usually on the stands, (ii) close-up, these are views taken from cameras around the field showing a single player. (iii) Medium views are also taken from cameras around the field but show more than one player. (iv) Out-of-field denotes those shots not showing any field action but either audience or the coaching bench. Such class label is stored as a How element within the StructuralAnnotation of the VideoSegment representing the visual information of the respective shot.

Soccer highlights such as corners, goals, etc can also be annotated. This is sensible, as soccer broadcasts usually follow a characteristic cinematic model. For example, most goal scenes start with the shot on the goal shown by an overview camera, followed by medium and/or close-up shots of celebrating players, coaches and audience. Goal scenes typically end with a replay, showing the goal shot from different perspectives. Soccer highlights can be stored using the same approach used for annotating events (see Section III-C).

Finally, players can be detected and tracked for the duration of their appearance. For identifying players, the most obvious way of performing player identification is by recognizing jersey numbers. Similar to other subjects (e.g., actors in a movie), a MovingRegion is used to represent a player's trajectory, while its name is stored in the Who element of the StructuralAnnotation type. In the following example, a shot of a soccer match is characterized as overview shot and a corner is stored as an event:

IV. Conclusions

In this paper we have presented a new way of using the AVDP profile of the MPEG-7 standard for 3D video content description that can accommodate multiple audio and video (left/right, color/disparity) channels. We have detailed how we can store the results of several audiovisual analysis algorithms within such a context and how specific 3D metadata can be incorporated in the framework. The proposed framework can be used for storing the analysis results in a 3DTV media asset management (MAM) system. Such a system can then be queried and return the video e.g., where actor X appears in the comfort zone in a 3D context. The proposed XML description can be easily extended to support multiview video coming from multiple cameras.

***Abstract*— THz is an emerging technology with many important applications in imaging and sensing, but due to lack of suitable low-loss waveguides future progress can be limited. A rigorous full-vectorial modal solution approach based on the computationally efficient finite element method is used to find the propagation properties of THz waveguides. Design approaches are presented to reduce the modal loss of such waveguides. Designs of several THz devices, including quantum cascade lasers, power splitters and narrow-band filters are also presented.**

***Index Terms*— Finite Element Method, Terahertz Waveguides, THz Devices.**

I. Introduction

The emerging terahertz (THz) region occupies a large portion of the electromagnetic spectrum, located between the microwave and optical frequencies and normally is defined as the band ranging from 0.1 to 10.0 THz. In recent years, this intermediate THz radiation band has attracted considerable interest, because it offers significant scientific and technological potential for applications in many fields, such as sensing [1], imaging [2] and spectroscopy [3]. However, waveguiding in this intermediate spectral region is a major challenge and strong dielectric and conductive losses in the terahertz frequency range have been a major problem for the development of practical low-loss waveguides. Due to the lack of suitable low-loss waveguides most of the present day THz systems uses free-spaces transmission. The availability of low-loss waveguides and followed up by THz guided-wave devices can improve the functionality and reliability of future THz systems. The conventional guiding structures exemplified by microstrips, coplanar striplines and coplanar waveguides are highly lossy and dispersive. However, so far the most promising dielectric waveguides have been the use of photonic crystal fibers at terahertz frequencies [4, 5] and metal coated guides [6] at terahertz frequencies. In this paper, various types of practical dielectric and metal coated waveguides are evaluated and design optimization of Quantum Cascade Lasers, MMI-based power splitters and narrow-band filters are presented, by using full-vectorial finite element method [7].

II. Page Layout

Dielectric waveguides in silica, silicon, polymer, and other semiconductors materials have been widely used at optical frequencies due to their low-loss values: however most of these materials are very lossy at the lower terahertz frequency range and not so suitable to fabricate THz waveguides. Particularly, silica has been extensively used to fabricate a new class of optical fibre, the photonic crystal fibres (PCF), however, as its material loss is prohibitively high at THz frequencies, only recently, Han *et al*. [4] have fabricated a PCF for THz using alternative high-density polyethylene (HDPE) with modal loss values of 0.2 cm^{-1} and Goto *et al*. [5] have reported a PCF-like waveguide using Teflon tubes and filaments with loss values of 0.5 cm^{-1}, showing their potential. A typical PCF cross section with a triangular array of holes is shown in Fig. 1. The structure predominantly consists of such periodic air-holes with diameter, *d*, and the pitch length between the two nearest holes is Λ. In this work, a refractive index value n_g = 1.444 is considered, at the operating frequency 1.2 THz (wavelength 0.25 mm). Variations of the effective indices for both the fundamental H^x_{11} and the second H^x_{21} modes for d/Λ = 0.9 are shown in Fig.2. It can be noted that for both the modes, the effective indices reduce monotonically as the pitch length is reduced. The variation of the n_{fsm} value with the pitch length is also shown by a chained line for d/Λ = 0.9 at 1.0 THz. The n_{fsm} represents a frequency dependent equivalent index of the perforated cladding region and this was calculated by solving a unit cell problem with periodic boundary conditions implemented around all the four sides. It can be observed that the effective index curve for the H^x_{21} mode crosses the n_{fsm} line at a pitch length, Λ_c = 0.24 mm, so when the pitch length is reduced below 0.24 mm, the second mode cannot be guided anymore. On the other hand, the effective index for the fundamental, H^x_{11} mode also crosses the n_{fsm} line, but at Λ_c = 0.11 mm. So, a PCF with d/Λ = 0.9 and pitch length between 0.11 mm to 0.24 mm would be strictly single moded. By controlling the d/Λ ratio and the pitch length the modal properties of such low-loss PCFs at THz operating frequency can easily be controlled. It is possible to broaden the single mode operating region or even design an endlessly single mode PCF by reducing the d/Λ value.

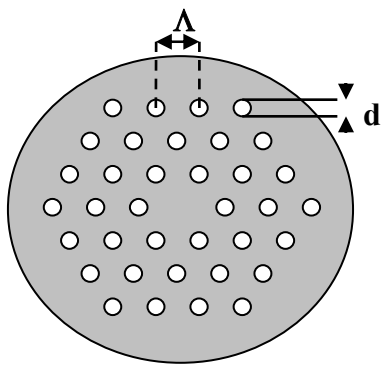

Fig. 1. Cross section of a Photonic Crystal Fiber

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

The modal loss of a guided mode in a PCF is due to the combination of the material loss and the leakage loss. The leakage loss arises due to the modal index being lower than the surrounding high index cladding regions. For this study a PCF with parameter d/Λ=0.5 is used. To consider the effect of the loss tangent, three different values of the n_i, (the imaginary part) have been considered. Additionally, Perfectly Matched Layers (PML) were added around the conventional waveguide boundaries to calculate the leakage losses. Figure 3 shows the loss mechanism in a PCF. In the absence of any material loss, for $n_i = 0$, the leakage loss is shown by a solid line. It can be observed that as the pitch length is reduced, the leakage loss increases almost linearly from a very low loss value. It should be noted that Perfectly matched Layers (PML) region around orthodox computational boundary should be introduced to obtain leakage loss of any waveguide. In the case of n_i = 0.00119, the total loss included both the leakage loss and the material loss, which is shown by a dashed line. At a higher pitch value, when the leakage loss is negligible, the total loss is mainly attributable to the material loss. However, it can be observed that modal loss is more than 100 dB/m, this is only because lack of suitable dielectric material in this frequency range.

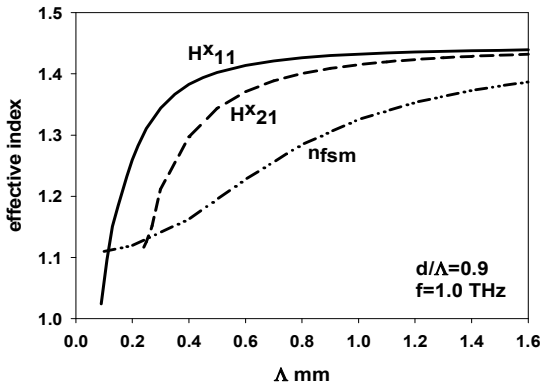

Fig. 2. Variation of the effective indices with the pitch length, Λ.

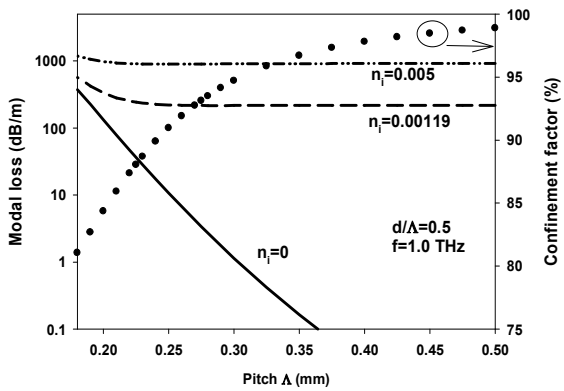

Fig. 3. Material and leakage losses of PCF

Since at present the available dielectric materials at THz frequencies are considerable lossy, a novel design approach is considered next, where besides the porous cladding with air-holes, additionally a porous core PCF is considered. As the waveguides dimensions for THz frequency are considerable bigger than that for the optical wavelength, it would be relatively easy to fabricate such microstructured core. Two different d/Λ values are used for core (d/Λ_i) and cladding (d/Λ_o), and for cladding this value has to be smaller to have higher equivalent index in the core for wave guidance. Variation of the power fraction in the air-region of the porous core is shown in Fig.4. As shown in this figure, the power confinement can be increased to 35% in the low-loss air-holes of the cores, and additionally another 25% in the cladding air-holes [8], but this is not shown here. So, in this design, the overall modal loss mainly arises due to the material loss of the polystyrene, and this can be reduced by 60% but using such perforated core besides air-holes in the cladding region. The overall reduction is significant, but still need more work to be done to make the more suitable for practical applications.

Amongst the various THz waveguides that have been suggested, the metal-clad waveguides supporting surface plasmon modes show the greatest promise as low-loss waveguides for use both in active components and as passive waveguides. Several waveguide structures incorporating metallic layers have been reported, such as low-loss and flexible hollow polycarbonate waveguide with copper and dielectric inner coatings, deposited by using a liquid chemistry approach [9].

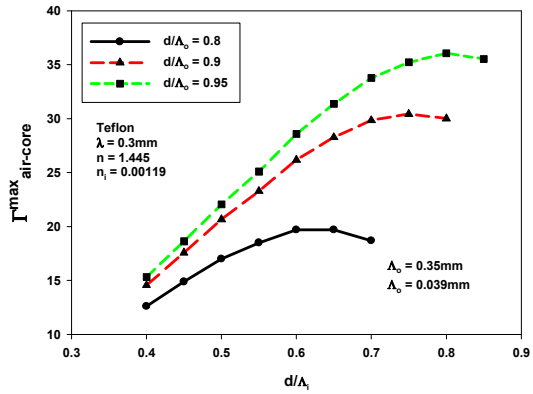

Fig. 4. Variation of power confinement in the porous air-holes in the core region with the pitch length, Λ

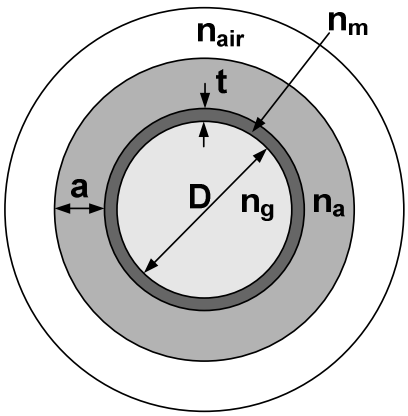

Fig. 5. Metal-coated hollow glass waveguide

A metal-coated hollow glass waveguide (HGW) [10] with an inner silver/polystyrene-coating, as shown in Fig.5, is considered for the better understanding of the various loss mechanisms and subsequently design optimization of a low-loss THz waveguide. For this waveguide the thickness of the silica tube (*s*) is taken as 0.5 mm and the bore diameter (*D*) of the HGW as 4 mm. Inside the hollow-core first metal and then polystyrene are coated. The thickness of the silver cladding (*t*) and polystyrene layer (*p*) are taken as t µm and p µm, respectively. The complex refractive index of the polystyrene,

the silver metal cladding layers and the silica ring are taken as n_p=1.58 –j0.0036, n_m=308-j532 and n_s=1.96 –j0.0061, respectively at an operating frequency of 2.5 THz. At this frequency, as the air is also not absolutely loss-free, to represent this loss factor its complex refractive index is taken as 1.0 - j 1.1x10^{-6}.

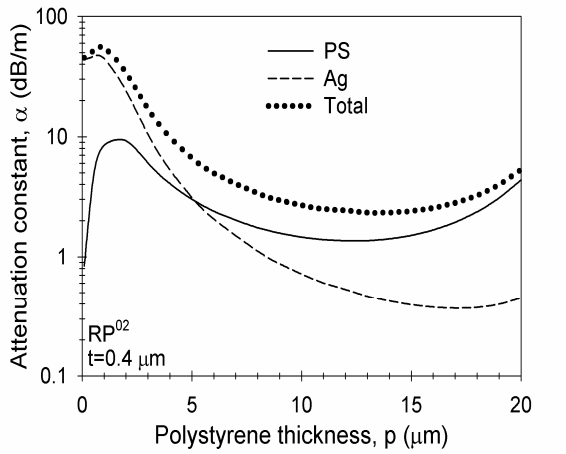

Fig. 6. Attenuation constant with the polystyrene thickness, *p*, for *t*=0.4μm

There are two metal/dielectric interfaces, which can support surface plasmon modes (SPM), one the outer silver/silica boundary and the other at the inner silver/polystyrene (or air, when p = 0 μm) boundary. This waveguide supports two SPMs along these two metal/dielectric interfaces. The refractive indices of the inner and outer cladding materials being very different, the two SPMs have widely different propagation constants and they do not interact with each other. However, at the right and left hand sides of the metal/dielectric interfaces, when the same electric-wall boundary condition is imposed, the H_x field is forced to be zero at the metal boundary and no SPM exists. Another mode with the dominant H_y field, would form a similar SPM; however, at the left and the right interfaces. The H_y field profile of this mode is similar to the H_x field profile, but rotated by 90 degrees. These two modes have identical propagation constants and being degenerate, they can be superimposed to form radially polarized RP-like modes.

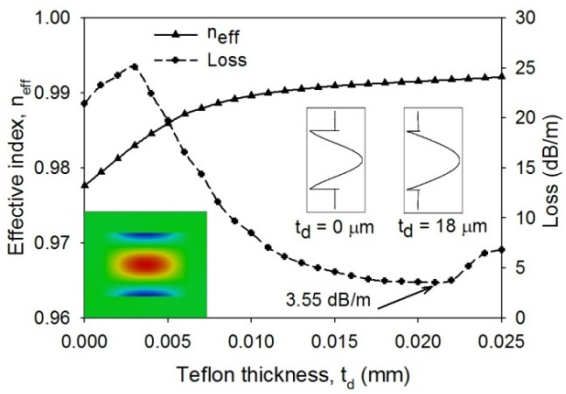

Fig. 7. Effective index and loss with Teflon thickness for the H^x_{10} mode

The loss values of the fundamental plasmonic mode increases with the PS thickness and not shown here, as this mode was more lossy. The attenuation characteristics of the RP^{02} mode, with the variation of the polystyrene thickness, for a silver thickness t = 0.4 μm, is shown in Fig. 6, where the loss contribution of the polystyrene and silver layers has also been examined. As can be seen from the above characteristics, the total attenuation shows a maximum and a minimum loss at a polystyrene thickness of about 1 μm and 13 μm, respectively. The attenuation curves due to the polystyrene and the silver layer exhibit similar trend with the total attenuation. Throughout the range of polystyrene thicknesses examined, the optical power confinement in the inner air-core is of the order of 99.9%, thus contributing a constant attenuation of about 0.25 dB/m. For a polystyrene thickness lower than 5 μm, the total attenuation is affected mainly due to the metal attenuation but as the polystyrene thickness increases above 5 μm the total attenuation is mainly governed by the loss in the polystyrene layer. This mode shows a greater promise to achieve low-loss guidance through a metal clad dielectric waveguides. It would also be easier to couple this mode since the field profile is also very close to a Gaussian shape [10]. The modal loss of this waveguide, when design is optimized, is significantly lower than most of the THz waveguides reported so far, as most of the power is being guided in the central air-hole region.

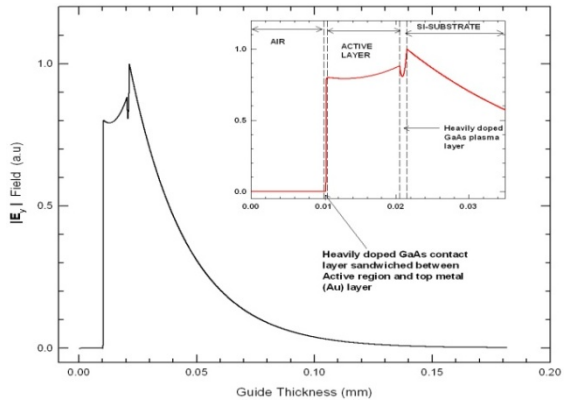

Fig. 8. Field profile of $\mathbf{E}_y$ mode in a THz Quantum Cascade Laser. The field inside the confinement layers is shown on the inset.

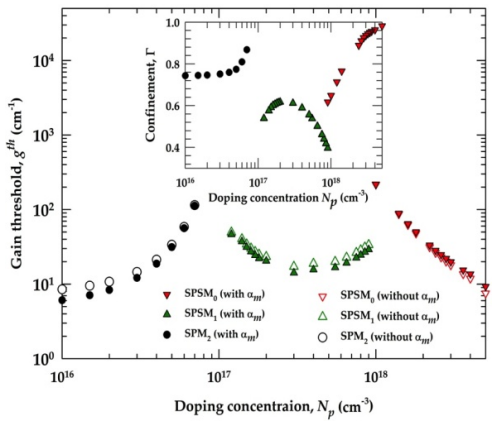

Fig. 9. Gain threshold of several plasmonic modes.

Next this novel approach of incorporating additional PS layer to draw away power from lossy metal layer is considered to design and optimize a low-loss rectangular core metal waveguide. If we consider its height and widths are different then the two polarized modes will not be degenerate. In our more recent work [11], we have shown that similarly a polarization maintaining rectangular core air-core dielectric-

clad metal-coated waveguide can also be less lossy. A thin metal coating would support plasmonic modes, but these are relatively lossy. However, a Teflon coating on the gold layer can draws field away from the lossy conducting layer and loss may reduce considerably. Figure 7 shows the variation of the loss value with the Teflon thickness for the H^x_{12} mode in an air-core 1 mm x 0.6 mm rectangular waveguide with 0.7 µm gold coating at 2.5 THz. It can be seen that at the optimum 21 µm Teflon thickness, the loss value can be 3.5 dB/m, one of the lowest reported so far [11]. The evolution of third order mode for no Teflon coating to a near Gaussian profile for 18 µm Teflon coating are shown as insets. In this guide also, the fundamental TE_{10} or TE_{01} mode was more lossy and its loss value rather increased with the polystyrene coating. Further improvement in the waveguide design to reduce loss and dispersion can encourage the development of THz guided-wave systems.

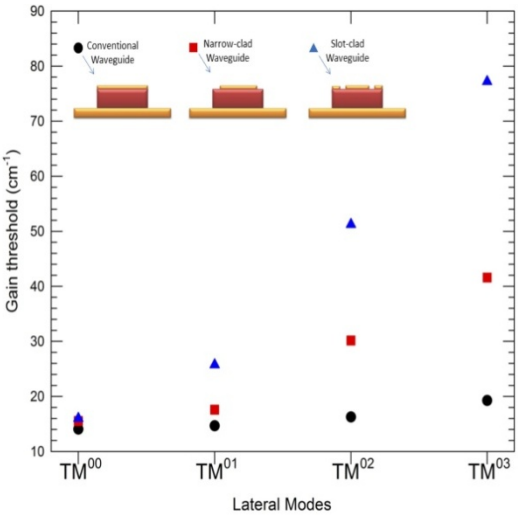

Fig. 10. Gain Threshold of the lower order modes for different waveguides

We also need good sources for THz generations. There are some convergences for the development THz sources from microwave engineering to increase the frequency and from photonics to reduce the frequency. Quantum cascading lasers [12] are emerging as efficient high power THz source for many important applications, such as imaging and sensing. However, for the THz frequency, it is not possible to grow the semiconductor materials comparable to the operating wavelength. For this reason, for THz QCL often smaller height needs to be considered and plasmonic confinement is used in that direction. The plasmonic confinement in the vertical direction is shown in Fig.8, which clearly shows the mode formation at the metal-dielectric interfaces. However, it is easily possible to have a wider guide, so mostly dielectric confinement is used in horizontal direction. The gain threshold for such QCL is shown in Fig.9. Because of the wider guides, the gain threshold difference between the fundamental and higher order (lateral) modes are very small. This allows possibility of mode hopping for any external changes. A novel design approach is considered [13] using slotted upper metal clad, to enhance the gain threshold of the higher order modes. Figure 10 clearly shows that gain threshold of the higher order modes are increased for slotted-electrode designs. This would reduce mode competition and the resulting output beam would be more stable with the environmental variations. Besides reducing waveguide loss of QCL, it may also be possible to increase the operating temperature of QCL, another critical issue in the further development of room-temperature QCLs.

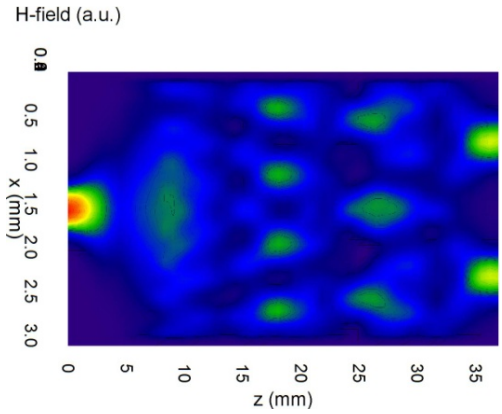

Fig. 11. FDTD Simulation of the MMI 3dB coupler

For the future THz system, it is essential to design various integrated guided-wave components. In that spirit, it is shown here that a compact power splitter can be designed by using the MMI principle. In Fig. 11, it is shown here that an efficient power splitter can be designed by using a 35 µm long multimoded section [14]. A Finite Difference Time Domain (FDTD) approach is used here to simulate this structure.

Next, a Terahertz frequency range band-stop filter for molecular sensing [15], where two 5 µm wide band-stop filter stubs with a length of 192 µm and 83 µm are placed at a 400 µm apart along the direction of propagation, as shown in the right inset of Fig.12, has been considered. The structure of the microstrip is also shown as an inset on the lower left side. Initially the above device has been simulated without a polysterene film on top of the metal layer, using the FDTD approach and the variation of the insertion loss with the frequency is presented in Fig.12. As can be seen from the above frequency response, the device exhibits two resonant frequencies due to the stubs at about 600 and 800 GHz, with a minimum insertion loss of about -55 and -30 dB. These resonant peaks will shift due to presence of any external materials on the microstrip and measuring this frequency shift, a THz sensor can be developed.

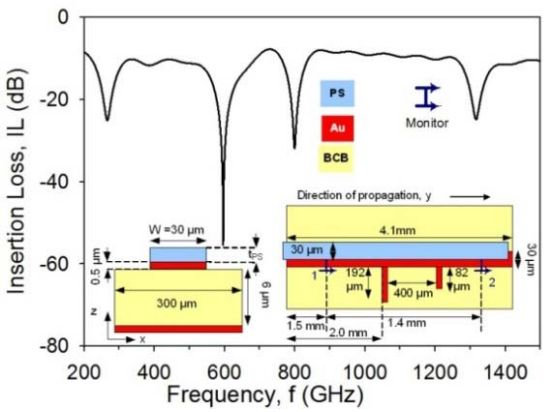

Fig. 12. Insertion Loss with frequency for the microstrip filter

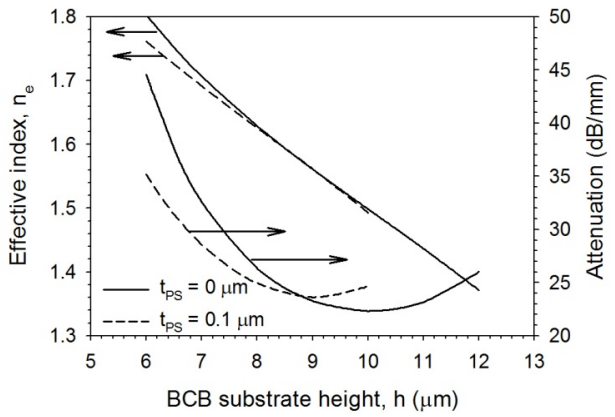

Fig. 13. Variation of the effective index and attenuation with BCB substrate height of the microstrip line.

Finally, the BCB substrate height, h, has then been varied and the effective index and attenuation of the microstrip structure with no polysterene layer on top of the metal and that with a 0.1 μm film thickness of the above material have been examined and presented in Fig.13. As can be seen from the above characteristics, as the substrate height increases both the effective index and the attenuation decrease, with the corresponding values of the structure with the polysterene film being lower than those obtained for the device without it. At a substrate height of about 9 μm, the above corresponding values are about the same for both the structures examined. However, the device with the polysterene film exhibits minimum attenuation at the above substrate height and as the substrate height increases further the attenuation of the structure with the polysterene layer becomes higher than that obtained for the structure without the above material.

III. Conclusions

A finite-element approach, based on a full-vectorial **H**-field formulation, has been used to study the detailed modal properties of dielectric and metal clad waveguides operating in the THz frequency range. It is also shown here that by using porous core the effect of material loss can be reduced significantly. It is also shown by using a thin but optimized dielectric over-layer plasmonic loss in a hollow-core waveguide can also be reduced. It is also shown here that by using a novel slot-type electrode, the differential loss of the higher order modes can be significantly increased to reduce mode hopping. Finally, simple guided-wave devices such as power splitters and band-pass filters are also presented here. The full-vectorial numerically efficient finite element based design approach used here can be extended to optimize not only THz waveguides but also more advanced guided-wave devices for future THz integrated circuits (TIC).

***Abstract*—Throughput in IEEE 802.11 based wireless local area networks (WLANs) significantly depends on the minimum contention window (CW) parameter of CSMA/CA medium access control protocol. The throughput-optimal value of the minimum CW is modeled by G. Bianchi for a single WLAN without considering co-channel interference as $N\sqrt{2T_c}$, where N is the number of contending nodes in the WLAN and T_c is the collision time in mini-slots [1]. In this paper, the throughput-optimal configuration of the minimum CWs of the CSMA/CA based WLANs is studied under co-channel interference via extensive simulations. From the simulation results, it is investigated that in a WLAN the optimal value of the minimum CW is 4% to 25% higher than the Bianchi optimal CW due to co-channel interference. However, in WLANs, the optimal throughput is very close to the throughput obtained at the Bianchi optimal CW. In WLANs, very close to the optimal throughput can be obtained by configuring each WLAN independently with the simple Bianchi model even when the co-channel interference is considered.**

***Index Terms*—Local area networks, throughput, medium access control, co-channel interference, the minimum contention window.**

I. Introduction

In the last two decades, the popularity of wireless local area networks (WLANs) increases dramatically as wireless technology has evolved to meet the fundamental requirements of all categories of users. The WLANs are rapidly deployed in homes, public places, universities, offices and enterprises. Most modern WLANs are based on IEEE 802.11 standard which use carrier sense multiple access with collision avoidance (CSMA/CA) medium access control (MAC) protocol for managing interference [2]. IEEE 802.11 based WLANs use two unlicensed frequency spectrum bands: 2.4 GHz Industrial, Scientific, and Medical (ISM) band and 5 GHz Unlicensed National Information Infrastructure (UNII) band [3]. There are 14 channels available in IEEE 802.11 b/g. However, only three channels are non-overlapping among the total 14 available channels [4], [5]. Due to the limited number of non-overlapping channels, WLANs reuse the same frequency spectrum and co-channel interference exists in WLANs. The throughput performance in WLANs severely degrades due to co-channel interference [6].

Throughput performance of WLANs are determined by the configuration of the physical layer and MAC layer parameters [7]. A threshold level of power known as carrier sensing threshold (CST) is used in CSMA/CA MAC protocol to sense whether the medium is free or not. The spatial reuse as well as throughput in WLANs depends on the joint configuration of node transmit power and CST. In [8], it is shown that the optimal value of CST is related to the node transmit power and for a particular data rate the product of transmit power and CST is constant. The effect of transmit power and CST on the throughput performance in WLANs is also studied in [5], [7], [9], and [10]. All these studies advocate to configure the transmit power and CST appropriately to achieve a good throughput performance in WLANs.

Appropriate configuration of transmit power and CST is not enough to achieve the optimal throughput in CSMA/CA based WLANs since the efficiency of the MAC protocol depends on its contention resolution technique. CSMA/CA MAC protocol uses slotted binary exponential back off (BEB) algorithm for contention resolution and the minimum contention window (CW) is the main parameter of the BEB algorithm on which the throughput of WLANs depends mostly. In WLANs, collision occurs due to concurrent transmissions and interference. If the minimum CW of the nodes is set to a low value, the collision rate will be very high and the throughput performance will be very poor. Collision rate reduces and the throughput increases with increasing the value of the minimum CW of the nodes from a low value. On the other hand, if the minimum CW is set to a very large value, the nodes pass a significant amount of time in backing off and hence, the throughput performance will be poor. Thus, there is an optimal value of the minimum CW for the nodes for which throughput in a WLAN is the optimal.

Under the *protocol interference model* without considering co-channel interference, an analytical model of throughput in a single WLAN is provided by G. Bianchi [1]. The expression of the optimal value of the minimum CW for a single WLAN is also derived as $N\sqrt{2T_c}$, where N is the number of contending nodes in the WLAN and T_c is the collision time in mini-slots. Throughout the paper this configuration of the minimum CW is called as Bianchi optimal CW. Recently, in [11], it is shown that the changes in the optimal value of the minimum CW is negligible for using the *physical interference model* instead of the *protocol interference model* in a single WLAN. So far the optimal configuration of the minimum CW is well understood for a single WLAN where there is no co-channel interference. However, there is no clear indication in the literature on how to configure the minimum CW sizes of the nodes in WLANs to achieve the optimal throughput when co-channel interference exists.

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

In this paper, the basic CSMA/CA MAC protocol of IEEE 802.11 and a single transmission rate are considered to address the problem of configuring the minimum CW in WLANs under co-channel interference. Via extensive simulation campaign, it is demonstrated that in a WLAN the optimal value of the minimum CW is 4% to 20% higher than the Bianchi optimal CW due to co-channel interference. However, the optimal throughput is very close to the throughput obtained by the Bianchi optimal CW. The main contribution in this paper is to provide the insight that a near optimal throughput is achievable in WLANs by configuring the minimum CW of each WLAN independently using the simple Bianchi model.

The rest of the paper is organized as follows. System model is presented in detail in Section II. Simulation results and the engineering insights are presented in Section III. This work is concluded in Section IV.

II. System Model

A. Network Topology

Consider a WLAN which has six co-channel WLANs. The WLANs are hexagonal in structure with cluster size of 3. Each WLAN has an AP which is located at the center. The users are randomly distributed in the WLANs and their positions are known. The total number of nodes including the APs in the WLANs is N and their set is denoted by $\mathcal{N}$. Each node of the WLANs has an omnidirectional antenna and cannot transmit and receive at the same time. The transmission power of all the nodes is assumed to be equal and fixed. Only uplink communication is considered in the WLAN system, i.e., only the users access their APs to send their data packets. Each node uses the basic CSMA/CA MAC protocol of IEEE 802.11. The CST for all the nodes is assumed to be fixed and equal. A single rate system is considered where all the users use the same modulation and coding scheme. The users are assumed to be in saturation, i.e., they always have packets to send.

B. Propagation Model

For simplicity, log-normal path loss model is considered in this study. For a transmission of node n_1, the received power at a node n_2 is $P_t G_{n_1,n_2}$, where P_t is the node transmit power and G_{n_2,n_2} is the channel gain between nodes n_1 and n_2. The channel gain is assumed to be quasi time-invariant and G_{n_1,n_2} is given by $(\frac{d}{d_0})^{-\eta}$, where d is the distance between the nodes, d_0 is the far-field cross-over distance and η is the path loss exponent of medium.

C. Interference Model

The *physical interference model* based on signal to interference plus noise ratio (SINR) is considered for wireless interference because it is more realistic interference model for wireless interference [12]. According to this model, a transmission is successful if the received SINR at the receiver is not less than a minimum required SINR. Let the minimum required SINR at the receiver for successful packet decoding is γ. Thus, a packet sent by a transmitter n_1 will be successfully received by a receiver n_2 if

$$\frac{G_{n_1,n_2} P_t}{N_0 + \sum_{n' \in \mathcal{N} \setminus n_1} G_{n',n_2} P_t Y_{n'}} \geq \gamma \tag{1}$$

where N_0 is the noise power and $Y_{n'}$ is a binary variable taking value 1 if node n' transmits and 0 otherwise.

D. Basic CSMA/CA MAC Protocol

In the basic CSMA/CA MAC protocol, each node senses the medium for a time equal to the distributed interframe space (DIFS) before initiating a transmission of a packet. A node n senses the medium as busy if the received power is higher than CST, i.e., if

$$\sum_{n' \in \mathcal{N} \setminus n} P_t G_{n',n} Y_{n'} + N_0 \geq CST. \tag{2}$$

If the medium is sensed idle by a node in DIFS period it transmits its data packet. Otherwise, the node sets a value of CW randomly choosing from a uniform distribution (0, CW_{min}-1), where CW_{min} is the minimum CW of the nodes. After the DIFS time, the time is divided into mini-slots and each node senses the channel in each mini-slot if they do not transmit. If a node senses the channel as busy in a mini-slot, the node does not reduce its CW. If the channel is found as idle in a mini-slot, the node reduces its CW by one. This is called back-off process. Each node continues the back-off process until their CWs become zero. A node transmits its data packet when its CW becomes zero. Since all the nodes randomly chose the values of CWs, more than one node might have the same CW. In that case, they will start transmission at the same time and the success or failure of a transmission will depend on the interference model. The data packet sizes of all the nodes are assumed to be equal. If a data packet transmission is successful, the receiver will send an acknowledgement (ACK) packet after a short inter frame space (SIFS) time. If a node receives an ACK packet which has already transmitted a data packet, it will attempt to send the next data packet according to the procedure mentioned above.

If transmission of a data packet fails, the packet will be retransmitted. During retransmission, the value of CW is randomly chosen from a uniform distribution (0, $2^m CW_{min}$-1), where m is the number of retransmission attempts to send the packet. This is called BEB mechanism. When a data packet (re)transmission is successful and an ACK packet is received by the sender, for the next data packet, CW will be reset by randomly choosing from a uniform distribution (0, CW_{min}-1). If a packet is not successful for five retries, the data packet is dropped.

III. Simulation and Results

In this section, the optimal configuration of the minimum CW of the nodes in WLANs is studied under co-channel interference via simulation.

A. Case Study - Equal Number of Users in Each WLAN

1) Networks and Algorithm Parameters: A WLAN and its six co-channel WLANs (Network-1) are considered as shown in Fig. 1. The radius of each WLAN is taken to be 100 m. The AP of each WLAN is labeled by a rectangular box. The number of users in each AP is taken to be 7. The physical layer and MAC layer parameters are given in Table I. The path loss exponent is taken to be 3.5 considering the environment of indoor. Another network (Network-2) similar to the network-1 is also considered.

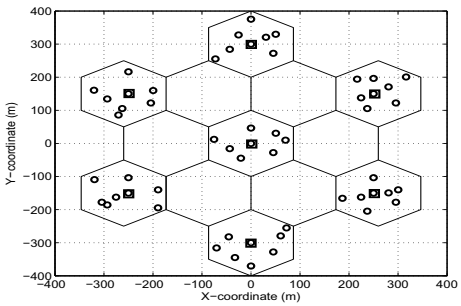

Fig. 1. The positions of the nodes in WLANs (Network-1).

TABLE I
PHYSICAL LAYER AND MAC LAYER PARAMETERS

Layer	Parameter	Value
Physical	SINR threshold, γ (dB)	6.4
	Noise power, N_0 (dBm)	-100
	Far-field crossover distance, d_0 (m)	1
	Data rate, C (Mbps)	2
MAC	SIFS (μs)	10
	DIFS (μs)	50
	a slot time, δ (μs)	20
	Data packet size, L_d (byte)	1058
	ACK packet size (byte)	14
	PHY + MAC header (byte)	24

2) Simulator Setup: A custom simulator written in C++ is used for simulation [11]. The commonly available network simulators are not used since they cannot provide the flexibility of tuning the network parameters. The average rates of the sources are set to be equal values and their traffic is assumed to be Poisson. The source rate of the users is kept sufficiently large to make their queues saturated. To determine the total throughput of the WLANs for a given network scenario, the network is simulated for 500 s and the total throughput of the WLAN is calculated as $1058 \times 8 \times N_{pkt}/500$ bps, where N_{pkt} is the total number of packets received by the APs of the WLANs at the end of the simulation. For a network scenario, the average throughput over five simulation runs is taken to determine the total throughput of the WLANs.

3) Configuration of Transmit Power and CST: The optimal values of transmit power and CST are used to study the optimal configuration of the minimum CWs of WLANs. These values are determined through extensive simulations by varying the node transmit power for different values of CST at the Bianchi optimal CW. For the WLAN system considered in this paper, the collision time is found to be 219 mini-slots using the following equation [1].

$$T_c = \frac{8(L_d + PHY + MAC)}{C\delta} + \frac{DIFS}{\delta} \tag{3}$$

where L_d is the data packet size, PHY and MAC are the physical layer and MAC layer headers, respectively, and δ is the duration of a mini-slot. The Bianchi optimal CW is found to be 146 for the users of each WLAN since the number of contending nodes is 7 in each WLAN. From the simulation results, the optimal values of transmit power and CST power are found to be -18 dBm and -94 dBm, respectively, for the both networks.

4) Optimal CW versus Bianchi Optimal CW: Using the optimal transmit power and CST, the total throughput of the both networks are determined via simulation by varying the minimum CW ranging from 31 to 320. The total throughput of each network is shown in Fig. 2 for different values of the minimum CW. The optimal values of the minimum CWs and the optimal throughputs of the both networks are determined from the figure. The optimal values are compared with the Bianchi optimal values in Table II, where CW_O and CW_B are the optimal value of the minimum CW and the Bianchi optimal CW, respectively and λ_O and λ_B are the optimal throughput and the throughput obtained by the Bianchi optimal CW, respectively. From the results in Table II, it is found that the optimal value of the minimum CW is 15% to 25% higher than the Bianchi optimal CW. However, the difference between the optimal throughput and the throughput obtained by the Bianchi optimal CW is less than 0.5%. Thus, the Bianchi optimal CW is sufficient to achieve a near-optimal throughput.

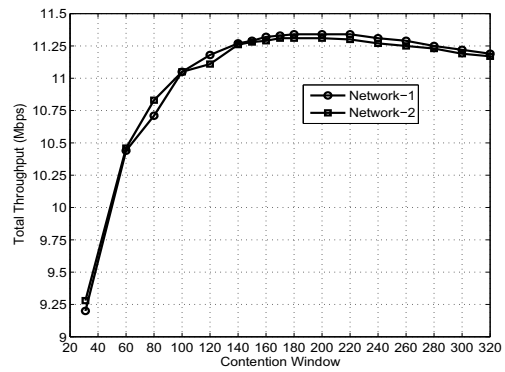

Fig. 2. Throughput performance at different values of the minimum CW.

TABLE II
COMPARISON OF THROUGHPUT PERFORMANCE

Network	CW_O	CW_B	% Diff.	λ_O (Mbps)	λ_B	% Diff
1	180	146	23.28	11.34	11.29	0.44
2	170	146	16.44	11.31	11.27	0.35

B. Case Study - WLANs with Different Number of Users

1) Networks and Algorithm Parameters: Two networks (Network-3 and Network-4) with different number of users in the WLANs are considered to study the impact of co-channel interference on the optimal configuration of the minimum CW in WLANs. One of the networks (Network-3) is shown in Fig. 3, where the WLANs are labeled as WLAN-1, WLAN-

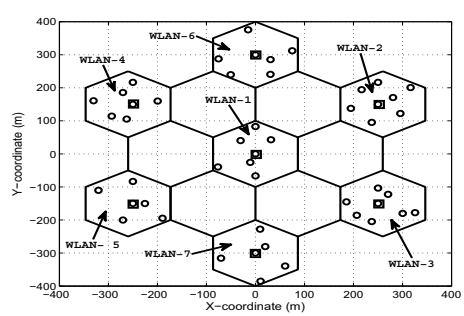

Fig. 3. The positions of the nodes in WLANs (Network-3).

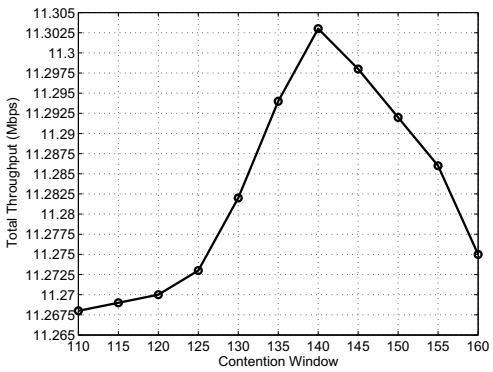

Fig. 4. Total throughput of the WLANs in Network-3 by varying the minimum CW of the users in WLAN-1.

TABLE III
COMPARISON OF THE OPTIMAL VALUE OF THE MINIMUM CW AND THE BIANCHI OPTIMAL CW

	Network-3			Network-4		
WLAN	CW_O	CW_B	% Diff.	CW_O	CW_B	% Diff
1	140	125	12.00	140	125	12.00
2	156	146	6.85	130	125	4.00
3	171	146	17.12	119	104	14.42
4	145	125	16.00	119	104	14.42
5	124	104	19.23	145	125	16.00
6	140	125	12.00	135	125	8.00
7	124	104	19.23	161	146	10.27

2, WLAN-3,... and WLAN-7. The physical layer and MAC layer parameters and the simulator setup are considered as in sub-section III-A. The optimal values of transmit power and CST are considered for the study which are determined via extensive simulations by varying the transmission power of the users at different CST power levels at the Bianchi optimal CW at each WLAN. For Network-3, the optimal values of transmission power and CST are found to be -16 dBm and -92 dBm, respectively. On the other hand, the optimal values of transmission power and CST are -18 dBm and -94 dBm, respectively for Network-4.

2) Optimal CW versus Bianchi Optimal CW: Using the optimal transmission power and CST, Network-3 as well as Network-4 is simulated by varying the minimum CW of a WLAN while keeping the minimum CW of the other 6 WLANs of the network to their Bianchi optimal CW. In Fig. 4, the total throughput of Network-3 is presented for different values of the minimum CW of WLAN-1. The number of users in WLAN-1 of Network-3 is 6 and for this WLAN the Bianchi optimal CW is calculated as 125. From Fig. 4, it is found that the optimal value of the minimum CW is 140 and the optimal throughput is 11.303 Mbps. The total throughput obtained for the Bianchi optimal CW is 11.273 Mbps. Thus, the optimal value of the minimum CW is higher than the Bianchi optimal CW. However, the optimal throughput and the throughput obtained by the Bianchi optimal CW are very close. Similar results are generated for the other WLANs of Network-3 and Network-4. In Table III, the comparison between the optimal value of the minimum CW and the Bianchi optimal CW of the both networks is presented. The comparison between the optimal throughput and the throughput obtained by the Bianchi optimal CW is presented in Table IV. From these tables, it can be observed that the difference between the optimal value of the minimum CW and the Bianchi optimal CW is 4% to 20%. However, the difference between the optimal throughput and the throughput at the Bianchi optimal CW is bounded by 0.5%. Thus, configuration of each WLAN independently with the Bianchi optimal CW provides a near optimal throughput.

TABLE IV
COMPARISON OF THE OPTIMAL THROUGHPUT AND THE THROUGHPUT OBTAINED BY THE BIANCHI OPTIMAL CW

	Network-3			Network-4		
WLAN	λ_O	λ_B	% Diff.	λ_O	λ_B	% Diff
1	11.303	11.273	0.27	11.278	11.277	0.01

5	11.306	11.285	0.19	11.282	11.272	0.09
6	11.292	11.285	0.06	11.281	11.277	0.04
7	11.297	11.285	0.11	11.285	11.277	0.07

IV. CONCLUSIONS

In this paper, the effect of co-channel interference on the optimal configuration of the minimum CWs in IEEE 802.11 based WLANs is studied via simulation. From the simulation results, it is found that the optimal value of the minimum CW is higher than the Bianchi optimal CW due to co-channel interference. However, the difference between the optimal throughput and the throughput at the Bianchi optimal CW is less than 0.5%. As it is very difficult to determine the optimal values of the minimum CWs in WLANs considering co-channel interference, this research advocates to use the simple Bianchi model to configure the minimum CW in each WLAN independently to obtain a very close throughput to the optimal throughput.

***Abstract*—In this paper, the performance of carrier sense multiple access with collision avoidance (CSMA/CA) based multi-user MIMO (MU-MIMO) uplink wireless local area networks (WLANs) is analysed. Analytical models are provided to compute the throughput of each user and the total energy consumption in a WLAN with a single user MIMO (SU-MIMO) technique as well as a MU-MIMO technique. By means of the analytical models, the throughput, fairness and energy consumption performances are studied for several WLAN scenarios. The numerical results show that the MU-MIMO technique provides higher throughput than the SU-MIMO technique only when the number of MIMO communication antennas is high and the medium access parameters of the users are configured properly. Further, the SU-MIMO technique is found to be more energy efficient than the MU-MIMO technique. However, the MU-MIMO technique provides better fairness over the SU-MIMO technique.**

***Index Terms*—Medium access control, wireless local area network, multi-user MIMO, interference, throughput, fairness.**

I. Introduction

Multiple-Input Multiple-Output (MIMO) technology is a wireless technology that uses multiple antennas at transmitter and receiver to transfer multiple data streams at the same time. In the recent years, MIMO transmission schemes have been adopted by many systems to achieve high spectral efficiency [1]-[2]. In these schemes, aggregate data rate can be increased by transmitting several independent data streams simultaneously through different antennas, which is called spatial multiplexing. If multiple data streams are originated from a single transmitter and transmitted to a single receiver then it is called single-user MIMO (SU-MIMO) technique. If a transmitter is allowed to transmit only one data stream by one of its antennas, a set of transmitters can transmit to a particular receiver simultaneously such that the receiver can receive multiple streams using its antennas. Such a technique is known as multi-user (MU-MIMO) [3], [4]. Presently, the researchers in wireless communications are showing tremendous interest to the MU-MIMO technique due to its advantages over the SU-MIMO technique.

Wireless local area networks (WLANs) are widely deployed in most of the counties to provide high speed Internet access to the users. The current WLANs are based on IEEE 802.11 standard and use carrier sense multiple access with collision avoidance (CSMA/CA) medium access control (MAC) protocol [5]. Like the others recent standards, the working group of IEEE 802.11 is also preparing MU-MIMO based physical layer standard IEEE 802.11ac to provide data rate up to 7 Gbps [3].

Throughput, fairness and energy consumption are the most important performance metrics in any wireless network. Throughput is a measure of traffic carrying capacity while fairness measures the fair share of system resources among the users. In a WLAN, a user near the access point (AP) may prevent a user located far away from the AP from achieving sufficient throughput. Moreover, with the rapid and radical evolution of information and communication technology (ICT), the total energy consumption in wireless networks is also growing at a staggering rate. So it is necessary to study the throughput, fairness and energy consumption performances in MU-MIMO based WLANs.

In [6], an analytical model is provided by G. Bianchi to calculate the total throughput in a single-input single-output (SISO) based WLAN. In [3], analytical model of total throughput is provided for a MU-MIMO WLAN and it is shown that the MU-MIMO scheme over performs the SU-MIMO scheme in term of total throughput. To the best of our knowledge, fairness and energy consumption performances of CSMA/CA based MU-MIMO WLANs are not yet studied.

To study the fairness among the users in a WLAN, analytical model to compute the throughput of each user of the WLAN is necessary. In [9], Libin and Jean propose a quasi-reversible distributed CSMA model and provide an explicit throughput formula of each user in SISO based multi-hop wireless networks. To study energy consumption in wireless networks, an analytical model is presented in [11] to predict energy consumption in saturated IEEE 802.11 single-hop ad hoc networks under ideal channel conditions. Analytical models of throughput of each user and the total energy consumption for MU-MIMO based WLANs are necessary to study fairness and energy consumption performances.

In this paper, a CSMA/CA based multi-rate uplink MU-MIMO WLAN with zero forcing (ZF) [7] MIMO decoding is considered. The *physical interference model* based on signal to interference plus noise ratio (SINR) is assumed for the study since it is a more realistic interference model for wireless interference [8]. The contributions in this paper are as follows.

- Analytical models are provided to compute the throughput of each user and the total energy consumption in a CSMA/CA based MU-MIMO WLAN.
- By means of the proposed analytical models, numerical results on throughput, fairness and energy consumption are provided for several WLAN scenarios. From the numerical results, the following engineering insights are obtained: (i) the MU-MIMO technique is beneficial in term of throughput only when the number of MIMO communication antennas is high, (ii) the MU-MIMO technique provides better throughput fairness than the SU-MIMO technique, and (iii) to achieve the same total throughput, the energy consumption in the SU-MIMO technique is significantly lower than that in the MU-MIMO technique.

978-1-4799-4166-7/14/$31.00 ©2014 IEEE

The rest of this paper is organized as follows. In Section II, the system model is described in detail. The throughput and energy consumption models are developed in Section III. In Section IV, numerical results are presented to compare the performance of the SU-MIMO and MU-MIMO techniques. Section V concludes this paper.

II. System Model

A. Network Topology

A WLAN consisting of U stationary users and an AP is considered. The set of users is given as $\mathcal{U} = \{1, 2, ..., U\}$. The transmission power of each user is P_t. The number of antennas at the AP and at each user is considered to be N. The antennas are omni-directional and cannot transmit and receive simultaneously. Only uplink communication is considered, i.e., only the users transmit data to the AP. It is also assumed that all the users are in saturation, i.e., they always have packets to send.

B. MIMO Schemes

1) SU-MIMO: In this scheme, only one user communicates to the AP at a time through its N antennas. The transmitter first encodes the input bits with one encoding block, generates N data streams and transmits through N antennas to the AP. The transmission power at each antenna for each data stream is P_t/N.

2) MU-MIMO: In this scheme, a user transmits using only one of its antennas and the transmission power at the transmitting antenna is P_t. Thus, the AP can successfully retrieve N data streams from N users at a time.

C. Propagation and Interference Model

The channel gain between the user of data stream i and the AP is given by $g_i = \left(\frac{d_i}{d_0}\right)^{-\eta}$; where, d_i is the distance between the user of data stream i and the AP, η is the path loss exponent, and d_0 is a reference distance in the far field of the antenna. Due to its simplicity, ZF MIMO decoding [7] technique is considered at the AP. Let β be the minimum required SINR at the receiver for successful reception of data stream i. It is assumed that the AP knows the channel gains of the desired data streams. According to [4], the data stream i is successful if $\frac{g_i E\left[|s_i|^2\right]}{N_0 + \sum_{j=1}^{J} g_j E[|s_j|^2]} \geq \beta$; where, $E\left[|s_i|^2\right]$ is the transmitted power of the received signal s_i of the data stream i, $g_j E\left[|s_j|^2\right]$ is the interference power at the AP from a undesired data stream j and N_0 is the background noise power.

D. Medium Access Control Protocol

The basic CSMA/CA protocol is considered for MAC operation where all the stations enter a back-off state when the shared channel is sensed busy in a specific distributed inter frame space (DIFS) time. Each station randomly chooses an integer value between 0 and (CW-1) as back-off counter value for a data packet, where CW is the contention window size. The initial value of CW is set to a minimum value CW_{min}. The time is divided into mini-slots after the DIFS period. A station decreases its back-off counter value by one whenever the medium is sensed idle in a mini-slot time. It keeps the back-off counter value unchanged if the medium is sensed busy in a mini-slot. The carrier sensing threshold of the nodes is set to such a value that all the other nodes sense the medium as busy if a node transmits. A station transmits its data stream(s) according to its MIMO scheme when its back-off counter reaches to zero. For simplicity of analysis, it is assumed that a station knows immediately whether its transmitted data stream(s) is successful or not. This assumption is valid since acknowledgement (ACK) packet transmissions by the AP will be always successful. If a packet transmission fails it is retransmitted and hence, the value of CW is chosen according to the binary exponential back-off mechanism of IEEE 802.11 standard [5].

E. Rate Selection for a Data Stream

It is assumed that a user can transmit at R different rates. The set of the rates $\mathcal{R}$ is given by $\mathcal{R} = \{r_1, r_2, ..., r_R\}$. The set of the required SINRs for the available data rates is given by $\mathcal{B} = \{\beta_1, \beta_2, ..., \beta_R\}$, where β_j is the SINR threshold for rate r_j. It is assumed that a user selects the highest possible rate for a data stream based on the signal to noise ratio (SNR) of the data stream at the AP, i.e., the rate of a data stream i is r_j if $\beta_j \leq \frac{g_i E\left[|s_i|^2\right]}{N_0} \leq \beta_{j+1}$. The transmission times of the data packets of each user are considered to be equal to L mini-slots regardless the data transmission rate.

III. Models for Throughput and Energy Consumption

A. Discrete Time Markov Chain Model of the CSMA/CA MAC Protocol

In the CSMA/CA MAC protocol, time is divided into equal length mini-slots or states where transition from one state to another state forms a discrete time Markov chain (DTMC). The steady state probability of transmission of each user in a mini-slot is considered as τ if the medium is idle. The relation between the steady state probability τ and CW_{min} can be approximated as $\tau = \frac{2}{CW_{min}}$ [6]. A state w of the CSMA/CA system can be expressed as $w := \{v, l_k \quad \forall k \in v\}$, where, v is the set of transmitting users and $l_k \in \{1, 2, 3, \ldots, L\}$ is the slot number of the transmitting data stream(s) of user k. The stationary distribution of a state w can be obtained as [9]

$$p(w) = \frac{1}{E}\tau^{|v|}(1-\tau)^{U-|v|} \tag{1}$$

where, $|v|$ is the cardinality of set v and E is the normalizing term given by $\sum_w p(w) = 1$.

The null set of v is denoted by ϕ. Due to carrier sensing mechanism of the CSMA/CA protocol, a set of users will start their transmissions simultaneously and end the transmissions at the same time. Since there are L states for a packet transmission and the probability in each state is equal, the fraction of time that the users of set v, $v \neq \phi$ transmit simultaneously is given by

$$\pi(v) = \frac{L\tau^{|v|}\left(1-\tau\right)^{U-|v|}}{E}. \tag{2}$$

Note that $\pi(\phi) = \frac{(1-\tau)^U}{E}$. Let $\mathcal{I}$ be the possible sets of v in the WLAN including the null set ϕ. The normalizing term E can be obtained as $E = L\sum_{v\in\mathcal{I}\setminus\phi}\tau^{|v|}\left(1-\tau\right)^{U-|v|} + \left(1-\tau\right)^U$. Since $\sum_{v\in\mathcal{I}}\tau^{|v|}\left(1-\tau\right)^{U-|v|} = 1$, E can be obtained as

$$E = L - (L-1)(1-\tau)^U. \tag{3}$$

B. Throughput Model
