We have presented an effective and efficient approach of compressing short English text message for low-powered embedded devices. Here we have employed modified syllable based dictionary matching and static coding to obtain the compression, which two was not previously adapted in the same model. Moreover, we have used a new theoretical concept of choosing the multi-grams, which has facilitated us to obtain mentionable compression ratio using a small number of knowledgebase entries than other methods consuming less resource. The overall strategy of computational simplicity has also ensured the reduced time complexity for the proposed compression and decompression process. The main aspect of our proposed scheme resides is the text ranking based knowledge-base construction with space integration that initiates a new arena of text compression methodology. A consistent and relevant mathematical analysis of the overall performance also establishes a strong technical basis of the proposed scheme. Moreover, the prime achievement is in the scale of starting threshold of text compression; that we have reduced to less than five characters. With limited knowledge-base size, the achieved compression is of no doubt efficient and effective. As the knowledge base is not accepted to be grown through the continuous applications, we may keep out the low-memory system from the risk of expanding its knowledgebase crossing optimal memory size and thus, the applicability of the proposed system even in any very low memory devices is ensured.

**Abstract**—A convex polyhedron  $P$  is  $k$ -equiprojective if for all of its orthogonal projections, except those parallel to the faces of  $P$ , the number of vertices in the shadow boundary is  $k$ . Finding an algorithm to construct all equiprojective polyhedra is an open problem first posed in 1968. In this paper we give lower bounds on the value of  $k$  and the size of an equiprojective polyhedron. We prove that there is no 3- or 4-equiprojective polyhedra and a triangular prism is the only 5-equiprojective polyhedron. We also discover some new equiprojective polyhedra.

**Keywords:** Algorithm, equiprojective polyhedra, Johnson solid, lower bound, orthogonal projection

## I. INTRODUCTION

The problem of constructing new polyhedra based on certain mathematical properties has been extensively studied since antiquity in the fields of architecture, art, ornament, nature, cartography, and even in philosophy and literature. (See the book [3] and the web page [6] for some interesting discussions on the history of discovering new polyhedra.) Regularity of faces, edges and vertices, and symmetry are some popular criteria for constructing new polyhedra. For example, in a platonic solid (platonic solids are the most primitive convex polyhedra) each vertex is incident to the same number of identical regular faces [3], [6].

A convex polyhedron  $P$  is  $k$ -equiprojective if its shadow (i.e., the boundary of orthogonal projection) is a  $k$ -gon in every direction, except directions parallel to faces of  $P$ . A cube is 6-equiprojective, a triangular prism is 5-equiprojective (in fact, any  $n$ -gonal prism is  $(n+2)$ -equiprojective [10], [11]), and a tetrahedron is not equiprojective. See Figure 1. In 1968, in a paper [13] entitled, “Twenty problems on convex polyhedra,” Shephard defined equiprojective polyhedra, gave the examples above, and asked for a method to construct all equiprojective polyhedra. Later, Croft, Falconer, and Guy included this problem in their book “Unsolved Problems in Geometry” [2].

So far little progress has been made in this problem. Hasan and Lubiw [10], [11] gave a new characterization and an  $O(n \log n)$  time recognition algorithm for equiprojective polyhedra. Their characterization shows that the class of equiprojective polyhedra is rich. For example, zonohedra, which is an infinite class of convex polyhedra, are equiprojective [10], [11].

Fig. 1. (a) Some equiprojective polyhedra, and (b) a non-equiprojective polyhedron.

Rahman *et. al.* [12] also proposed some new non-trivial equiprojective polyhedra, which they achieved by cutting and gluing some existing convex polyhedra. In other related work, Hasan, in his PhD thesis [7], extended the idea of equiprojectivity from the number of vertices in the shadow to the number of visible faces, visible edges, and visible vertices in the projection. However, the original problem of constructing all equiprojective polyhedra still remains open.

In this paper we further explore the class of equiprojective polyhedra. As a lower bound on smallest equiprojective polyhedra, we prove that there is no 3- or 4-equiprojective polyhedra and a triangular prism is the only 5-equiprojective polyhedron (Section 3). We also discover some new equiprojective polyhedra by cutting some existing polyhedra (Section 4). Most of our newly discovered equiprojective polyhedra are non-trivial and to our knowledge, none of them has been discovered before as an equiprojective polyhedron.

## II. PRELIMINARIES

For rest of the paper by polyhedra we mean convex polyhedra and by projection (shadow) of a polyhedron we mean its non-degenerate orthogonal projection (shadow) (i.e., the projection direction is not parallel to any face).

The idea of characterization of an equiprojective polyhedron  $P$  is based on partitioning the edge-face pairs of  $P$  into “compensating pairs” [10], [11]. Any edge  $e$  of the shadow of  $P$  corresponds to some edge of  $P$ . As the projection direction changes,  $e$  may leave the shadow boundary. This only happens when a face  $f$  containing  $e$  in  $P$  becomes parallel to the projection direction. In order to preserve the size of the shadow, some other edge  $e'$  must join the shadow boundary. In

order for these events to occur simultaneously,  $e'$  must be an edge of  $f$ , or of a face  $f'$  parallel to  $f$ , and  $e$  and  $e'$  work as compensating each other during the change in the shadow boundary due to  $f$  and  $f'$ . For all such changes in the shadow boundary of  $P$ , each edge in each face, that means each edge-face pair, must be compensated by another edge-face pair.

More precisely, for edge  $e$  in face  $f$ , we call  $(e, f)$  an *edge-side*. Two edge-sides  $(e, f)$  and  $(e', f')$  are *parallel* if  $e$  is parallel to  $e'$  and  $f$  is parallel or equal to  $f'$ . Since in a convex polyhedron, a face can have at most one parallel face, an edge-side has at most three parallel edge-sides. The *direction* of edge-side  $(e, f)$  is the unit vector in the direction of edge  $e$  as encountered in a clockwise traversal of the outside of face  $f$ . Edge-sides  $(e, f)$  and  $(e', f')$  *compensate* each other if they are parallel and their directions are opposite (i.e. one is the negation of the other). In particular, this means that either  $f = f'$  and  $e$  and  $e'$  are parallel edges of  $f$ , or  $f$  and  $f'$  are distinct parallel faces and  $e$  and  $e'$  are parallel edges lying at the “same end” of  $f$  and  $f'$ , where “same end” means a plane through  $e$  and  $e'$  put  $f$  and  $f'$  in the same half space. Note that an edge-side has at most two compensating edge-sides, one within the same face and the other one in the parallel face. When the edges of a face  $f$  are in parallel pairs, they are compensated within  $f$  and in that case  $f$  is called a *self-compensating* face. See Figure 2(a).

**Theorem 1:** [10], [11]  $P$  is equiprojective iff its set of edge-sides can be partitioned into compensating pairs.

Consider a direction  $d$  in the plane of a face  $f$  of  $P$  and its parallel face  $f'$  (if  $f'$  exists) but not in the plane of any other face. While looking from  $d$  the edges of  $f$  are partitioned into two chains, one is visible and the other one is invisible from  $d$ . We call these two chains *lower chain* and *upper chain* of  $f$  and denote them by  $L_d(f)$  and  $U_d(f)$  respectively. Similarly, let  $L_d(f')$  and  $U_d(f')$  be the lower and upper chains of  $f'$  (if it exists) from  $d$ . Let  $\varepsilon$  be a small vector normal to the face  $f$ . Consider the directions  $d + \varepsilon$  and  $d - \varepsilon$ . Choose  $\varepsilon$  small enough such that the above two directions make  $f$  (similarly  $f'$ , if it exists) invisible (visible) and visible (invisible), respectively, and does not change the visibility status of any other face. That means between  $d + \varepsilon$  and  $d - \varepsilon$  the change in the shadow boundary is due to  $f$  and  $f'$  only, and from  $d + \varepsilon$  (similarly from  $d - \varepsilon$ ) the edges of  $f$  and  $f'$  that are in the shadow of  $P$  are  $U_d(f)$  and  $L_d(f')$  (similarly  $L_d(f)$  and  $U_d(f')$ ) respectively. See Figure 2(b) that illustrates the above facts by showing for face  $f$  only. So, the following lemma is obvious.

**Lemma 1:** Assuming both  $L_d(f')$  and  $U_d(f')$  are empty if  $f'$  does not exist, the edges in  $U_d(f) \cup L_d(f')$  have compensating pairs in  $U_d(f') \cup L_d(f)$ .

### III. MINIMALITY

One important subclass of equiprojective polyhedra are *zonohedra*. (There exist more than one definition of zonohedra [1], [4], [5] and we consider the original and “generalized” definition [14] of it). A zonohedron is a convex polyhedron whose edges in each face are in parallel pairs (i.e., each face is self-compensating). A zonohedron has the property that its faces are in parallel pairs with corresponding edges parallel [11], [14].

An *n-gonal prism* is a convex polyhedron with two parallel copies of a convex  $n$ -gon with each pair of corresponding vertices connected by an edge. For an  $n$ -gonal prism, edges in one  $n$ -gonal face are compensated by their parallel pairs in the other  $n$ -gonal face and all other faces are parallelograms (and thus self-compensating). Thus all prisms are equiprojective.

Observe that both a zonohedron and a prism have at least one pair of parallel faces. In fact, in the following lemma we prove that this is true for any equiprojective polyhedron.

**Lemma 2:** Let  $P$  be an equiprojective polyhedron. Then  $P$  has at least one pair of parallel faces.

*Proof:* By way of contradiction assume that  $P$  has no parallel faces. Since  $P$  is equiprojective, by Theorem 1 all of its edge-sides are partitioned into compensating pairs. By definition, an edge-side can be compensated by another one within the same face or in the parallel face. So in  $P$  each edge-side is compensated within the same face, which implies that all faces of  $P$  are self-compensating, further implying that  $P$  is a zonohedron. But the faces of a zonohedron are also in parallel pairs, a contradiction. ■

By Lemma 2, let  $f$  and  $f'$  be two parallel faces of  $P$ .

**Lemma 3:** From direction  $d + \varepsilon$  (similarly from  $d - \varepsilon$ ), in the shadow boundary of  $P$ ,  $U_d(f)$  and  $L_d(f')$  (similarly  $U_d(f')$  and  $L_d(f)$ ) are disjoint.

*Proof:* We prove this for  $U_d(f)$  and  $L_d(f')$ . Proof for the other pair is analogous.

Observe that in a convex polyhedron, two parallel faces are vertex disjoint. So,  $f$  and  $f'$ , as well as  $U_d(f)$  and  $L_d(f')$ , are disjoint in  $P$ . Now we will prove that the disjointness of  $U_d(f)$  and  $L_d(f')$  in  $P$  implies their disjointness in the shadow boundary of  $P$ . Remember that  $P$  is convex and that we only consider its non-degenerate orthogonal projections. It implies that an edge and a vertex in the shadow boundary of  $P$  correspond exactly to an edge and a vertex of  $P$  respectively. (In the contrary, if  $P$  is non-convex and/or the projection of  $P$  is a degenerate one, then a vertex in the shadow boundary of  $P$  could represent an edge, a crossing of two edges, overlapping of two vertices, etc. of  $P$  and similarly, an edge in the shadow boundary could represent a face of  $P$ ). Thus  $U_d(f)$  and  $L_d(f')$  do not overlap or cross each other in the shadow boundary of  $P$ . ■

Fig. 2. (a) Examples of some compensating edge-sides.  $(e_1, f_1)$  is compensated by  $(e_2, f_1)$  and by  $(e_4, f_2)$  but not by  $(e_3, f_2)$ . Face  $f_3$  is self-compensating. (b) Illustration of  $U_d(f)$  and  $L_d(f)$ : (i,ii) Face  $f$  lies in the  $x$ - $z$  plane and  $d$  is in the  $z$  direction;  $U_d(f)$  is the chain  $k, p, o, n$ , and  $L_d(f)$  is the chain  $k, l, m, n$ . Vector  $\varepsilon$  is in the  $y$  direction. (iii, iv) From  $d + \varepsilon$  and  $d - \varepsilon$ , edges of  $f$  that are in the shadow of  $P$  are  $U_d(f)$   $L_d(f)$  respectively.

**Corollary 1:** Both  $U_d(f) \cup L_d(f')$  and  $U_d(f') \cup L_d(f)$  have at least three edges.

*Proof:* Both  $f$  and  $f'$  are at least triangles. We know that  $U_d(f) \cup L_d(f) = f$  and  $U_d(f') \cup L_d(f') = f'$ . By Lemma 3,  $U_d(f)$  and  $L_d(f')$  are disjoint and  $U_d(f')$  and  $L_d(f)$  are disjoint. By Lemma 1,  $U_d(f) \cup L_d(f') = U_d(f') \cup L_d(f)$ . So the lemma holds. ■

**Theorem 2:**  $P$  is  $k$ -equiprojective for  $k \geq 5$ .

*Proof:* Consider the projection of  $P$  from direction  $d + \varepsilon$ . By Corollary 1,  $U_d(f) \cup L_d(f')$  has at least three edges. Since by Lemma 3,  $U_d(f)$  and  $L_d(f)$  are disjoint in the shadow boundary of  $P$ , there are at least two edges in the shadow boundary that are not the edges of  $U_d(f)$  or  $L_d(f)$ . So the size of the shadow boundary is at least five. Finally, since  $P$  is equiprojective, it holds for any other direction. ■

**Corollary 2:** If  $P$  is 5-equiprojective, then  $f$  and  $f'$  are triangles.

**Theorem 3:** A triangular prism is the only 5-equiprojective polyhedron.

*Proof:* Let  $P$  be 5-equiprojective. By Corollary 2, two parallel faces  $f$  and  $f'$  of  $P$  are triangles. We first show that  $P$  has no vertex other than the six in  $f$  and  $f'$ . By way of contradiction if  $P$  has an extra vertex  $v$ , then there must be a direction  $d$  in the plane of  $f$  and  $f'$  and not in the plane of any other face such that  $v$  is in the shadow boundary (see Figure 3(a)). Then projections from  $d + \varepsilon$  and  $d - \varepsilon$  have at least six vertices each in the shadow boundary: at least five from  $f$  and  $f'$  (by Lemma 3 and Corollary 1) and  $v$ . See Figure 3(b). This leads to a contradiction that  $P$  is 5-equiprojective.

So the remaining faces of  $P$ , let their set be  $F$ , are formed by the vertices of  $f$  and  $f'$ . We now show that  $F$  has exactly three parallelograms which form a triangular prism with  $f$  and  $f'$ . Let the counter-clockwise vertex-edge sequences of  $f$  (from

outside of  $f$ ) be  $v_1, e_1, v_2, e_2, v_3, e_3$  and the clockwise vertex-edge sequences of  $f'$  (from outside of  $f'$ ) be  $v'_1, e'_1, v'_2, e'_2, v'_3, e'_3$ . So  $e_1, e_2, e_3$  in  $f$  are compensated by  $e'_1, e'_2, e'_3$  in  $f'$  respectively. See Figure 3(c). For any  $i = 1, 2, 3$ , if  $e_i$  is an edge of a face  $g \in F$ , then  $v'_{i+2}$  can not be a vertex of  $g$ , otherwise it would violate the convexity of  $P$ . Now, if  $v'_i$  is a vertex of  $g$ , then  $v'_{i+1}$  must also be a vertex of it, since  $e_i, v'_i, v'_{i+1}$  are coplanar and thus must form a single face of  $P$ . Moreover, no other vertex of  $P$  is coplanar with  $e_i, v'_i, v'_{i+1}$ . Therefore, in summary,  $F$  has only three faces  $f_i$ , for  $i = 1, 2, 3$ , where  $f_i$  has exactly four edges  $e_i, e'_i, (v_i, v'_i), (v_{i+1}, v'_{i+1})$ . Now it is obvious that none of  $f_i$ 's has a parallel pair. Since  $P$  is equiprojective,  $f_i$  must be self compensating. Since  $e_i$  and  $e'_i$  are parallel,  $(v_i, v'_i)$  must be parallel to  $(v_{i+1}, v'_{i+1})$ , which makes  $f_i$  a parallelogram. Therefore,  $P$  is nothing but a triangular prism. ■

#### IV. NEW EQUIPROJECTIVE POLYHEDRA

In this section we obtain four new equiprojective polyhedra from a tetrahedron, a quadrilateral pyramid, a triangular cupola (the third Johnson solid) and a pentagonal rotunda (the sixth Johnson solid), respectively, by cutting them suitably. *Johnson solids* are convex polyhedra with regular faces. We describe our new equiprojective polyhedra as equitruncated tetrahedra, equitruncated pyramid, equitruncated triangular cupola, and equitruncated pentagonal rotunda respectively. For the proof of their equiprojectivity we only give the sketch, rigorous proofs can be found in [8]. We have also implemented these new polyhedra in VRML and their code can be found in [9].

Fig. 3. (a) Projection when  $d$  is in the plane of  $f$  and  $f'$  only. (b) Projections from  $d + \varepsilon$  and  $d - \varepsilon$  have at least six vertices each in the shadow boundary (shown in filled circles). (c) Vertex-edge sequence of  $f$  and  $f'$ .

Fig. 4. (a) An equitruncated tetrahedron obtained from a tetrahedron. (b) An equitruncated pyramid obtained from a pyramid.

#### A. Equitruncated tetrahedra

A *cut* to a polyhedron  $P$  we mean a plane that cuts  $P$  into two pieces. By a cut  $C$  through a line  $l$  or a point  $p$  denotes a plane  $C$  which contains  $l$  or  $p$ .

An *equitruncated tetrahedron*  $P$  is obtained by cutting an arbitrary tetrahedron  $P'$ , i.e.,  $P'$  may not be regular. Two types of cuts are applied here. See Figure 4(a). The *top cut* is parallel to the base and cuts the apex into a triangle. All the remaining six *side cuts* are pairwise similar and are defined as follows. Let the apex of  $P'$  be  $o$  and let the three edges adjacent to  $o$  be  $a, b$  and  $c$ . Take three points  $p_a, p_b, p_c$  on  $a, b, c$  and imagine three parallel lines  $l_a, l_b, l_c$  through  $p_a, p_b, p_c$  such that the lines properly intersect the base (e.g., they are perpendicular to the base). Take a pair of parallel side cuts through  $l_a$  and  $l_b$  such that they are parallel to  $c$ . Similarly, take two other parallel pairs of side cuts, where one pair is through  $l_a$  and  $l_c$  and is parallel to  $b$  and the other pair is through  $l_b$  and  $l_c$  and is parallel to  $a$ . That ends the construction of  $P$ . See Figure 4(a).

**Theorem 4:** An equitruncated tetrahedron is 10-equiprojective.

*Proof:* Edges in the top triangle of  $P$  are compensated by the three (old) edges of the base. Each pair of parallel cuts creates a pair of parallel triangles with corresponding edges compensating each other. Six (new) edges of the base are themselves in parallel pairs and thus compensate each other within the base. The remain-

ing three hexagonal faces are self-compensating. By Theorem 1,  $P$  is equiprojective. Finally, the projection of  $P$  in Figure 4(a) shows that it is 10-equiprojective. ■

#### B. Equitruncated pyramid

An *equitruncated pyramid*  $P$  is obtained by cutting an arbitrary quadrilateral pyramid  $P'$ . Again, two types of cuts are applied here. See Figure 4(b). The *top cut* is parallel to the base and creates a quadrilateral at the top. For all the *side cuts*, consider the four edges that are incident to the apex of  $P$ . These four edges can be partitioned into two paths  $\mathcal{P}_1$  and  $\mathcal{P}_2$  where each path  $\mathcal{P}_i$ , for  $i = 1, 2$ , contains two edges from two different faces. Observe that the two edges of  $\mathcal{P}_i$  are coplanar and let this plane be  $\pi_i$ . For each  $i$ , apply two side cuts at the two ends of  $\mathcal{P}_i$  such that they are parallel to  $\pi_{i+1}$ . This ends the construction of  $P$ . See Figure 4(b). We get the following theorem whose proof is similar to the previous one and we omit it here.

**Theorem 5:** An equitruncated pyramid is 10-equiprojective.

#### C. Equitruncated triangular cupola

We obtain an *equitruncated triangular cupola*  $P$  from a triangular cupola  $P'$ . Before we go to the actual construction we review some properties of  $P'$ . See Figure 5(a) for two complementary views of  $P'$ . Beside the regularity of its faces (being a Johnson solid), we observe that the edges of  $P$  that are not edges of the hexagonal base can be partitioned into three similar paths, where each path contains three edges including one from the top triangle. Moreover, edges in each path are coplanar and their plane is parallel with one of the three triangles that are adjacent to the base. See Figure 5(b).

To construct  $P$  we use four different cuts *cut1*, *cut2*, *cut3*, and *cut4*. See Figure 5(b). Let  $\mathcal{P}_1, \mathcal{P}_2, \mathcal{P}_3$  be the three paths of  $P'$  (as mentioned above). Let  $t_1, t_2, t_3$  be three triangles adjacent to the base of  $P'$  with  $t_i$ , for  $i = 1, 2, 3$ , parallel to the plane of  $\mathcal{P}_i$ . *cut1* is parallel to  $t_1$ , cuts two end edges of  $\mathcal{P}_2$  and  $\mathcal{P}_3$ , and creates a quadrilateral  $q_1$  with two edges parallel. Next, a parallel pair of *cut2*, which are perpendicular to the base and the plane of  $t_1$ , are applied to the two end edges of  $\mathcal{P}_1$ . These two cuts create two parallel triangles

Fig. 5. (a) A triangular cupola  $P'$ . A path is shown in bold. (b) The four cuts applied to  $P'$ . (c) The equitruncated triangular cupola obtained from  $P'$ .

$t_4$  and  $t_5$ . Cut3, which is parallel to the base and the top triangle, is applied at the top and converts the top triangle into a hexagonal face. Next, a cut4 is applied to the common vertex of  $\mathcal{P}_2$  and  $\mathcal{P}_3$ , let this vertex be  $v$ , such that it creates a rectangle. Observe that since the faces around  $v$  are equilateral triangles and squares in alternate fashion and since cut3 is parallel to the top triangle, such a rectangle is guaranteed by the cut4. Cut4 also converts the triangle  $t_1$  into a quadrilateral  $q_2$  with two edges parallel.

**Theorem 6:** An equitruncated triangular cupola is 11-equiprojective.

*Proof:* In  $P$ , all faces, except the triangles  $t_4$  and  $t_5$  and the quadrilaterals  $q_1$  and  $q_2$ , are self-compensating. Edges of  $t_4$  are compensated by the edges of  $t_5$ . In each of  $q_1$  and  $q_2$ , two edges are parallel and thus compensate each other within the same face. The remaining two edges of  $q_1$  are compensated by the remaining two edges of  $q_2$ . Finally, from Figure 5,  $P$  is 11-equiprojective. ■

#### D. Equitruncated pentagonal rotunda

In this section we get two different *equitruncated pentagonal rotunda*  $P_1$  and  $P_2$ , each one from a pentagonal rotunda  $P'$ . Their construction are similar to that of an equitruncated triangular cupola. As before, let us first study some properties of  $P'$ . Figure 6(a) shows two opposite views of  $P'$ . Its base is a regular decagon and its other edges are partitioned into five paths, each of length five and each containing one edge from the top pentagon. Each path lie in a single plane. Let  $e_1, \dots, e_5$  be the ordering of the edges of the top pentagon. We denote the paths as  $\mathcal{P}_1, \dots, \mathcal{P}_5$  assuming that  $\mathcal{P}_i$  contains  $e_i$ . We call two paths  $\mathcal{P}_i$  and  $\mathcal{P}_j$  *non-adjacent* if  $e_i$  and  $e_j$  are nonadjacent. See Figure 6(b).

To construct the first equitruncated pentagonal rotunda  $P_1$ , three types of cuts are used: *cut1*, *cut2*, and *cut3*. See Figure 6(b). A cut4 is applied at each vertex of  $P'$  that is not incident to the base of  $P'$  and it is applied in such a way that it creates a rectangle. Let  $e_1$  and  $e_2$  be two parallel edges of the base decagon. The other two faces adjacent to  $e_1$  and  $e_2$  are a pentagon and a triangle, and let them be  $p$  and  $t$  respectively. A pair

of cut2 and cut3 are applied simultaneously. The cut2 is parallel to  $p$ , cuts  $t$ , and creates a new quadrilateral  $q_1$ . On the other hand, the cut3 is parallel to  $t$ , cuts  $p$ , and creates a new quadrilateral  $q_2$ . This pair of cut2 and cut3 cut the (four) end edges of two non-adjacent paths, and let them be  $\mathcal{P}_1$  and  $\mathcal{P}_3$ . We apply another pair of a cut2 and a cut3 such that they cut the end edges of  $\mathcal{P}_2$  and  $\mathcal{P}_4$ . Finally, a pair of cut1, which are perpendicular to the base and the plane of  $\mathcal{P}_5$ , are applied to the two end edges of  $\mathcal{P}_5$  and create two parallel triangles.

The second equitruncated pentagonal rotunda  $P_2$  is obtained similar to  $P_1$ , except by replacing the second pair of cut2 and cut3 by two parallel pairs of cut1 at the ends of  $\mathcal{P}_2$  and  $\mathcal{P}_3$ , which create two pairs of parallel triangles.

**Theorem 7:** The above two equitruncated pentagonal rotunda are 21- and 23-equiprojective respectively.

*Proof:* Let the two quadrilaterals created by the second pair of cut2 and cut3 be  $q'_1$  and  $q'_2$ , and let the second pair of pentagon and triangles parallel to them be  $p'$  and  $t'$  respectively. For  $P_1$ , all faces except  $p, t, p', t', q_1, q_2, q'_1$  and  $q'_2$  are self-compensating. For each of  $p, p', t$  and  $t'$ , two edges are compensated by two edges of  $q_1, q'_1, q_2$  and  $q'_2$ , respectively. All other edges of  $p, p', t, t', q_1, q'_1, q_2$  and  $q'_2$  are compensated within the same face. Proof for  $P_2$  is similar.

For the equiprojectivity of  $P_1$  to be 21, consider the direction  $d + \varepsilon$ , where  $d$  is perpendicular to the base and does not see the base and  $\varepsilon$  is perpendicular to  $t_1$ . Then for  $\varepsilon$  small enough, the projection boundary of  $P_1$  from  $d + \varepsilon$  consists of six edges from  $q_1, q_2$ , another six edges from  $q'_1, q'_2$ , two edges from  $t_2$  and seven edges from the base.

For  $P_2$ , two pairs of parallel triangles replaces  $q'_1, q'_2$ . As a whole  $P_2$  has three parallel pairs of triangles adjacent to the base. So for a projection of  $P_2$  from a direction  $d + \varepsilon + \varepsilon' + \varepsilon''$ , where  $\varepsilon, \varepsilon', \varepsilon''$  are perpendicular to the three planes of the triangles, respectively, the projection boundary consists of six edges from  $q_1, q_2$ , six edges from the triangles, and eleven edges from the base. ■

At this moment an interesting observation is that if

Fig. 6. Obtaining an equitruncated pentagonal rotunda  $P_1$  from a pentagonal rotunda  $P'$ . (a) Two opposite views of  $P'$ . (b) Cuts used in  $P'$  to obtain  $P_1$ . (c) Two complementary views of  $P_1$ .

we apply five pairs of cut1 at the ends of five paths (and thus no cut2 or cut3), then we get a polyhedron which is the half of the *truncated icosahedron*. This polyhedron is a zonohedron and is 25— equiprojective.

## V. CONCLUSION

In this paper we give lower bounds on the value of  $k$  and the size of an  $k$ -equiprojective polyhedron. We prove that there is no 3- or 4-equiprojective polyhedra and a triangular prism is the only 5-equiprojective polyhedron. We also discover some new equiprojective polyhedra.

The problem of constructing all equiprojective polyhedra still remains open. However, we observe that our concept of partitioning the non-base edges into disjoint paths is somewhat similar for all the new equiprojective polyhedra, which might be helpful for deriving a generalized algorithm for constructing equiprojective polyhedra.

## ACKNOWLEDGMENT

We thank Therese Biedl for discussions on the minimality proofs. We thank Anna Lubiw and Craig Kaplan for numerous discussions.

**Abstract** — Rahman and Kaykobad introduced a shortest distance based condition for finding the existence of Hamiltonian paths in graphs as follows: Let  $G$  be a connected graph with  $n$  vertices, and if  $d(u) + d(v) + \delta(u, v) \geq n + 1$ , for each pair of distinct non-adjacent vertices  $u$  and  $v$  in  $G$ , where  $\delta(u, v)$  is the length of a shortest path between  $u$  and  $v$ , then  $G$  has Hamiltonian path. Rao Li proved that under the same condition, the graph is Hamiltonian or belongs to two different classes of graphs. Recently, Mehedy, Hasan and Kaykobad showed case by case that under the condition of Rahman and Kaykobad, the graph is Hamiltonian with exceptions for  $\delta(u, v) = 2$ . Shengjia Li et. al. mentions a graph to be Hamiltonian whenever  $d(u) + d(v) \geq n - 1$ , for all  $\delta(u, v) = 2$ , otherwise  $n$  is odd and the graph falls into a special class. This paper relates the results of Mehedy, Hasan and Kaykobad with the two exceptional classes of graphs introduced by Rao Li and the graph class introduced by Shengjia Li et. al. The paper also provides a thorough analysis of the graph classes and shows the characteristics of a graph when it falls into one of those classes.

**Index Terms** — Hamiltonian cycle, Hamiltonian path, Graphs.

## I. INTRODUCTION

We consider only simple undirected graphs- graphs that do not contain loops or multiple edges. A Hamiltonian cycle is a closed path passing through every vertex of a graph. A graph containing a Hamiltonian cycle is said to be simply Hamiltonian. By Hamiltonicity we mean the virtue of a graph to be Hamiltonian. Naturally every Hamiltonian graph contains a Hamiltonian path and not necessarily vice versa. We define  $\delta(u, v)$  as the shortest distance between  $u$  and  $v$ ,  $K_p$  as the complete graph with  $p$  vertices,  $K_p^c$  complement of  $K_p$  (a set of  $p$  independent vertices),  $K_{p,q}$  as complete bipartite graph with  $p + q$

vertices. ‘ $\vee$ ’ denotes join operator. We term the condition: “ $d(u) + d(v) + \delta(u, v) \geq n + 1$ , where  $|V| = n$  and  $u, v$  are distinct non-adjacent vertices of  $G$ ”, as Rahman and Kaykobad condition.

We also describe three families of graph  $C_n$ ,  $D_n$  and  $L_n$ , defined in [4],[4],[5] respectively.

$C_n$  is defined as  $\{G : V(G) = V(K_1) \cup V(G_1) \cup V(G_2), E(G) = E(G_1) \cup E(G_2) \cup \{ab : a \in V(K_1) \text{ and } b \in V(K_{p_1}) \cup V(K_{p_2})\}\}$ , where  $K_1$  consisting of one single vertex,  $G_1 = K_{p_1} \vee K_{q_1}$  is a complete graph with  $p_1 + q_1$  vertices such that  $p_1 \geq 1$  and  $q_1 \geq 0$ ,  $G_2 = K_{p_2} \vee K_{q_2}$  is a complete graph with  $p_2 + q_2$  vertices such that  $p_2 \geq 1$  and  $q_2 \geq 0$  and  $V(K_1), V(G_1)$  and  $V(G_2)$  are pair wise disjoint

$D_n$  is defined as  $\{G : K_{p,p+1} \subseteq G \subseteq K_p \vee (p+1)K_1\}$ , where  $|V(G)| = 2p+1 \geq 3$ , where  $(p+1)K_1$  denotes  $(p+1)$  isolated vertices.

$L_n$  is defined as  $L_n = L_{2m+1} = \{Z_m \vee (K_m^c + \{u\}) \mid Z_m \text{ is a graph with } m \text{ vertices}\}$ , where  $K_m^c$  is a set of  $m$  independent vertices (also as the complement of the complete graph  $K_m$ ) and  $u$  is another single vertex, furthermore, the edge set of  $L_n$  consists of  $E(Z_m)$  and  $xy \mid x \in V(Z_m) \text{ and } y \in K_m^c \cup \{u\}$

It is to be noted that  $D_n$  and  $L_n$  are actually the same class of graphs with different names. We adapt the notation  $D_n$  in our results to represent both the classes.

## II. EXISTING RESULTS

To prove our results, we need some existing theorems. We list them in this section for the same of completeness of this article.

**Theorem 1.1** (Rahman and Kaykobad [3]). *Let  $G = (V, E)$  be a connected graph with  $n$  vertices such that for all pairs of distinct non-adjacent vertices  $u, v \in V$ , we have  $d(u) + d(v) + \delta(u, v) \geq n + 1$ . Then  $G$  has a Hamiltonian path.*

**Theorem 1.2** (Rao Li [4]). *Let  $G = (V, E)$  be a connected graph with  $n$  vertices. If  $d(u) + d(v) + \delta(u, v) \geq n + 1$  for each pair of distinct non-adjacent vertices  $u, v \in V$ , then  $G$  is Hamiltonian or  $G \in C_n \cup D_n$ .*

**Theorem 1.3** (Mehedy, Hasan, and Kaykobad [1]). *Let  $G = (V, E)$  be a 2-connected graph with  $n$  vertices such that for all pairs of distinct non-adjacent vertices  $u, v \in V$  we have  $d(u) + d(v) + \delta(u, v) \geq n + 1$  then*

- i)  $\delta(u, v) \leq 3$ , for all  $u, v \in V$
- ii) If for any  $u, v \in V$   $\delta(u, v) = 3$ ,  $G$  is Hamiltonian
- iii) If  $\delta(u, v) = 2$  for all non-adjacent vertices,  $G$  may or may not be Hamiltonian. To make the graph Hamiltonian, it needs only one extra edge added to the graph.

Theorem 1.3 is cumulative results of the work [1], to help our analysis.

**Theorem 1.4** (Shengjia Li et. al.[5]). *Let  $G$  be a 2-connected graph with  $n \geq 3$  vertices. If  $d(u) + d(v) \geq n - 1$  for every pair of vertices  $u$  and  $v$  with  $d(u, v) = 2$ , then  $G$  is Hamiltonian, unless  $n$  is odd and  $G \in L_n$ .*

**Theorem 1.5** (Ore [2]). *If  $d(u) + d(v) \geq n$  for every pair of distinct non-adjacent vertices  $u$  and  $v$  of  $G$ , then  $G$  is Hamiltonian.*

We take Theorem 1.3 as the base and fulfill the missing results in the theorem by using other theorems above. We also provide a through analysis of the graph classes and show the characteristics of a graph when it falls into one of those classes.

## III. MAIN RESULTS

This paper relates the results of Mehedy, Hasan and Kaykobad [1] with the two exceptional classes of graphs introduced by Rao Li [4] and the graph class introduced by Shengjia Li et. al. [5] and brings the results of all three works under Rahman and Kaykobad condition. We analyze when a graph falls in the two classes  $C_n$  and  $D_n$  and what the characteristics of a graph instance are. We provide a unified theorem as follows:

**Theorem 2.1.** *Let  $G = (V, E)$  be a **connected** graph with  $n$  vertices such that for all pairs of distinct non-adjacent vertices  $u, v \in V$  we have  $d(u) + d(v) + \delta(u, v) \geq n + 1$  then*

- i)  $\delta(u, v) \leq 4$ , for all  $u, v \in V$
- ii) If there are vertices  $u, v \in V$  with  $\delta(u, v) = 4$ , then  $G \in C_n$
- iii) If there are vertices  $u, v \in V$  with  $\delta(u, v) = 3$  and no other vertices  $u', v' \in V$  with  $\delta(u', v') > 3$ , then  $G$  is Hamiltonian if 2-connected or else  $G \in C_n$
- iv) If  $\delta(u, v) = 2$  for all non-adjacent vertices,  $G$  is Hamiltonian or  $G \in D_n$ , given  $n = \text{odd}$ . If  $G$  is not Hamiltonian, then adding just one extra edge makes the graph Hamiltonian.

**Proof:** Theorem 1.3 along with Lemma 2.1, Lemma 2.2, Lemma 2.3 and Lemma 2.4 proves the theorem 2.1.

**Lemma 2.1.** *If  $d(u) + d(v) + \delta(u, v) \geq n + 1$ , then for all pair of distinct non-adjacent vertices  $u, v \in V$ ,  $\delta(u, v) \leq 4$*

**Lemma 2.2.** *If  $d(u) + d(v) + \delta(u, v) \geq n + 1$ , and there are vertices  $u, v \in V$  with  $\delta(u, v) = 4$ , then  $G \in C_n$*

**Lemma 2.3.** *If  $d(u) + d(v) + \delta(u, v) \geq n + 1$  and for any  $u, v \in V$   $\delta(u, v) = 3$  and no other vertices  $u', v' \in V$  with  $\delta(u', v') > 3$  and  $G$  is not 2-connected, then  $G \in C_n$*

**Lemma 2.4.** *If  $d(u) + d(v) + \delta(u, v) \geq n + 1$  and for every non-adjacent pair  $u, v \in V$   $\delta(u, v) = 2$  and  $n = \text{odd}$ , then  $G \in D_n$ .*

**Proof of Lemma 2.1:** Theorem 1.3[1] proves that under Rahman and Kaykobad condition  $\delta(u, v) \leq 3$  when  $G$  is 2-connected. On the other hand Theorem 1.2[4] proves

that under Rahman and Kaykobad condition  $G \in C_n \cup D_n$  where  $G$  is 2-connected or just connected.

Now lets find out the maximum possible  $\delta(u, v)$  in  $C_n$  and  $D_n$ . In  $C_n$  maximum  $\delta(u, v) = 4$  is possible only when  $u \in K_{q1}$  and  $v \in K_{q2}$ . In  $D_n$  maximum  $\delta(u, v) = 2$ .

So, under Rahman and Kaykobad condition,  $\delta(u, v) \leq 3$ , when  $G$  is 2-connected and  $\delta(u, v) = 4$ , when  $G$  is not two connected. In general,  $\delta(u, v) = 4$ , under Rahman and Kaykobad condition.

**Proof of Lemma 2.2:** In the proof of Lemma 2.1 section we discussed that under Rahman and Kaykobad condition,  $\delta(u, v) = 4$ , only when  $G$  is not 2-connected. If a graph is not two connected, it cannot be Hamiltonian. So, according to Theorem 1.2[4], the graph falls into  $C_n$  or  $D_n$ . But as  $\delta(u, v) = 4$ , the graph cannot fall in  $D_n$  and hence falls into the category  $C_n$ .

**Proof of Lemma 2.3:** We prove the lemma using the same arguments Rao Li [4] used to prove his theorem.

Let  $P: = u s_1 s_2 v$  be the shortest path between  $u$  and  $v$  with length 3. So there exists at least a single pair of distinct non-adjacent vertices in  $G$  (example  $u$  and  $s_2$  or  $s_1$  and  $v$ ) such that the shortest distance between them is 2.

Since  $G$  is not 2-connected (has cut vertex), there exist a vertex say,  $x$  in  $G$  such that  $G[V(G) \setminus \{x\}]$  is disconnected. Let  $G_i$  be the components in  $G[V(G) \setminus \{x\}]$  and the number of vertices in  $G_i$  is  $n_i$ , where  $2 \leq l$  and  $1 \leq i \leq l$ .

So, there must be two vertices in two different components  $u_i \in V(G_i)$ , such that  $u_i x \in E(G)$ , where  $i=1, 2$  and  $\delta(u_1 u_2) = 2$ . Now,

$$n+1 \leq d(u_1) + d(u_2) + 2 \leq n_1 + n_2 + 2 \\ \leq n_1 + n_2 + n_3 + \dots + n_l + 2 = n+1$$

So,  $d(u_1)=n_1$ ,  $d(u_2)=n_2$  and  $n_3=n_4=\dots=n_l=0$ . So, there will be only two components and  $u_i$  will be connected to all the vertices in  $V(G_i) \cup \{x\}$ ,  $i=1, 2$  and  $n=n_1+n_2+1$ . Now let's, define the four set of graphs present in  $C_n$ :

$$U_1 = \{u \in V(G_1) : ux \in E\}, |U_1| \neq 0$$

$$V_1 = \{v \in V(G_1) : vx \notin E\}, |V_1| \geq 0$$

$$U_2 = \{u \in V(G_2) : ux \in E\}, |U_2| \neq 0$$

$$V_2 = \{v \in V(G_2) : vx \notin E\}, |V_2| \geq 0$$

Any vertex  $u'$  other than  $u_1$  in the set  $U_1$  will show  $\delta(u', u_2)=2$  and  $d(u') = n_1$ . So  $u'$  is adjacent to all the vertices in  $V(G_1) \cup \{x\}$ . Symmetrically, it can be

shown that any vertex  $u''$  in  $U_2$  is adjacent to all vertices in  $V(G_2) \cup \{x\}$ .

Let  $v'$  be any vertex in  $V_1$  and so  $\delta(v', u_2) = 3$ .  $n+1 \leq d(v') + d(u_2) + 3 \leq n_1 - 1 + n_2 + 3 = n+1$ , which indicates  $d(v') = n_1 - 1$  and  $v'$  is exactly adjacent to all the vertices in  $V(G_1)$ . Similarly any vertex  $v''$  in  $V_2$  is adjacent to all the vertices in  $V(G_2)$ . Hence  $G \in C_n$ .

The lemma can be proved by the discussion in Lemma 2.1 also. As  $G$  is not 2-connected, it is not Hamiltonian. So, according to Theorem 1.2[4],  $G \in C_n \cup D_n$ . But as maximum  $\delta(u, v) = 2$  in  $D_n$ ,  $G$  is actually of class  $C_n$ .

Now we analyze the characteristics of  $G \in C_n$ . For any non-adjacent vertex pair  $u, v \in E(G)$ ,  $\delta(u, v) = 3$  implies that no vertex  $w \in V$  can be adjacent to  $u, v$  at the same time since then  $\langle u \rightarrow w \rightarrow v \rangle$  would have been a path of length 2.  $\delta(u, v) = 3$ , also implies  $d(u) + d(v) \geq n - 2$ . As,  $u$  and  $v$  cannot have a common neighbor, and the number of vertices that can be connected is  $(n-2)$ . Hence, by contradiction,  $d(u) + d(v) = n - 2$  is proved. So,  $u, v$  connects to all the vertices in the graph, having no common neighbor.

As we assume 1-connected graph (Fig.1.), there should be no cross over edges like  $(1, i+1), (i, n) \in E$ . Because cross over edge will make the graph 2-connected, and also Hamiltonian. In Fig.1, we see that there is two cut vertices  $k$  and  $(k+1)$ .

We know that under Rahman and Kaykobad condition  $\delta(u, v) \leq 3$  for all  $u, v \in V$ . To maintain this, vertices from  $u=1$  to  $(k-1)$ , all should be connected to  $k$ , so than  $\delta(i, v=n) = 3$ ,  $i \in \{1 \text{ to } k-1\}$ . Similarly vertices from  $(k+2)$  to  $v=n$  should be connected to  $(k+1)$  to maintain  $\delta(i, v=1) = 3$ ,  $i \in \{k+2 \text{ to } n\}$ . Now, the non adjacent vertices on the sides  $\{1 \text{ to } k\}$  and  $\{k+1, \text{ to } n\}$ , have a distance 2. So, any two non adjacent vertices  $\{u', v' \in (1 \text{ to } k-1) \text{ or } (k+2 \text{ to } n)\}$  should maintain  $d(u') + d(v') \geq n - 1$ . But maximum possible  $d(u') + d(v') = n - 2$ , only when  $k=2$  or  $k=n-1$ . Hence to maintain Rahman Kaykobad condition, the graph component composed of vertices  $\{1 \text{ to } k\}$  will be complete and similarly the component with vertices  $\{k+1 \text{ to } n\}$  is complete. So, the graph falls in  $C_n$ .

We define this class of graph as  $C_n' \subset C_n$ , where  $\{V(K_{p1}) = \{k\}, V(K_{q1}) = \{1 \text{ to } k-1\}\}$ ,

$V(K_1) = \{k+1\}$  ,  $V(K_{p_2}) = \{k+1 \text{ to } n\}$  ,  
 $V(K_{q_2}) = \{\emptyset\}$   
and  $k \in \{2 \text{ to } n-1\}$

**Proof of Lemma 2.4:** It is to be noted that Rahman and Kaykobad condition fulfills the condition given in theorem

satisfying the above condition is:  $|V(Z_p)|=p$  and  $|(p+1)K_1|=p+1$ ,  $n=2p+1$

In this setup, adding just one edge in  $(p+1) K_1$  makes the graph Hamiltonian, which is a finding of work[1]. It is to be noted that adding that edge reduces the independent set size by two, and becomes  $p-1$  whereas  $|V(Z_p)|$  becomes  $p+2$  ( $|(p+1)K_1| \leq |V(Z_p)|$ ), which implies Hamiltonicity in the graph.

Fig.1. An 1-connected graph G fulfilling Rahman and Kaykobad condition, with  $\delta(u, v) = 3$

1.4 [5]. In Rahman and Kaykobad, for any pair  $u, v \in V$  if  $\delta(u, v) = 2$ ,  $d(u) + d(v) \geq n-1$ . If for all non-adjacent pair  $u, v \in V$   $\delta(u, v) = 2$ , Rahman and Kaykobad condition ensures 2-connectedness. So, the Lemma can directly be derived from Theorem 1.4.

Part (iii) of Theorem 1.3 [1] misses one fact that G is Hamiltonian when  $n$ =even. Lets see why  $n$ =even makes the graph Hamiltonian. We define a graph class  $D_n$   $\{G : K_{p,q} \subseteq G \subseteq K_p \vee qK_1$ , where  $|V(G)| = \text{even}\}$ .  $D_n$  is similar to class  $D_n$ , with the exceptions that  $n$ =even and hence  $q \neq p+1$ . Note that any graph G with  $|V(G)| = \text{even}$ , falls into this class.

To keep  $\delta(u, v) = 2$  for all non-adjacent pair  $u, v \in V$ , the graph  $G \in D_n$  should provide an independent set  $\{V(qK_1)\}$ , to which all other vertices  $\{V(Z_p \subseteq K_p, |V(Z_p)| = p)\}$  should be connected. The independent set should be  $> n/2$  to avoid Hamiltonicity, but doing so breaks the Rahman Kaykobad conditions (one can verify the fact easily by drawing a graph). So  $q \leq p$ , which eventually makes the graph Hamiltonian:  $\{u \in V(Z_p) s_1 \in V(qK_1) s_2 \in Z_p s_3 \in V(qK_1) \dots v \in Z_p, a \in V(qK_1) u, \delta(u, v) = 2\}$ .

Now for  $n$ =odd, the number of independent vertices should be kept larger than the number of vertices in  $Z_p$  and at the same time the Rahman and Kaykobad condition should be satisfied. The only possible configuration

**Corollary 2.1.**  $C_n$  and  $D_n$  have Hamilton-path.

Graph classes  $C_n$  and  $D_n$  fulfills the Rahman and Kaykobad condition but are not Hamiltonian. So, according to Theorem 1.1 [3], they both have Hamilton-path.

**Corollary 2.2.** Under the condition of Rahman and Kaykobad, if every non-adjacent  $u, v \in V$   $\delta(u, v) = 2$ , then the graph is Hamiltonian or the size of the independent set is  $\left\lfloor \frac{n}{2} \right\rfloor$

**Proof:** To avoid Hamiltonicity The size of the independent set should be  $> n/2$ . However, doing so breaks the Rahman Kaykobad conditions, when  $n$ =even. So, the graph is Hamiltonian when  $n$ =even. This is also proven in Theorem 1.4[5] in a different way.

When  $n$ =odd, it is possible to maintain Rahman and Kaykobad condition even making size of

the independent set  $> n/2$  only when the independent set size is  $\frac{n+1}{2} = \left\lceil \frac{n}{2} \right\rceil$ . This can also be obtained by

examining the graph family  $D_n$  found in [4],[5].

Hence the corollary is proved. We also generalize two corollaries derived by rao Li[4].

**Corollary 1.1** (Rao Li[4]). Let G be a 2-connected graph with n vertices. If  $d(u) + d(v) + \delta(u, v) \geq n+2$  for each pair of distinct non-adjacent vertices u and v in G, then G is pancyclic or  $G \in \{K_{n/2, n/2} : \text{where } n \geq 4 \text{ is even}\}$ .

**Corollary 2.3.** Given the condition in Corollary 1.1, G is Hamiltonian.

**Proof:** If for all  $u, v \in V$   $\delta(u, v) = 2$ , the condition given reduces to  $d(u) + d(v) \geq n$  which is actually Ore's condition [2], implying Hamiltonicity (see theorem 1.5). If for any  $u, v \in V$   $\delta(u, v) = 3$ , the condition becomes  $d(u) + d(v) \geq n - 1$ . However, Mehedy, Hasan and Kaykobad [1] (see theorem 1.3) proved that for  $\delta(u, v) = 3$ , with  $d(u) + d(v) \geq n + 1 - 3 = n - 2$ , the graph becomes Hamiltonian. It is also proved in theorem 1.3 [1] that  $\delta(u, v)$  cannot be greater than 3 for  $d(u) + d(v) + \delta(u, v) \geq n + 1$ .  $d(u) + d(v) + \delta(u, v) \geq n + 2$  is a relaxed condition allowing more edges to be present in the graph and hence the finding  $\delta(u, v) \leq 3$ , is also applicable here. So, we say that Corollary 1.1 can be more generalized and the condition given in Corollary 1.1 proves the graph to be Hamiltonian.

**Corollary 1.2** (Rao Li[4]). *Let  $G$  be a 3-connected graph with  $n$  vertices. If  $d(u) + d(v) + \delta(u, v) \geq n + 3$  for each pair of distinct non-adjacent vertices  $u$  and  $v$  in  $G$ , then  $G$  is Hamilton-connected.*

**Corollary 2.4.** *Given the condition in Corollary 1.2,  $G$  is Hamiltonian.*

**Proof:** The same arguments provided for Corollary 2.3 applies here also. It is to be noted that for  $\delta(u, v) = 2$ , the condition is:  $d(u) + d(v) \geq n + 1$ , which is more relaxed than Ore's condition[2]. We also argue that  $\delta(u, v) \leq 3$  and for  $\delta(u, v) = 3$ , the graph is Hamiltonian by using theorem 1.3 [1] and because the graph is 3-connected (2-connected graph is more constrained by number of edges than 3 connected). So, the graph is Hamiltonian.

## IV. CONCLUSION

We relate three seminal works for finding the Hamiltonicity of a graph observing Rahman and Kaykobad condition or a subset of the condition. We determine when the graph is Hamiltonian. If we cannot, we characterize the non-Hamiltonian graph by using two families of graphs and which instances of graphs in those two families, the graph falls in. Our work provides a comprehensive understanding of graphs following Rahman and Kaykobad condition.

# Design of a Fractional-order Self-tuning Regulator using Optimization Algorithms

Deepyaman Maiti, Mithun Chakraborty, Ayan Acharya, and Amit Konar

Department of Electronics and Telecommunication Engineering, Jadavpur University, Kolkata, India

**Abstract** — The self-tuning regulators form an important sub-class of adaptive controllers. This paper introduces a novel scheme for designing a fractional order self-tuning regulator. Original designs for all the sub-modules of the self-tuning regulator are proposed. The particle swarm optimization algorithm is utilized for online identification of the parameters of the dynamic fractional order process while the subsequent tuning of the controller parameters is performed by differential evolution. Results show that the proposed self-tuning regulator is both precise and robust.

**Index Terms** — Controller tuner, differential evolution, fractional order self-tuning regulator, parameter identifier, particle swarm optimization.

## I. INTRODUCTION

Development of a control system involves many tasks such as modeling, design of a control law, implementation and validation. The self-tuning regulator (STR) attempts to automate several of these tasks. This is illustrated in Fig. 1, which shows the block diagram of a process with an STR. It is assumed that the structure of the process is specified.

Parameters of the process are estimated on-line by the block labeled ‘parameter identifier’. The block labeled ‘controller tuner’ contains computations that are required to perform the design of a controller with a specified method and a few design parameters that can be chosen externally. The design problem is called the *underlying design problem* for systems with known parameters. The block labeled ‘controller’ is an implementation of the controller whose parameters are obtained from the ‘controller tuner’ block [1].

In this paper we have presented a scheme for the design of a fractional order STR. This means that the physical process that needs to be controlled as well as the controller that will control it are both of fractional order. The real world objects or processes that we want to estimate are generally of fractional order [2].

A typical example of a non-integer (fractional) order system is the voltage-current relation of a semi-infinite lossy RC line or diffusion of heat into a semi-infinite solid, where heat flow  $q(t)$  is equal to the half-derivative of temperature  $T(t)$ :  $\frac{d^{0.5}T(t)}{dt^{0.5}} = q(t)$ .

So far, however, the usual practice when dealing with a fractional order process has been to use an integer order approximation. Disregarding the fractional order of the

system was caused mainly by the non-existence of simple mathematical tools for the description of such systems. Since major advances have been made in this area recently, it is possible to consider also the real order of the dynamical systems. Such models are more adequate for the description of dynamical systems with distributed parameters than integer-order models with concentrated parameters.

It is necessary to understand the theory of fractional calculus in order to realize the significance of fractional order integration and derivation. Fractional calculus is the branch of calculus that generalizes the derivative or integral of a function to non-integer order, allowing calculations such as deriving a function to  $1/2$  order. For instance  $s^\alpha$  indicates derivation to the order  $\alpha$ . Knowledge in the subject of fractional calculus is essential to design fractional order controllers. Of the several definitions of fractional derivatives, the Grunwald-Letnikov and Riemann-Liouville definitions are the most used [3]. These definitions are required for the realization of discrete control algorithms.

The design of an STR can be divided into sub-tasks such as designing the modules for parameter estimation [4] and controller design [5]. For a chosen structure of a fractional order system, we have designed the ‘parameter identifier’ and ‘controller tuner’ blocks of Fig. 1. As a matter of fact, the controller we have considered is of a fractional order PID type, which differs from the usual integral order PID controller by the property that the orders of integration and derivation are positive real rather than restricted to only positive integers (conventionally unity). Fractional order PID controllers are much superior to their integer order counterparts, especially when controlling fractional order processes [6].

For designing the ‘parameter identifier’ block, we have made use of a stochastic optimization strategy from the family of evolutionary computation, namely particle swarm optimization (PSO) [7] – [8]. The ‘controller tuner’ block utilizes differential evolution (DE) [9] – [10].

Verification of the precision of our design is performed by operating the STR on a system with known parameters, and also by simulation. The robustness of our design is also displayed.

## II. STOCHASTIC OPTIMIZATION ALGORITHMS

### A. The Optimization Problem

The optimization problem consists in determining the global optimum (in our case, minimum) of a continuous real-valued function of  $n$  independent variables  $x_1, x_2, x_3, \dots, x_n$ , mathematically represented as  $f(\vec{X})$ , where

$\vec{X} = (x_1, x_2, x_3, \dots, x_n)$  is called the parameter vector. Then the task of any optimization algorithm reduces to searching the  $n$ -dimensional hyperspace to locate a particular point with position-vector  $\vec{X}_D$  such that  $f(\vec{X}_D)$  is the global optimum of  $f(\vec{X})$ .

### B. Particle Swarm Optimization

The PSO algorithm [7] - [8] attempts to mimic the natural process of group communication of individual knowledge, which occurs when a social swarm elements flock, migrate, forage, etc. in order to achieve some optimum property such as configuration or location.

The 'swarm' is initialized with a population of random solutions. Each particle in the swarm is a different possible set of the unknown parameters to be optimized. Representing a point in the solution space, each particle adjusts its flying toward a potential area according to its own flying experience and shares social information among particles. The particles swarm toward the best fitting solution encountered in previous iterations with the intent of encountering better solutions through the course of the process and eventually converging on a single minimum error solution.

Let the swarm consist of  $N$  particles moving around in a  $D$ -dimensional search space. Each particle is initialized with a random position and a random velocity. Each

particle modifies its flying based on its own and companions' experience at every iteration. The  $i^{\text{th}}$  particle is denoted by  $X_i$ , where  $X_i = (x_{i1}, x_{i2}, \dots, x_{iD})$ . Its best previous solution (pbest) is represented as  $P_i = (p_{i1}, p_{i2}, \dots, p_{iD})$ . Current velocity (position changing rate) is described by  $V_i$ , where  $V_i = (v_{i1}, v_{i2}, \dots, v_{iD})$ . Finally, the best solution achieved so far by the whole swarm (gbest) is represented as  $P_g = (p_{g1}, p_{g2}, \dots, p_{gD})$ . The fitness function evaluates the performance of particles to determine whether the best fitting solution is achieved. The particles are manipulated according to the following equations:

$$v_{id}(t+1) = \omega v_{id}(t) + c_1 \cdot \phi_1 \cdot (p_{id}(t) - x_{id}(t)) +$$

$$c_2 \cdot \phi_2 \cdot (p_{gd}(t) - x_{id}(t))$$

$$x_{id}(t+1) = x_{id}(t) + v_{id}(t+1).$$

(The equations are presented for the  $d^{\text{th}}$  dimension of the position and velocity of the  $i^{\text{th}}$  particle.)

Here,  $c_1$  and  $c_2$  are two positive constants, called cognitive learning rate and social learning rate respectively,  $\phi_1$  and  $\phi_2$  are two random functions in the range  $[0,1]$ ,  $\omega$  is the time-decreasing inertia factor which balances the global wide-range exploitation and the nearby exploration abilities of the swarm.

### C. Differential Evolution

DE [9] - [10] belongs to the class of evolutionary algorithms guided by the principles of *Darwinian Evolution* and *Natural Genetics* where each time-varying parameter vector (candidate solution) in the population is called a chromosome and each time-step represents a generation. The first step of the algorithm, as usual, is:

*Initialization*: This step is identical to the random initialization of position vectors in PSO.

Each iteration consists of the following three steps:

*Mutation*: For each chromosome  $\vec{X}_i(t)$  belonging to the current generation, three other chromosomes  $\vec{X}_p(t)$ ,  $\vec{X}_q(t)$  and  $\vec{X}_r(t)$  are randomly selected from the same

generation (i, p, q and r are distinct); the scaled difference of  $\vec{X}_q(t)$  and  $\vec{X}_r(t)$  is added to  $\vec{X}_p(t)$  to generate a donor vector  $\vec{V}_i(t+1) = \vec{X}_p(t) + F \times (\vec{X}_q(t) - \vec{X}_r(t))$  where F is a constant scalar in (0,1). We take  $F = 0.8$ .

**Recombination:** A trial offspring vector  $\vec{T}_i(t+1)$  is created for each current-generation parent vector  $\vec{X}_i(t)$  by first choosing a constant CR ( $0 < CR < 1$ ) called the crossover constant and then setting the jth component  $\vec{T}_{i,j}(t+1)$  of  $\vec{T}_i(t+1)$  according to:

$$T_{i,j}(t+1) = \begin{cases} V_{i,j}(t) & \text{if } \text{rand}_j(0,1) < CR, \\ X_{i,j}(t) & \text{otherwise,} \end{cases}$$

where  $\text{rand}_j(0,1)$  is a random number selected from the interval (0, 1),  $j = 1, 2, \dots, n$ . We take  $CR = 0.96$ .

**Selection:** This step is be mathematically expressed as:

$$\vec{X}_i(t+1) = \begin{cases} \vec{T}_i(t+1) & \text{if } f(\vec{T}_i(t+1)) < f(\vec{X}_i(t)), \\ \vec{X}_i(t) & \text{otherwise,} \end{cases}$$

$\forall i = 1, 2, \dots, m$ .

Thus, the next-generation population is generated, keeping the population-size m always unchanged.

### III. DETAILED DESIGN SCHEME OF THE PARAMETER IDENTIFIER BLOCK

We have considered a fractional process whose transfer function is of the form  $\frac{1}{a_1 s^\alpha + a_2 s^\beta + a_3}$ . It should be noted that without loss of generality, we may presume the dc gain to be unity so that the dc gain and its possible fluctuations are included in the coefficients  $a_1$ ,  $a_2$  and  $a_3$ . This fractional order system has five varying parameters, namely three coefficients  $a_1$ ,  $a_2$  and  $a_3$ , and two fractional powers  $\alpha$  and  $\beta$ . (Of course any other structure can be chosen due to the generalness of our design method. This particular structure merely serves as an example.)

#### A. Design Principles of the Identifier

Let  $R(s)$ ,  $C(s)$ ,  $E(s)$  and  $U(s)$  denote respectively the reference input, the output, the error signal (input to the controller) and the control signal (input to the process) respectively.

The controller we have considered (as already mentioned) is a fractional order PID controller, whose transfer function is of the form  $K_p + T_i s^{-\lambda} + T_d s^\delta$ .

$K_p, T_i, T_d$  are the proportional, integral and derivative constants respectively,  $\lambda, \delta$  are the orders of integration and derivation. We can have by simple block diagram algebra,

$$\frac{C(s)}{R(s)} = \frac{K_p + T_i s^{-\lambda} + T_d s^\delta}{K_p + T_i s^{-\lambda} + T_d s^\delta + a_1 s^\alpha + a_2 s^\beta + a_3},$$

$$\Rightarrow E(s) = R(s) - C(s) = R(s) \left[ 1 - \frac{C(s)}{R(s)} \right].$$

For reference input  $R(s) = \frac{1}{s}$  (unit step),

$$U(s) = \frac{(K_p + T_i s^{-\lambda} + T_d s^\delta)(a_1 s^\alpha + a_2 s^\beta + a_3)}{s(K_p + T_i s^{-\lambda} + T_d s^\delta + a_1 s^\alpha + a_2 s^\beta + a_3)},$$

$$\Rightarrow C(s) = \frac{K_p + T_i s^{-\lambda} + T_d s^\delta}{s(K_p + T_i s^{-\lambda} + T_d s^\delta + a_1 s^\alpha + a_2 s^\beta + a_3)}.$$

We sample the output values  $c(t)$  in discrete time domain and store them. The PSO algorithm will search the solution space to come up with a process model which will replicate the observed values of  $c(t)$  for the same signal  $U(s)$ . At the moment of parameter identification, the controller has retained its old values of  $K_p, T_i, T_d, \lambda, \delta$  (fixed the last time the controller was tuned), but the process parameters  $a_1, \alpha, a_2, \beta, a_3$  have changed. So the optimization problem is five-dimensional since we know the controller parameters from its last tuning.

Let, for a process model, the output response is  $p(t)$ . We

will define a parameter  $F = \sum_{t=1}^f [c(t) - p(t)]^2$ , which gives

a measure of the deviation of the output of the trial process model from the output of the actual process. F is the fitness function that the PSO algorithm will try to minimize. At  $F = 0$ , the unknown parameters are optimized. The position vector of the best particle, i.e. the optimized value of  $\{a_1, \alpha, a_2, \beta, a_3\}$  is the identified parameter set. The process model for the optimized solution set should provide output identical to  $c(t)$ .

There are five unknown parameters to be optimized. So the present problem of system identification can be solved by a straightforward application of the PSO algorithm for optimization on a five-dimensional solution space, each particle having a five-dimensional position and velocity vector. This approach gives very accurate results, even when the input data is corrupted to a significant extent. We studied this scheme under both ideal and non-ideal (random error component added to readings) conditions.

#### B. Illustration of the Identifier

Synthetic data for  $c(t)$  is created using  $a_1 = 0.8$ ,  $\alpha = 2.2$ ,  $a_2 = 0.5$ ,  $\beta = 0.9$ ,  $a_3 = 1$ . The controller parameters are:

$K_p=410$ ,  $T_i=650$ ,  $T_d=50$ ,  $\lambda=0.25$ ,  $\delta=1.25$ . Sampling frequency is 20 samples per second. Error in taking readings of  $c(t)$  is simulated by adding a random number in the range  $[-0.05, 0.05]$  to each reading.

The PSO parameters used are: the inertia factor  $\omega$  decreases linearly from 0.9 to 0.4; the cognitive learning rate  $c_1=1.4$ , the social learning rate  $c_2=1.4$ . Number of particles in the population is 50. The PSO algorithm is run for 200 iterations, and this is kept as the stop criterion. The search ranges are:  $a_1, a_2, a_3$ : 0 to 2.0 (for all three parameters),  $\alpha$ : 2.0 to 2.4 and  $\beta$ : 0.7 to 1.1. The velocity ranges are:  $a_1, a_2, a_3$ :  $-0.5$  to  $0.5$  (for all three parameters),  $\alpha, \beta$ :  $-0.1$  to  $0.1$  (for both parameters).

Fig. 2. Output waveform  $c(t)$  used for identification

Fig. 3. Variation of best fitness with number of iterations

TABLE I.

IDENTIFICATION AND PERCENTAGE ERRORS

| Parameter | Estimate | Percentage Error |
|-----------|----------|------------------|
| $a_1$     | 0.8000   | 0.0002           |
| $\alpha$  | 2.2000   | 0.0000           |
| $a_2$     | 0.5000   | 0.0035           |
| $\beta$   | 0.9000   | 0.0042           |
| $a_3$     | 1.0000   | 0.0030           |

Table 1 gives results of the identification when the readings are accurate (error component is not added). After 200 iterations, the best fitness is  $2.5946 \times 10^{-14}$ .

Even when the random error component is added, the identification is very accurate.

### C. Analysis

The challenge in fractional order system identification is that the fractional powers are not restricted to assume only discrete integral values, but are distributed in a continuous interval. However, the use of the stochastic optimization strategy makes an accurate identification possible.

So the parameter identifier block can estimate the process parameters with a very high degree of accuracy. Now the controller tuner module should use these values of the identified parameters to tune the controller parameters on-line.

## IV. DETAILED DESIGN SCHEME OF THE CONTROLLER TUNER BLOCK

### A. Design Principles: Formulation of the Objective Function and its Optimization

Our approach is based on the *root locus* method (*dominant poles* method) of designing integral PID controllers [11]. As in the traditional root locus method, the peak overshoot  $M_p$  and rise time  $t_{rise}$  (or, in other words, requirements of stability and damping levels) are specified. From these specifications, we find out the damping ratio  $\zeta$  and the undamped natural frequency  $\omega_n$ , making use of (1), (2):

$$\zeta = -\frac{\ln(M_p)}{\sqrt{\{\ln(M_p)\}^2 + \pi^2}} \quad (1)$$

$$\omega_n = \frac{\pi - \tan^{-1}\left(\frac{\sqrt{1-\zeta^2}}{\zeta}\right)}{t_{rise}\sqrt{1-\zeta^2}} \quad (2)$$

Using these computed values of  $\zeta$  and  $\omega_n$ , we then determine the desired positions of the dominant poles  $p_{1,2}$  of the closed loop system:

$$p_{1,2} = -\zeta\omega_n \pm j\omega_n\sqrt{1-\zeta^2} = -a \pm jb \quad (3)$$

where  $a = \zeta\omega_n$ ,  $b = \omega_n\sqrt{1-\zeta^2}$ ,  $a, b > 0$ .

Let  $G_p(s)$  be the transfer function of the process we want to control,  $G_c(s)$  the transfer function of the controller to be designed and  $H(s)$  the transfer function of the feedback-path. Then, the closed loop transfer function of the controlled system is:  $T(s) = \frac{G(s)}{1 + G(s)H(s)}$ ,

$G(s) = G_c(s).G_p(s)$  being the forward path transfer function:

(4)

Assuming unity feedback, we have  $H(s)=1$ . In this case, the characteristic equation becomes  $1+G(s)=0$ ,

$$\begin{aligned} \Rightarrow 1+G_c(s).G_p(s) &= 0 \Rightarrow 1+G_c(s).\frac{P(s)}{Q(s)} = 0 \\ \Rightarrow Q(s)+G_c(s).P(s) &= 0 \end{aligned} \quad (5)$$

where  $P(s)$  and  $Q(s)$  are respectively the numerator and denominator polynomials of  $G(s)$ ,  $P(s)$  and  $Q(s)$  have no common factor.

As  $p_{1,2}$  must be poles of the closed loop system, each of them must be a root of the characteristic equation and hence must satisfy equation (5). Thus, putting  $s = p_1 = -a \pm jb$  in equation (5), we obtain

$$\begin{aligned} Q(p_1) + G_c(p_1).P(p_1) &= 0 \\ \Rightarrow Q(-a + jb) + (K_p + T_i(-a + jb)^{-\lambda} + T_d(-a + jb)^{\delta})P(-a + jb) &= 0 \end{aligned} \quad (6)$$

Equation (6) is a complex equation in five unknowns, namely  $K_p$ ,  $T_i$ ,  $T_d$ ,  $\lambda$ ,  $\delta$  and our problem of designing a controller that makes the closed loop dominant poles of the system coincide with  $p_{1,2}$  now reduces to determining the set of values of  $\{K_p, T_i, T_d, \lambda, \delta\}$  for which (6) holds good. But as the number of unknowns exceeds the number of equations, there exists an infinite number of solution sets and the equation cannot be unambiguously solved by traditional methods.

This necessitates the application of stochastic global search techniques, which, in turn, requires the formulation of a suitable *objective function* or *cost function*.

Let,  $R$  = real part of the L.H.S. of equation (6),  
 $I$  = imaginary part of the L.H.S. of equation (6),

$$P = \tan^{-1} \frac{I}{R}.$$

We define  $f(K_p, T_i, T_d, \lambda, \delta) = |R| + |I| + |P|$  as our objective function. Clearly,  $f \geq 0$ , in general, and  $f = 0$  if and only if  $R = 0$  and  $I = 0$  and  $P = 0$ , i.e. if and only if equation (6) is satisfied.

So, we now employ DE to scour the five-dimensional search space and home in on the optimal solution set  $\{K_p^*, T_i^*, T_d^*, \lambda^*, \delta^*\}$  for which  $f = f_{\min} = 0$ .

It is germane to mention here that the formulae (1), (2) and (3) hold strictly only for a *second order system* with its *complex conjugate pole-pair* at  $p_{1,2}$ . However, for a higher-order system with a *dominant pole-pair* (real part of this pole-pair is much smaller than those of other poles), these formulae are widely used in control engineering applications with a fair degree of accuracy [11]. Nevertheless, after designing our controller with the

help of these formulae, we perform a simulation to obtain the *unit step response* of the closed-loop control system as a check.

### B. Illustration of the Tuner

The process (control objective) has the transfer function

$$G_p(s) = \frac{1}{0.8s^{2.2} + 0.5s^{0.9} + 1}.$$

We want to design a controller such that the closed loop system has a peak overshoot  $M_p \leq 10\%$  and rise-time  $t_{rise} \leq 0.3$  seconds.

Using the formulae (1) and (2), we obtain  $\zeta = 0.5912$  and  $\omega_n = 9.107 \text{ s}^{-1}$ . Thus the dominant poles for the closed loop controlled system should lie at  $p_1 = (-5.384 + j7.345)$  and  $p_2 = (-5.384 - j7.345)$ .

As per convention, we use unity feedback. The controller transfer function is given by (4). Putting  $s = p_1 = (-5.384 + j7.345)$  in the characteristic equation,

$$1 + \frac{K_p + T_i(-5.384 + j7.345)^{-\lambda} + T_d(-5.384 + j7.345)^{\delta}}{0.8(-5.384 + j7.345)^{2.2} + 0.5(-5.384 + j7.345)^{0.9} + 1} = 0 \quad (7)$$

After separating the real and imaginary parts, we have:

$$R = (K_p + 13.4235) + \frac{T_i}{9.107^{\lambda}} \cos(2.203\lambda) + \quad (8)$$

$$T_d(9.107)^{\delta} \cos(2.203\delta)$$

$$I = -\frac{T_i}{9.107^{\lambda}} \sin(2.203\lambda) + \quad (9)$$

$$T_d(9.107)^{\delta} \sin(2.203\delta) - 98.9237$$

$$P = \tan^{-1} \frac{I}{R}. \quad (10)$$

Thus, (8), (9) and (10) give us our objective function  $f(K_p, T_i, T_d, \lambda, \delta) = |R| + |I| + |P|$ .

We set the limits on the components of the position-vectors of the chromosomes (i.e. the controller parameters) as follows: as a practical consideration, we assume  $0 \leq K_p, T_i, T_d \leq 1000$ ,  $0 \leq \lambda, \delta \leq 2$ .

The stop criterion used is a tolerance value  $f = 0.0001$ .

After the DE algorithm is run, the position vector of the best particle gives the parameters of the optimum PID controller. The transfer function of the identified controller is  $962.80 + 197.55s^{-1.79} + 46.27s^{1.37}$ .

Although we have constructed the objective function  $f$  by making use of the dominant pole  $p_1 = -a + jb$  in the second quadrant, we would arrive at the same  $f$  if we had started with the third-quadrant dominant pole  $p_2 = -a - jb$ . This is because, in the latter case, the imaginary part of the reduced characteristic equation (6) would just be the negative of what we have obtained in (7) so that  $f$ , which involves absolute values only, would

remain unaltered. This is true not only for the particular problem in question but in general as well.

Fig. 4 shows the unit step response of the uncontrolled system as well as the unit step response of the system controlled by the designed STR. The peak overshoot is 5.2%, and the rise time is 0.054 seconds.

Fig. 4. Unit step responses of the control objective

### C. Analysis of the Tuner Designing Scheme

The controller meets the rise-time and peak overshoot requirements more than satisfactorily. The rise-time performance especially far exceeds the design requirement, which means that the controller tuner is actually over-performing and we can have a significant safety margin. We also considered using PSO in the 'controller tuner' block as well. However we found that DE offers significantly better performance in this case.

An important point is to be noted in this context. For the final system to exhibit the desired performance, it is necessary that the evaluated pole-values  $p_{1,2}$  truly correspond to the *dominant poles* of the closed-loop controlled system. However, the optimization of our cost function ensures only that  $p_{1,2}$  are poles of the system but does not guarantee that these are the dominant poles. In other words, equation (7) embodies a *necessary*, but not *sufficient*, condition for the dominance of  $p_{1,2}$ . Obviously, there may be a number of possible combinations of values of the parameters  $[K_p, T_i, T_d, \lambda, \delta]$  for which the resulting characteristic equation is satisfied by  $p_{1,2}$  but, in each such case, the

characteristic equation will have other roots (closed-loop system poles), too, and these poles will also play an important role in determining the overall system response. This is a possible explanation of the observation that the performance of the final designed system with fractional controller is actually better than desired.

## V. COMMENTS AND CONCLUSIONS

An elegant and effective design scheme for a fractional order STR is proposed. A simple computer program in C or MATLAB using sampled data acquisition and other interfaces with the physical process can actually implement the complete STR. Of course, the same design can easily be employed to implement an integer order STR as well. Apart from the example shown, we also considered several other similar problems and solved them by our proposed method. These have not been included in this paper owing to paucity of space. We also intend to apply other well-known algorithms such as Genetic Algorithm, Bacterial Foraging Optimization and their many variants to the same optimization problems and compare their performance with the presented scheme.

Department of Computer Science & Engineering, Premier University, 1/A, O.R.Nizam Road, Probortok Circle, Chittagong-4203, Bangladesh.

**Abstract** — Circuit partitioning plays an important role in physical design automation of very large scale integration (VLSI) chips. In this brief we present a new connectivity based top down as well as bottom up approach to clustering algorithm for VLSI circuit partitioning. The proposed clustering algorithm partitions the circuit by focusing on highly interconnected cell groups. This clustering algorithm leads to a parallel implementation in which multiple processors are used to identify clusters simultaneously. The process starts with forming clusters by grouping the cells that are tightly connected and as well as the cells that are loosely connected. Considering both types of groups has the advantage that clusters formed from this technique will be highly connected and compact too. Therefore the proposed clustering method can reduce the size and also speed-up the large-scale partitioning problem without losing partitioning solution qualities. The performance of the proposed clustering algorithm is evaluated on a standard set of partitioning benchmark-ISPD98 benchmark suite.

**Index Terms** — Base, cluster, partition, push-pop, threshold.

## I. INTRODUCTION

A cluster is a group of strongly connected components in a circuit. The goal of clustering algorithms is to identify the clusters in a circuit. In VLSI layout design, clustering algorithms can be used to construct the natural hierarchy of the circuit. The circuit-partitioning problem can be expressed in graph theoretic terms by modeling each circuit as a hypergraph with circuit components (cells) represented by vertices, and the nets connecting the components represented by hyperedges. A general objective of the circuit partitioning is to minimize the *netcut* or the number of nets that span the partitions. Bottom-up clustering algorithms provide a solution to the problems encountered when partitioning very large circuits [1]. A parallel clustering algorithm can be integrated into the partitioning process by using clustering as a preprocessing step to partitioning. First, clustering is performed on the circuit to obtain a condensed circuit in which each cluster of components has been collapsed to form a single component. Partitioning is then performed on the clustered circuit instead of the original circuit. Since the number of components in a clustered circuit is usually much smaller than that of the original circuit, the

time and space required by the partitioning algorithm is reduced significantly [2]. Clusters with a higher density are considered to be of higher quality.

Here, we propose a new clustering method for VLSI circuit partitioning. The proposed clustering method focuses on finding the natural clusters in a circuit and thus tends to cluster the original circuit without loss of partitioning solution quality. The algorithm first groups a cell and its neighbor cells to form an initial cluster, then the initial cluster is further refined by using a PUSH-POP mechanism to move the cells that have more connections with cells outside the initial cluster. In this way, the cells that are highly connected with one another are identified and merged. To provide a flexible criterion for finding natural clusters and as well as maintaining density of the clusters, the sizes of the clusters are not fixed. Furthermore, instead of ordering cells randomly like most clustering algorithms [2], [3], the proposed clustering algorithm incorporates two nonrandom ordering methods based on local cell connectivity information. Both nonrandom ordering methods can lead to clusters with balanced sizes and high density and consequently good partitioning solutions.

The remainder of this paper is organized as follows. In Section II, a background on the clustering algorithms is given. Section III presents the proposed clustering algorithm in detail. In Section IV, the experimental results of the proposed clustering algorithm on the ISPD98 benchmarks [4] are reported. Finally, conclusions are made in Section V.

## II. BACKGROUND & MOTIVATION

In the past two decades, partitioning problems have been studied by many researchers. The Fiduccia-Mattheyses (FM) [5] heuristic is one of the most widely used iterative improvement approaches. The FM algorithm can provide reasonable solutions for small to medium size circuits, but as VLSI circuits become larger, the solution quality deteriorates [3]. Recent works have focused on multilevel partitioning algorithms that exploit clustering approaches to gradually merge clusters in multiple clustering levels [6], [7]. Currently, hMetis [3], [6] and

MLPart [2] are regarded to be the state-of-the-art partitioners due to their superior performances in terms of speed and the final partitioning solution.

Clustering algorithms play a crucial role in VLSI circuit partitioning. The multilevel partitioning algorithms are based on clustering a large circuit into a sequence of smaller circuits. Clustering is an important factor in determining the performance of partitioning algorithms, where different clustering approaches can lead to different partitioning solutions. A large number of clustering algorithms have been proposed in the past decade [2], [3], [6], [7]. In [2], heavy-edge matching that clusters pairs of cells with highest connectivity is used. The clustering is done based on *edge separability* in [7]. This technique uses a graph model and exploits the global connectivity information for clustering. Edge clustering, hyperedge clustering, modified hyperedge clustering, and FirstChoice clustering schemes are presented in [3] and [6]. The edge clustering scheme groups two nodes that are highly connected to form a cluster. Hyperedge clustering and modified hyperedge clustering group the nodes belonging to a hyperedge to form a cluster. The FirstChoice clustering scheme groups the nodes such that each node in a cluster is highly connected with at least one other node in the same cluster. Among various clustering algorithms, edge clustering is one of the most commonly used clustering approaches and has been successfully used in hMetis and MLPart. However, the edge clustering scheme is likely to ignore natural clusters of a circuit [8]-[10]. Therefore, it may not produce optimal results. An example of a circuit's natural clusters is illustrated in Fig.1 [8]-[9].

Fig. 1. Example of natural clusters in a circuit

The graph in Fig. 1, contains two natural clusters made of cells ((1),(2),(3),(4)) and ((5),(6),(7),(8)). In the edge clustering scheme, given a cell, the edge clustering will try to find an unclustered cell with the highest connectivity. Therefore, assuming that all cells in Fig. 1, have equal area and no cell already belongs to a cluster, the edge clustering scheme may group cells and together, eliminating the two natural clusters.

### III. PROPOSED CLUSTERING PROCEDURE

Before going to the details let us first define the following terms:

**Base:**-The cell from which clustering can be initiated and which is not a part of any cluster.

**Unclassified cell:**-The cell that is not a part of any cluster.

#### A. Clustering with Parallel Base Selection

1. Sort the cells according to their degree.
2. While any cell is unclassified
3. Select highest and lowest degree cell(s) as base cell(s).
4. Beginning with the base(s) cell start clustering.
5. If area of a cluster is less or equal to 10% of the whole circuit, continue clustering.
6. Else go to step 3.
7. Push & Pop the cells from one cluster to another to balance the cluster size but the number of wire connections should remain same or decline.

In the rest of this section, the preceding steps are discussed in detail. In addition, implementation details and discussion of the proposed algorithm are presented.

In Fig. 2 we present a simple circuit diagram to determine the cell ordering and neighbor relationship table. In Table 1 neighbors of only the base cells are considered.

Fig. 2. Graph representation of a circuit

From Fig. 2 we can construct the partial neighbor relationship table for all the cells in the circuit considering neighbors of the base only.

TABLE 1  
NEIGHBOR RELATIONSHIP TABLE

| Cell     | Cell Deg. | 1 <sup>st</sup> level neig. | 2 <sup>nd</sup> level neig. | 3 <sup>rd</sup> level neig. | 4 <sup>th</sup> level neig. | 5 <sup>th</sup> level neig. |
|----------|-----------|-----------------------------|-----------------------------|-----------------------------|-----------------------------|-----------------------------|
| $c_1$    | 2         | -                           | -                           | -                           | -                           | -                           |
| $c_2$    | 4         | $c_1, c_3, c_4$             | $c_5, c_6$                  | $c_7, c_9$                  | $c_8, c_{10}$               | -                           |
| $c_3$    | 3         | -                           | -                           | -                           | -                           | -                           |
| $c_4$    | 3         | -                           | -                           | -                           | -                           | -                           |
| $c_5$    | 3         | -                           | -                           | -                           | -                           | -                           |
| $c_6$    | 3         | -                           | -                           | -                           | -                           | -                           |
| $c_7$    | 2         | -                           | -                           | -                           | -                           | -                           |
| $c_8$    | 1         | $c_7$                       | $c_6$                       | $c_3, c_5$                  | $c_2, c_4, c_9$             | $c_1, c_{10}$               |
| $c_9$    | 2         | -                           | -                           | -                           | -                           | -                           |
| $c_{10}$ | 1         | $c_9$                       | $c_5$                       | $c_4, c_6$                  | $c_2, c_3, c_7$             | $c_1, c_8$                  |

### B. Cell Ordering

Order the cells according to the degree. Here we have  $c_2 > c_3 = c_4 = c_5 = c_6 > c_1 = c_7 = c_9 > c_8 = c_{10}$  from Fig. 2 and Table 1.

### C. Base Cell Selection

The cells with the highest degree as well as lowest degree are base cells. If more than one highest or lowest degree cells exists then all of them are considered as base cells

Here the approach of base cell(s) selection is parallel i.e. the procedure starts from both end of the ordered list of cells. Also the approach considers all the cells (if any) of identical highest and lowest degree.

*Advantages of parallel selection of the base cell (s):* Higher density increases the compactness of each cluster due to highly connected cells accommodated in the same cluster. After PUSH-POP of cells in the initially created clusters, balanced size clusters can be found. Again parallel selection of base cell(s) can faster the clustering procedure.

### D. Initial Clustering

Each base cell initiates clustering with 1<sup>st</sup> level neighbors and then 2<sup>nd</sup> level neighbor (if exist, i.e. a 2<sup>nd</sup> level neighbor can enter the initial cluster if any how it is not a 1<sup>st</sup> level neighbor of the base cell), then 3<sup>rd</sup> level neighbor if they are not the 2<sup>nd</sup> level neighbor and so on up to the threshold. A cell can't be a member of more than one cluster at a time, in that case if more than one base cells try to win the cell than the base cell that have the closer level of connectivity to that will have the cell, if that also doesn't solve the problem i.e. if all the base cells have same level of connectivity to that cell than consider the wirelength between the base and target cell. Again if that also doesn't break the tie than the random assignment of that cell will take place. For the sake of determining the

wirelength we have placed the nodes on a grid and each grid segment assigned a unique weight.

### E. Threshold

Consider each cluster up to the 10% of the total circuit i.e. if there are n number of cells in the total circuit, then each cluster will possess a maximum n/10 cells.

### F. Clustering Remaining Cells

After the 1<sup>st</sup> level of clustering i.e. initial clustering there may remain unclustered cells in the circuit. From the remaining cells construct a list of cells in descending order of node degree and then apply the whole steps that are performed in the initial clustering. Continue the process until all of the cells are being clustered.

### G. PUSH-POP

The initial clusters formed with the cells having highest degree will have larger sizes thus it will not be possible to enter all the nth level neighbors. At the same time clusters formed with lower degree cells will have fewer cells i.e. small size. So to overcome this type of unbalanced problem we apply the PUSH-POP procedure. Where each PUSH will enter a cell from a large size cluster to another large or small size cluster if the no. of connections between those clusters remain same or decrease and at the same time the area of the cluster satisfies the threshold. Each cluster will maintain a stack of cells by its own. The cell having more connections to outside the cluster than inside will be the TOP element of the stack. Remaining cells of the cluster will be stacked in decreasing order of outside connectivity so that the BOTTOM element of the stack will have the cell that have more connections to inside than outside.

### H. Example

Fig. 3. Grid representation of a circuit

Clustering starts from all the base cells in parallel. Here we have considered the cells as nodes in the grid where each side of a square in the grid is 1 unit. In Fig. 3 Highest degree base cells are 3, 7, and 8 and lowest degree base cell is only 9

Now initial clustering begins with all the base cells at a time. Therefore we will start with four initial clusters. The figure below shows the clusters created from the Fig. 3.

So we have in Fig. 4 cell 2 is the 1<sup>st</sup> level neighbor of base cells 3 and 7, but cell 2 entered the cluster of the base 7 due to wirelength. Similarly 6 entered the cluster of 8 instead of cluster of 3 and 10 entered cluster of 9 instead of 7.

Fig. 4. Initial cluster created from the circuit of Fig. 3

Thus there are four initial clusters more or less balanced size, so PUSH-POP not required here. The connectivity among the clusters also displayed here. Now consider another sample circuit of Fig. 5 to cluster with PUSH-POP function. The circuit has 12 cells. Among them base cells are 7, 3 and 1.

Fig. 5. Example circuit to explain PUSH-POP

Here we have got three initial clusters from the figure beginning with the base cells 7, 3 and 1.

The initial clusters from Fig. 5 are given below

Fig. 6. Initial cluster created from the circuit of Fig. 5

From Fig. 6 we see that the cluster sizes are unbalanced so we can apply the PUSH-POP process here. If we push cell 2 from the cluster of 7 to 3 and cell 6 from cluster of 7 to 1. Then the refined clusters are given in Fig. 7 as follows:

Fig. 7. Refined cluster after PUSH-POP

The number of inter cluster connectivity remain same after PUSH-POP. But the sizes of the cluster are better than the previous one.

#### IV. EXPERIMENTAL RESULTS

The proposed clustering technique has been implemented in C++ and tested as a preprocessing step for multilevel partitioning.

The following table shows a comparison of our proposed algorithm with Net Cluster (NC), best-choice clustering (BC), FirstChoice (FC) clustering. From Table 2 we can say that our algorithm has better runtime. The percentage improve in performance has found by considering the selected IBM benchmarks.

TABLE 2  
COMPARISON OF AVERAGE RUNTIME

| Circuit | Comparison of average runtime |       |       |                    |
|---------|-------------------------------|-------|-------|--------------------|
|         | NC                            | BC    | FC    | Proposed algorithm |
| Ibm01   | 1.024                         | 1.056 | 1.086 | 1.063              |
| ibm05   | 1.028                         | 1.046 | 1.035 | 1.033              |
| Ibm10   | 1.015                         | 1.021 | 1.052 | 1.041              |

The next table shows the improvement of cluster size with no. of runs. After level 3 of clustering we found that the maximum difference between the sizes of cluster is almost near about 10%.

TABLE 3  
ILLUSTRATION OF DIFFERENCES AMONG CLUSTER SIZES  
FROM THREE LEVELS OF PROPOSED PARALLEL  
CLUSTERING PROCEDURE FOR SELECTED IBM  
BENCHMARKS

| Circuit | % reduction of differences between cluster sizes |         |         |
|---------|--------------------------------------------------|---------|---------|
|         | Level 1                                          | Level 2 | Level 3 |
| ibm01   | 50%                                              | 20%     | 10%     |
| ibm05   | 55%                                              | 24%     | 11%     |
| Ibm10   | 47%                                              | 18%     | 9%      |

## V. CONCLUSION AND FUTURE WORK

In this work, a new connectivity-based clustering algorithm is proposed and applied to VLSI circuit partitioning. Experimental results illustrate the effectiveness of the proposed technique. As the cluster size is restricted so there may be a situation that some cells may be unclustered but which is very small in number. Future work involves full implementation of the proposed clustering algorithm within the context of VLSI placement.

**Abstract** — We propose a multiuser Quantum Key Distribution system based on entanglement property which is simple, more efficient, cost effective and easy to implement in laboratory environment. Existing protocols uses base communication to provide security, as 50% of the time sender and receiver's base is not agreed there are 50% bit loss during key distribution but our protocol does not need the base communication hence we achieve 3dB performance improvement.

**Index Terms** — QKD, quantum networking, data security.

## I. INTRODUCTION

Quantum Key Distribution (QKD) is more secure and provides some interesting benefits when it is done utilizing entanglement property rather than single photon superposition property. In typical systems, base is communicated after sending a sequence of bits. As Alice and Bob select the base randomly, so in 50% case their base will agree and in other 50% case they will disagree. They discard the bit values in which case they disagree in base selection and keep the bit values in which they agree in base selection. Here we see that they loss 50% of bits that have been generated. But in our system correct bit value is not

dependent on base agreement. Hence, we can save 50% bit loss and our system achieves performance improvement of 3dB (two times) than the present systems. We have done analysis and confirmed that our system does not require base comparison for secure communication.

## II. ARCHITECTURE

Pairs of photons can be produced in various sorts of entangled states, including:

- 1) Polarization entangled [1]
- 2) Time-frequency entangled [2]
- 3) Momentum entangled [3]

In our proposed experiment we have used polarization entangled photons pair. In the recent teleportation field experiment by the Vienna group [2], polarization-entangled photons were transmitted using glass fiber in a channel underneath the Danube River in Vienna. Above the river, there was a direct microwave connection for the classical channel. The two stations were physically separated by approx. 600m. So we hope our architecture will work well.

### A. System Configuration

Fig 1: Proposed architecture of multiuser QKD using entanglement.

Fig 2: Function of EOM

In our system there is a dedicated server that produces polarization entangled photon pairs. We call the two photons P1 and P2. P1 goes to switch1 and P2 goes to switch2 through two standard telecom optical fiber lines (SMF28). Switch1 and switch2 are two MEMS optical switches which are used for routing and by this way we provide multiuser facility. Each party that engages to the QKD must be connected to both switch1 and switch2 by standard telecom optical fiber line (SMF28). Also they have classical lines to communicate the classical information. We call one party Alice and the other party Bob that are engaged at any particular time in QKD. P1 and P2 propagate and reach Alice's and Bob's EOM (Electro-Optical Modulator) and then polarization detector. High-speed data handling boards, designed and implemented at NIST, are installed in both Alice and Bob's computer. The board collects the detection events and communicates with each other to run the protocol of QKD. Alice and Bob's boards then send the bit value to their own computers for the subsequent error reconciliation and privacy amplification. The computers of Alice and Bob then use the shared secret keys for application-level data encryption as necessary to implement secure communications through an unsecured network.

#### B. Function of Electro-Optical Modulator (EOM) in the setup

The Electro-Optical Modulator - In order to control the polarization of the photons an EOM is used (KD\*P crystal and  $3 \times 3$  mm<sup>2</sup> aperture) which is basically a delay plate controlled by a voltage; it uses the Pockels Effect. For example, at 633 nm, the "half wave plate" voltage is approximately 200 V; if 0 V is applied, the crystal has no effect on the light. We choose polarization between 0°, circular left, 90° and circular right. These circular states are defined by

$$\begin{aligned} |\psi\rangle &= \frac{\sqrt{2}}{2} (|\rightarrow\rangle + i|\uparrow\rangle) \\ |\psi\rangle &= \frac{\sqrt{2}}{2} (|\rightarrow\rangle - i|\uparrow\rangle) \end{aligned} \quad (1)$$

They can easily be obtained by a single EOM applying a "quarter wave plate" or a "minus quarter wave plate" voltage.

### III. PROTOCOL DESCRIPTION

#### A. Possible attacks from Eve

There are many potential attacks for Eve. But quantum mechanics comes into play and guarantees a secure transmission of the key [4, 10]:

- 1) Eve can try to take over the source in the middle and prepare photon pairs with distinct polarization, however Alice and Bob can perform tests of the entanglement. If the Bell's inequality (we have given a short note on Bell's inequality below.) is violated then the source really emits entangled pairs which could have not been tampered with by Eve.
- 2) Eve cannot copy the quantum state of the photon perfectly and then wait for basis reconciliation to measure in the appropriate basis. The no cloning theorem in quantum mechanics prohibits such actions.
- 3) If Eve decides to measure and resend the photon, she will only half of the time pick the right basis. In the other cases Eve will get random information and the photon she sends to Bob is necessarily also uncorrelated to the photon of Alice. Eve therefore introduces an error between otherwise perfectly correlated events and she can be detected. Using the intercept-resend strategy, Eve's tampering will amount to 50% qubit error rate (QBER).

Bell's inequality:

Einstein was challenging the uncertainties of quantum mechanics in the EPR paradox [5] and his famous thought

experiment suggested that for certain quantum states – Schrödinger called them ‘entangle states’ – quantum mechanics seems to require some ‘faster than light’ influence between separated parts of a quantum system. In 1964, nearly 30 years after the EPR paper and 9 years after Einstein’s death, John Bell derived an ‘inequality’ for the correlations originating from ‘common-sense’ pre-determined conditions that was violated by the correlations predicted by quantum mechanics. Bell’s inequality makes it possible to put quantum mechanics to the test. A series of beautiful experiments designed to measure these EPR correlations were performed by Alain Aspect and his group in Paris in the late 1970s and early 1980s [6]. These experiments confirmed that Bell’s inequality was indeed violated and that the predictions of quantum mechanics agreed with the data.

### B. Protocol

- 1) A source of entangled-photon pairs is configured to send one photon to Alice and one photon to Bob.
- 2) Alice and Bob’s detectors are both configured to measure the polarization in a particular base – (0, 90) or (circular left, circular right).
- 3) Randomly deflect the photon (i.e., change polarization) when it passes through EOM.
- 4) Alice and Bob record the bit value and exact time for each detection. Arrival times are used to establish coincident detections.
- 5) Alice and Bob then communicate the measurement time using classical medium.
- 6) Both Alice and Bob keep the bit value that agree in time and discard the other.
- 7) Randomly select some bit positions in the string of quantum bits. Then communicate the bit values in these positions using classical channel to see if they agree hence calculate bit error rate for determining the presence of eavesdropper.
- 8) If no eavesdropper is detected then use bits to make secret key otherwise discard it.

### C. How It Works

Server emits two entangle photons and one of them goes to Alice and other goes to Bob. Both Alice and Bob’s photons goes to polarization detector after passing through the EOM. Alice and Bob change voltage level of their EOM (-100 v, 0 v, 100 v, 200 v) randomly, that is they change polarization of photon randomly. But whatever polarization they impose on one photon, according to quantum mechanics the other photon will be in the same polarization state and before measurement photon’s polarization state is nondeterministic and unknown to them. Whenever measurement is performed (i.e. detection) whatever polarization is detected in one detector, other detector will detect the same polarization (i.e. if one detect vertical other

will also detect vertical). As in our system measurement is performed after the operation of EOM so there is no effect of EOM operation on outcome, that is Alice and Bob will get same output. In this system only one base (0 - 90 or circular left - circular right) will be used for measurement hence they do not need to communicate the base. By excluding base communication from the system we can use 100% data that are communicated and this is two times (3 dB) efficient than the existing system (which needs base communication hence can use only 50% data on average that are communicated). Now the question is how our system will detect the presence of eavesdropper. This can be done very easily. The following example will clear the matter. Let in a situation one of the photons goes to Alice and the other is intercepted by the eavesdropper. After detecting the polarization of the photon eavesdropper will send the photon to Bob using the same polarization that he detected. Whenever eavesdropper detected the photon, entanglement has been collapsed down and Alice and Bob’s photons are no longer correlated with each other. When the photons go through the EOM of Alice and Bob they will be changed in polarization in 75% time. As two photons are no longer correlated so Alice and Bob will get different value on average in 50% time. That is if eavesdropper is not present they will get same value in 100% time and if eavesdropper is present they will get different value in 50% time. We see that presence of eavesdropper introduces certain level of error. So calculating the error level we can detect the presence of eavesdropper.

## IV. PERFORMANCE DISCUSSION

The key rate and quantum bit error rate (QBER) are widely used as the criteria of QKD system performance. For an active QKD network, it is also important to achieve a short system switching time (the time used to establish the connection between Alice and Bob). We discuss these parameters here.

The point-to-point QKD key rate is determined by the mean photon number,  $\mu$ , at server’s output; the loss in the transmission fiber, including fiber attenuation, bending, coupling and connectors; the protocol related loss; and the detection efficiency of the APD. These factors are the principle influence to the key rate in QKD network systems. Besides these factors, the insertion loss in the optical switch should be taken into account.

The mean photon number,  $\mu$ , at Alice is assumed to 0.1 (as it is typical value). The loss in the transmission fiber is 2dB/km, while other losses such as bending, coupling and connection losses in the quantum channel amount to approximately 3 dB. The silicon APD’s detection efficiency is approximately 50%.

### A. Advantages of Using Entanglement:

1) A major benefit of this method is that the server cannot cheat or eavesdrop on the key without being caught with overwhelming probability [7]. In other words, the server does not need to be trusted.

2) There is no encoding of a random number to form the basis of the key, as the randomness comes from the entangled state, e.g.,

$$|\Psi\rangle = \frac{1}{\sqrt{2}}(|0\rangle_1|0\rangle_2 + |1\rangle_1|1\rangle_2) \quad (2)$$

which is in a superposition of two possible 100% correlated states ( $|1\rangle = |V\rangle$ ,  $|0\rangle = |H\rangle$  in a polarization system).

3) The entanglement allows for “automatic source checking” [8]. In systems in which the various qubit states are produced by several different lasers (or even single-photon generators), information about the state of the qubit can be leaked to other degrees of freedom (thus allowing an eavesdropper to detect the qubit state without inducing any errors). This is prevented if entangled photons are used—any leakage of information to other degrees of freedom of the photon automatically shows up as an increased bit error rate (BER). (Note: leakage of information via some classical means, e.g., detector after pulsing [9], is not eliminated using entanglement.) The security of the key exchange is also not compromised even if the source itself is in the hands of an eavesdropper.

4) It is, in principle, possible to store the photons in some “quantum memory” until the key is required. The key does not exist until the photons are measured. As a corollary, this means that one can, in principle, generate a key even when no quantum channel is available (as long as it was previously available and the quantum bits can be stored). Also, as long as no eavesdropper was present at the time of entanglement distribution, the protocol is secure, even if the measurements are not made—and the secret key not created—until some later time when there is an eavesdropper.

5) The maximum range to date is tens of kilometers in fiber; in free space, only table-top demonstrations have been carried out, though very recently entangled photons were distributed (without key exchange) over ~1km in free space[4]. In principle the range of secure communication is high because the background-induced coincidence rate (leading to errors) can be extremely low [10]. Lumped loss tolerance up to 50 dB is expected, based on a 1ns gate and 1000 counts.sec-1 (this implies a background rate of only 1 millicoincidence.sec-1; however, detector noise will increase this.) The availability of “quantum repeaters” would also increase the usable distance [11].

6) One can remove empty pulses, since the detection of one photon of a pair reveals the presence of a companion. In principle, it is thus possible to have a probability of emitting a non-empty pulse equal to one. It is beneficial only because

presently available single-photon detectors feature high dark count probability. The difficulty to always collect both photons of a pair somewhat reduces this advantage.

7) One frequently hears that photon-pairs have also the advantage of avoiding multi-photon pulses, but this is not correct. For a given mean photon number, the probability that a nonempty pulse contains more than one photon is essentially the same for weak pulses and for photon pairs. However, the fact that passive state preparation can be implemented prevents multiphoton splitting attacks [12, 13], since the different photon pairs are independent. So, even if multiple photon pairs don't increase Eve's information, they lead to an increase in the QBER [12].

8) Using entangled photons pairs prevents unintended information leakage in unused degrees of freedom [14]. Observing a QBER smaller than approximately 15 %, or equivalently that Bell's inequality is violated, indeed guarantees that the photons are entangled and so that the different states are not fully distinguishable through other degrees of freedom.

9) Entangled photons offer interesting possibilities in the context of cryptographic optical networks. The photon pairs source can indeed be operated by a key provider and situated somewhere in between potential QC customers. In this case, the operator of the source has no way to get any information about the key obtained by Alice and Bob.

### B. Drawbacks of Using Entanglement:

1) Pair-photon generation rates limit systems at the moment. Highest rates are  $4 \times 10^5$  to  $1.3 \times 10^6$  coincidences per second [13, 14] measured in the laboratory, significantly lower in fibers.

2) The disadvantage clearly is the increased experimental difficulty.

3) Decoherence is more serious when using photon pairs, because of the larger spectral width. In case of polarization-entangled photons, this gradually destroys their correlation. Hence, although perfectly fine for free-space QC, polarization entanglement is thus not adequate for QC over long optical fibers. A similar effect arises when dealing with energy-time entangled photons. Here, the chromatic dispersion destroys the strong time-correlations between the photons forming a pair. However, it is possible to passively compensate for this effect using either additional fibers with opposite dispersion, or exploiting the inherent energy correlation of photon pairs. Recent studies suggest that faint laser QC is secure over distances of about 50 km that are possible with the detectors available today [15]. Hence in the short term entangled photons won't be used for the realization of industrial prototypes.

C. Our proposed system provides the following extra benefits:

- 1) More efficient (3 dB more efficient than the existing protocols).
- 2) It is cost effective.
- 3) It is simple.
- 4) Easy to implement in laboratory environment.
- 5) Less complex solution to multiuser access.
- 6) More secure distribution system than single photon system as the protocol uses entanglement property.

## V. CONCLUSION

Security in data communication is a major headache now a days. Among the encryption technologies that are available at present, secret key is the most reliable one, which depends on secure key generation and distribution. The quantum key distribution is a perfect solution in this regard because, according to the no cloning theorem of quantum mechanics any attempt to intercept the key by the eavesdropper will be detected immediately. In this paper we have proposed a simple, more efficient and cost effective architecture and corresponding protocol for quantum key distribution. The proposed system achieves 3dB performance improvement than conventional one as it does not depend on communication of measurement base.

**Abstract**—In this paper, we analyze the performance of a non-data aided near maximum likelihood (NDA-NML) estimator for symbol timing recovery in binary digital communications. The analysis of the estimator is performed for an additive noise only channel and the simulation results are extended to a flat fading channel. The probability distribution of the timing estimates is derived, presented and compared with simulation results. The performance of the estimator is presented in terms of the bit error rate (BER) and the error variance of the estimates. The BER is computed when the estimator is operating under additive white Gaussian noise (AWGN) channel and Rayleigh fading channel. The variance of the estimates is computed for the noise only case and compared with the Cramer Rao bound (CRB) and modified Cramer Rao bound (MCRB).

**Index Terms**—BER, CRB, Flat fading channel, Near Maximum Likelihood Estimation, MCRB, Symbol Timing Error, Timing Synchronization.

## I. INTRODUCTION

Timing in a receiver must be synchronized to the symbols of the incoming transmitted signal. In the analog implementation of digital modems a free running clock at the symbol rate is phase adjusted in a feedback manner to find the optimum sampling point of the symbol. In feedforward arrangement, timing wave is generated from incoming signal. Mueller and Muller [1] presented a novel technique for symbol timing recovery in the analog era. With the advancement of the digital and microprocessor systems, came digital signal processors and FPGAs, which allows us to implement complicated open loop systems.

In this paper, we present a non-data aided symbol timing estimation technique and evaluate its performance. Symbol timing can be performed with synchronous sampling where exploiting some sort of error signal, the signal sampling clock is adjusted in a feedback manner and non-synchronous sampling where the sampling is not locked to the incoming signal. Non-synchronous sampling is used in this paper to estimate the symbol timing on received baseband signal. The optimum symbol strobing point is estimated using the samples with minimum intersymbol interference. Obtained samples from nonsynchronously sampled signal may not include the sample which is at the

optimum sampling point and therefore interpolation is used to reduce the error produced by nonsynchronous sampling process. While performing interpolation and upsampling with the available high processor speeds of the latest digital signal processor, no significant limitations are noted. In this paper, interpolations are assumed available for convenience. A good review on interpolation techniques for symbol timing estimation is given by Gardner [2], [3] where some useful interpolation filter functions and the use of them for timing recovery to improve performance of nonsynchronously sampled systems are discussed. Many feedback and/or feedforward symbol timing estimation techniques for synchronous and/or nonsynchronous sampled systems for either continuous time or burst mode transmissions are available in the literature [4]. Techniques for synchronizing receivers can be divided into data aided and non-data aided. The former is the case where synchronization relies on knowledge of the information symbols. The latter is the case where training sequences are impractical or inconvenient, and the decision process is not sufficiently reliable for decision feedback [5].

The performance of the estimator can be evaluated in terms of BER performance and measuring the variance of the estimator and comparing with CRB and MCRB. The BER performance under the assumption of perfect timing estimates is well documented for various modulation formats [6]. In practice timing estimates exhibit small random fluctuations (jitter) about their optimum values that give rise to a BER degradation when compared to perfect synchronization [7], which degrades further when the signal undergoes fading in wireless communications [8]. A joint symbol timing estimation and data detection on flat fading channel based on particle filtering is demonstrated in [9]. We evaluate the performance of the symbol timing estimator operating under a Rayleigh fading channel. We consider the timing estimator as described in [4] and analyze its performance by finding the statistical distribution of the estimates, the distribution can then be used to characterize the average BER theoretically. The analysis are further extended to a flat fading Rayleigh channel using Monte-Carlo simulations. A tighter CRB

and a MCRB are also derived to study the performance of the estimator for the noise only case. Although the considered timing estimator is not optimal we consider it here because of its design simplicity which can be easily used in software defined radios at the baseband. In the following sections we present the timing estimator, the probability distribution of the estimator, the CRB and MCRB, and the performance analysis for a flat fading channel.

## II. SIGNALS AND SYSTEMS MODEL

The system considered here is depicted in figure 1. In our model we consider both the additive noise only channel as well as the fading channel. A conventional baseband pulse amplitude modulation (PAM) signal can be represented as

$$s(t) = \sum_{m=-\infty}^{\infty} c_m g(t - mT) \quad (1)$$

where  $c_m$ 's are the transmitted symbols,  $g(\cdot)$  is the pulse shape used to control the spectral characteristics of the transmitted signal and  $T$  is the signaling interval ( $\frac{1}{T}$  is the symbol rate). The  $c_m$ 's are assumed to be independently and identically distributed, and take on the values  $\pm 1$  with equal probability. The channel introduces a delay of  $\tau$ , and additive white Gaussian noise is considered at the receiver with a double sided power spectral density of  $\frac{N_0}{2}$  W/Hz. Then the signal becomes

$$\begin{aligned} y(t) &= s(t - \tau) + w(t) \\ &= \sum_{m=-\infty}^{\infty} c_m g(t - mT - \tau) + w(t) \end{aligned} \quad (2)$$

where the noise process  $w(t)$  is stationary and Gaussian with a mean of zero. The frequency response of the pulse shaping filter in the transmitter is  $G(f)$ . The received signal is passed through a receiving filter. In general, the optimum filter at the receiver is matched to the received signal pulse  $g(t)$ . Hence the frequency response of this filter is  $G^*(f)$ . Then the received signal is

$$z(t) = \sum_{m=-\infty}^{\infty} c_m g_o(t - mT - \tau) + n(t) \quad (3)$$

where  $g_o$  is the signal pulse response of the receiving filter-that is  $G_o(f) = G(f)G^*(f) = |G(f)|^2$ -and  $n(t)$  is a bandlimited Gaussian noise independent and identically distributed with the same statistics as  $w(n)$ . Now if  $z(t)$  is sampled at times  $kT_s$ ,  $k = 0, \pm 1, \pm 2, \dots$  where  $T_s$  is the sampling interval, we have

$$z(kT_s) = \sum_{m=-\infty}^{\infty} c_m g_o(kT_s - mT - \tau) + n(kT_s) \quad (4)$$

When the symbols are transmitted over flat fading channel

Fig. 1: Block diagram of signal detection using square root raised cosine filter.

$h(t)$ , the faded discrete signal at the baseband can be written as,

$$z^f(kT_s) = \sum_{m=-\infty}^{\infty} h(kT_s) c_m g_o(kT_s - mT - \tau) + n(kT_s) \quad (5)$$

where  $h(kT_s)$  denotes the multiplicative fading process introduced by the flat fading channel sampled at times  $kT_s$ ,  $k = 0, \pm 1, \pm 2, \dots$ . As is shown in figure 1, square root raised cosine (SRC) filter is used as the pulse shaping filter and also as the receiving filter, the overall response is therefore similar to a raised cosine filter. The impulse response of SRC filter is given by:

$$g_{src}(t) = \begin{cases} \frac{\pi(1-\alpha)+4\alpha}{\pi\sqrt{T}} & t = 0 \\ \frac{4\alpha}{\pi\sqrt{T}} \left( \frac{\cos\left(\frac{(1+\alpha)\pi t}{T}\right) + \sin\left(\frac{(1-\alpha)\pi T}{4\alpha T}\right)}{1 - \left(\frac{4\alpha t}{T}\right)^2} \right) & t \neq 0, \pm \frac{T}{4\alpha} \\ \frac{\alpha}{\pi\sqrt{2T}} \left( (\pi - 2)\cos\left(\frac{\pi}{4\alpha}\right) + (\pi + 2)\sin\left(\frac{\pi}{4\alpha}\right) \right) & t = \pm \frac{T}{4\alpha} \end{cases} \quad (6)$$

where  $\alpha$  is called the roll-off factor, which takes values in the range  $0 \leq \alpha \leq 1$  and  $T$  is the symbol period. The theoretical bit error probability  $P_b$  for bipolar signaling is

$$P_b = Q\left(\sqrt{\frac{2E_b}{N_0}}\right) \quad (7)$$

where  $Q(x)$  is called the complementary error function or co-error function and is defined as

$$Q(x) = \frac{1}{\sqrt{2\pi}} \int_x^{\infty} \exp\left(-\frac{u^2}{2}\right) du \quad (8)$$

## III. TIMING ESTIMATOR

Here a near maximum likelihood (NML) timing estimation technique is described to estimate the symbol timing error as described in [4]. We assume that the sampled received baseband waveform for the additive noise only channel as given by (4) is:

$$z(kT_s) = \sum_{i=0}^{L-1} c_i g_o(kT_s - iT - \tau) + n(kT_s). \quad (9)$$

The noise process  $n(kT_s)$  is a zero mean bandlimited Gaussian process with a variance of  $\sigma^2$  and  $L$  is the number of symbols. In this case we ignore the channel  $h(kT_s)$  to derive the estimator. The probability density function of  $n(kT_s)$  is given by:

$$f_n(n) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp \left[ -\frac{\{n(kT_s)\}^2}{2\sigma^2} \right] \quad (10)$$

If we let  $\mathbf{R}$  to be a vector of the sample set  $z(kT_s)$  then using (9) and (10)

$$f_{\mathbf{R}}(\mathbf{R}|\tau) = \frac{1}{(2\pi\sigma^2)^{\frac{L}{2}}} \exp \left\{ -\frac{\sum_{i=0}^{L-1} [E - F]^2}{2\sigma^2} \right\} \quad (11)$$

where

$$\begin{aligned} E &= z_i(kT_s) \text{ and} \\ F &= \sum_{i=0}^{L-1} c_i g_0(kT_s - iT - \tau) \end{aligned}$$

We use the Maximum Likelihood (ML) principles to derive the symbol timing estimator assuming no a-priori knowledge of the received symbol sequence  $c_i$ . Let a matrix of samples be given as

$$\mathbf{Z} = \begin{bmatrix} Z_1 \\ Z_2 \\ \vdots \\ Z_i \\ \vdots \\ Z_L \end{bmatrix} = \begin{bmatrix} z_1(1) & z_1(2) & \cdot & \cdot & z_1(N) \\ z_2(1) & z_2(2) & \cdot & \cdot & z_2(N) \\ \vdots & \vdots & \cdot & \cdot & \vdots \\ z_i(1) & z_i(2) & \cdot & \cdot & z_i(N) \\ \vdots & \vdots & \cdot & \cdot & \vdots \\ \vdots & \vdots & \cdot & \cdot & \vdots \\ z_L(1) & z_L(2) & \cdot & \cdot & z_L(N) \end{bmatrix} \quad (12)$$

where,

$$Z_i = \sum_{i=1}^L z_i(k') \quad (13)$$

and,

$$z_i(k') = \sum_{k'=1}^N c_m g_0(k'T_s - iT - \tau) + n(k'T_s) \quad (14)$$

Here,  $k' = \text{mod}(k, N)$ ,  $L$  is the number of symbols used to estimate the timing offset and  $N$  is the number of samples per symbol. The estimator is then given by:

$$\hat{\tau} = \arg \max \{ \Gamma_1(k', \tau) = \sum_{i=1}^L |z_i(k', \tau)| \} \quad (15)$$

The validity of the technique demands the constraint on number of samples to be integer multiple of symbols. When the estimator operates under fading channel, it becomes,

$$\hat{\tau} = \arg \max \{ \Gamma_2(k', \tau) = \sum_{i=1}^L |z_i^f(k', \tau)| \} \quad (16)$$

where

$$z_i^f(k') = \sum_{k'=1}^N h(k'T_s) c_m g_0(k'T_s - mT - \tau) + n(k'T_s) \quad (17)$$

#### IV. PROBABILITY DISTRIBUTION OF THE TIMING ESTIMATOR

In order to determine the probability of bit error in the receiver, the distribution of the timing estimate errors must be taken into account. When using feedback techniques, the probability density function (pdf) of the timing error may be modelled using a Tichanov pdf [6]. Alternatively if the signal to noise ratio (SNR) is greater than the inverse of twice the variance of the timing offset a Gaussian pdf may be used [10], and since this holds true for the feed forward symbol timing recovery schemes, a Gaussian pdf can be used. However, in our case the timing estimates relate to the maximum energy of the signal. The instant of time at which the signal energy becomes maximum is taken as the estimate. Hence, the distribution of the timing estimates corresponds to the distribution of the maxima of the signal. Considering this, we find an expression for the probability mass function of timing estimates. The analytical expression is then compared with the simulated distribution. Let  $N = 2N' + 1$ , and consider the two vectors,  $\tau = [\tau_{-N'}, \dots, \tau_0, \dots, \tau_{k'}, \dots, \tau_{N'}]$  and  $\Gamma_1(k', \tau) = [\Gamma_1(-N'), \dots, \Gamma_1(0), \dots, \Gamma_1(k'), \dots, \Gamma_1(N')]$  with  $q = \max(\Gamma_1(k', \tau))$ . Then, when the particular time instance  $\tau_{k'}$  is chosen as the timing estimate  $\hat{\tau}$ , that is  $\hat{\tau} = \tau_{k'}$ , the probability can be written as

$$\begin{aligned} P(\hat{\tau} = \tau_{k'}) &= P(q = \Gamma_1(k', \tau)) \\ &= P(q > \Gamma_1(-N'), \dots, q = \Gamma_1(k'), \dots, q > \Gamma_1(N')) \\ &= f_{\Gamma_1(k')}(q) \prod_{j=-N', j \neq k'}^{N'} F_{\Gamma_1(j)}(q) \end{aligned} \quad (18)$$

where,  $f_{\Gamma_1(k')}(q)$  and  $F_{\Gamma_1(j)}(q)$  are the probability density function and cumulative distribution function of  $\Gamma_1(k')$  respectively. The expression for the probability mass function (pmf) for the timing estimates is given by,

$$f_{\hat{\tau}}(\tau) = \begin{cases} P(\hat{\tau} = \tau); & \tau \in [\tau_{-N'}, \dots, \tau_{k'}, \dots, \tau_{N'}] \\ 0; & \tau \notin [\tau_{-N'}, \dots, \tau_{k'}, \dots, \tau_{N'}]. \end{cases} \quad (19)$$

Figure 2 shows the analytical probability mass function and the simulated probability density function for the timing estimates. It is seen that the analytical results closely match with the simulated pdf.

#### V. PERFORMANCE OF THE ESTIMATOR

The statistics of the estimates are the key elements in determining the performances of the symbol timing recovery method. For example, if the estimates are biased, the resulting sampling location selected by the symbol timing estimator will be biased from the true optimum

Fig. 2: Analytical and simulated probability distribution function for timing estimates.

and performance will suffer. Similarly, if the estimates have a high variance, the variance of the selected sampling location will also be high. Clearly it is desirable to keep the variance of the estimates as low as possible. The performance bounds for the symbol timing estimator are the CRB and MCRB. We evaluate the performance of the estimator finding bit error probability with matched filter detection and measuring variance of the estimator. Bit error probability is compared to the theoretical bit error probability for AWGN and variance is compared with the lower bounds CRB and MCRB. Figure 3 shows the bit error performance for the NDA-NML estimator when roll-off factor is 0.6 and the number of symbols used for timing estimates is 100. NDA-NML estimator exhibits good bit error performance compared with theoretical BER of AWGN.

#### A. Cramer Rao Bound (CRB)

We consider the additive noise only case to derive the CRB here, assume that the received continuous waveform as given in (3) has complex envelope given by

$$z(t) = s(t) + n(t) \quad (20)$$

which is observed over an interval  $T$ .  $s(t)$  is the information bearing signal and  $n(t)$  represents complex-valued additive white Gaussian noise with two-sided power spectral density. A few of its parameters are unknown. Typically this happens with the carrier phase  $\theta$ , the symbol epoch  $\tau$ , the carrier frequency error  $\nu$  and the transmitted data.

To estimate of a single element of  $\{\theta, \tau, \nu\}$  denoted by  $\lambda$ , which is assumed to be deterministic (non-random), all the other parameters, including the data, are collected in a random vector  $\mathbf{u}$  having a known probability density

Fig. 3: Bit error performance: NDA-NML estimator.

function  $p(\mathbf{u})$  which does not depend on  $\lambda$ . If  $\hat{\lambda}(\mathbf{z})$  is any unbiased estimator of  $\lambda$ , a lower bound to the variance of the error  $\hat{\lambda}(\mathbf{z}) - \lambda$  is given by the Cramer-Rao formula [11]

$$CRB(\lambda) = \frac{1}{E_{\mathbf{z}} \left\{ \left[ \frac{\partial \ln p(\mathbf{z}|\lambda)}{\partial \lambda} \right]^2 \right\}} \quad (21)$$

where  $E_{\mathbf{z}}$  denotes statistical expectation with respect to the subscripted variable, and  $p(\mathbf{z}|\lambda)$  is the probability density function of  $\mathbf{z}$  for a given  $\lambda$ .

To compute  $CRB(\lambda)$  we need  $p(\mathbf{z}|\lambda)$  which, in principle, can be obtained from the integral

$$p(\mathbf{z}|\lambda) = \int_{-\infty}^{\infty} p(\mathbf{z}|\mathbf{u}, \lambda) p(\mathbf{u}) d\mathbf{u} \quad (22)$$

where  $p(\mathbf{z}|\mathbf{u}, \lambda)$ , the conditional probability density function of  $\mathbf{r}$  given  $\mathbf{u}$  and  $\lambda$  is easily available, at least for additive Gaussian channels. Unfortunately, in most cases of practical interest, the computation of (21) is impossible because either the integration in (22) cannot be carried out analytically or the expectation in (21) poses insuperable obstacles. Using the general form of CRB given by [12], the CRB for timing estimates for AWGN channel can be written as:

$$\overline{CRB}\left(\frac{\tau}{T}\right) = \left[ -\frac{2E_b}{N_0} g_0''(0) L T^2 \right] \quad (23)$$

where  $L$  represents the number of symbols used to make the estimate of the timing offset,  $T$  is the symbol period,  $g_0''(0)$  is the second derivative of the pulse shaping filter with respect to time  $t$  evaluated at  $t = 0$ . For a raised cosine channel when the signal energy normalized to unity,  $g_0''(0)$  is given by [13]

$$g_0''(0) = -\left( \frac{\pi^2}{3} + \alpha^2(\pi^2 - 8) \right) \quad (24)$$

where  $\alpha$  is the roll off factor of the raised cosine filter.

### B. Modified Cramer Rao Bound (MCRB)

The MCRB by [14] to the variance of  $\hat{\lambda}(\mathbf{z}) - \lambda$  is the following

$$MCRB(\lambda) = \frac{1}{E_{\mathbf{z},\mathbf{u}} \left\{ \left[ \frac{\partial \ln p(\mathbf{z}|\mathbf{u},\lambda)}{\partial \lambda} \right]^2 \right\}} \quad (25)$$

This bound is found by [14] observing that

$$\begin{aligned} E_{\mathbf{z},\mathbf{u}} \left\{ [\hat{\lambda}(\mathbf{z}) - \lambda]^2 \right\} &= E_{\mathbf{u}} \left\{ E_{\mathbf{z}|\mathbf{u}} [(\hat{\lambda}(\mathbf{z}) - \lambda)^2] \right\} \\ &\geq E_{\mathbf{u}} \left\{ \frac{1}{E_{\mathbf{z}|\mathbf{u}} \left[ \left( \frac{\partial \ln p(\mathbf{z}|\mathbf{u},\lambda)}{\partial \lambda} \right)^2 \right]} \right\} \\ &\geq \frac{1}{E_{\mathbf{u}} \left\{ E_{\mathbf{z}|\mathbf{u}} \left[ \left( \frac{\partial \ln p(\mathbf{z}|\mathbf{u},\lambda)}{\partial \lambda} \right)^2 \right] \right\}} \\ &= \frac{1}{E_{\mathbf{z},\mathbf{u}} \left\{ \left[ \frac{\partial \ln p(\mathbf{z}|\mathbf{u},\lambda)}{\partial \lambda} \right]^2 \right\}} \end{aligned} \quad (26)$$

where the first inequality derives from application of the CRB to the estimator  $\hat{\lambda}(\mathbf{r})$  for a fixed  $\mathbf{u}$ , while the second is true in view of Jensen's inequality and the convexity of the function  $\frac{1}{x}$  for  $x > 0$ .

In spite of having same structure of CRB and MCRB, MCRB is much easier to use. For Gaussian Channel, the probability density for (25) is a well-known exponential function whose argument is a quadratic form in the difference between  $\mathbf{z}$  and the signal  $\mathbf{s}$ . Thus the logarithm of  $p(\mathbf{z}|\mathbf{u},\lambda)$  equals this quadratic form and the expectation in (25) is readily derived.

The MCRB of symbol epoch ( $\tau$ ) by [5] is given by

$$MCRB(\tau) = \frac{1}{8\pi^2 L \xi} \frac{T^2}{E_s/N_0} \quad (27)$$

where  $L$  is the number of symbol intervals on which receiver bases its timing estimate on the observation on the received signal,  $T$  is the symbol interval,  $E_s$  is the energy of one symbol waveform and  $\xi$  is an adimensional coefficient depending on the shape of  $g_0(t)$ :

$$\xi = \frac{\int_{-\infty}^{\infty} T^2 f^2 |G(f)|^2 df}{\int_{-\infty}^{\infty} |G(f)|^2 df} \quad (28)$$

MCRB for a normalized  $\tau$  is given by [15] where  $\tau$  is between 0 and 1. The MRCB is

$$MCRB(\tau) \geq \frac{1}{2L\Gamma(E_s/N_0)} \quad (29)$$

where

$$\Gamma = \frac{T^2}{E_s} \int_0^T g_d^2(t) dt \quad (30)$$

where  $g_d(t)$  denote the time derivative of  $g_0(t)$ ,  $E_s$  is the symbol energy. For a raised cosine pulse  $\Gamma = \frac{4\pi^2}{3}$ .

Fig. 4: NDA-NML estimator error variance performance.

Figure 4 shows variance of the NDA-NML estimator with respect to CRB and MCRB. It is demonstrated in [14] that MCRB is generally lower than (at most equal) to the true CRB. The simulation result exhibits that the CRB is always greater than MCRB and the variance of the estimator is greater than CRB and MCRB as well. The variance of the estimator decreases as the number of symbols contributed for the timing estimation increases. It is easy to implement the NDA-NML estimator and the complexity is low as well.

### VI. TIMING ESTIMATOR OPERATING UNDER RAYLEIGH FADING CHANNEL

The statistical characteristics of a fading channel can be modelled using various probability density functions. In mobile radio channels, the Rayleigh distribution is commonly used to describe the statistical time varying nature of the received envelope of a flat fading signal, or the envelope of an individual multipath component. It is well known that the envelope of the sum of two quadrature Gaussian noise signals obeys a Rayleigh distribution [16], [17], [18]. The Rayleigh distribution has a probability density function given by

$$f(r) = \begin{cases} \frac{r}{\sigma_h^2} \exp\left(-\frac{r^2}{2\sigma_h^2}\right), & 0 \leq r \leq \infty \\ 0, & r < 0 \end{cases} \quad (31)$$

where  $\sigma_h$  is the root mean square (rms) value of the received signal before envelope detection. In our system model the sampled received signal experiencing Rayleigh fading can be expressed by (5) where the fading process  $h(kT_s)$  is Rayleigh-distributed. If we use  $h$  in place of  $h(kT_s)$ , it can be expressed as:

$$h = (\sqrt{h_I^2 + h_Q^2}) \quad (32)$$

where  $h_I$  and  $h_Q$  are uncorrelated and independent of each other and follow correlated Gaussian distribution. The correlations among the samples are achieved passing the Gaussian distributed samples through a spectral shaping filter. In our case we use a digital one dimensional filter to correlate the samples. The coefficients of the filter are given by:

$$\mathbf{A} = \left[ 1 \quad -\exp\left(-\frac{\gamma}{Fs}\right) \right], \text{ and } \mathbf{B} = \gamma \quad (33)$$

where  $\gamma$  defines the amount of correlation in  $h(kT_s)$  and  $F_s$  is sampling frequency. The filter is a "Direct form II Transposed" implementation of the standard difference equation:

$$A(1)y(n) = B(1)x(n) - A(2)y(n-1) \quad (34)$$

where  $X$  is the input to the filter and  $Y$  is the filtered output. The channel energy is maintained to be unity so that the received SNR is not changed. Figure 5 shows

Fig. 5: Bit error performance of NDA-NML estimator under fading conditions.

the bit error performance for timing estimator operating under Rayleigh fading channel. The amount of correlation has a significant effect on BER performance. Figure 5 exhibits that the BER performance for the timing estimator improves as the  $\gamma$  increases under fading conditions.

## VII. CONCLUSION

Statistical performance of a NDA-NML timing estimator was presented. Several interesting aspects of the timing estimator were revealed examining the statistical distribution of the estimator. The expression for the probability mass function of the timing estimates was derived and compared with the simulated density function. The performance of the estimator was assessed considering the BER, and the error variance was compared to the CRB and MCRB for AWGN channel. The performance of the estimator

was also studied when operating under a Rayleigh flat fading channel by calculating the BER for different fading conditions.

**Abstract** — Inter-technology roaming is known as one of the interesting challenges toward fourth generation of mobile and wireless communication. While FMIPv6 standardizes the fast handoff solutions in IP layer, the issues of media independency are being investigated through IEEE802.21 project. The integration of these two standards is believed to result in solutions for vertical handoffs between different network technologies. This paper presents an improved link layer mechanism to assist FMIPv6 for seamless vertical handoffs. We introduce a new access router discovery method and propose a vertical handoff algorithm accordingly. Further, we report the implementation details performed through simulations. The simulations evidence performance improvements in terms of latency and packet loss. It is also analytically shown that by enabling access router discovery method and improving link layer event services, an MN can be well prepared for handoff and perform faster movements.

**Index Terms** — Vertical handoff, Heterogeneous networks, FMIPv6, MIH, Access router discovery.

## I. INTRODUCTION

The coexistence of various communication systems with different network characteristics (i.e. bandwidth, delay, cost etc) requires seamless mobility solutions to facilitate a Mobile Node (MN) for inter-technology roaming which in turn requires a seamless inter-system handoff. Fast handoff for Mobile IPv6 (FMIPv6) provides solutions for intra-system handoffs in wireless IP networks. IEEE802.21 on the other hand, deploys link layer solutions for heterogeneous media in inter-system handoff. Alongside the standards, the integration of these two protocols has been the concern of several proposals which were based on using link layer triggers for access network independency purpose and preparing information for FMIPv6 protocol which in turn, can result in seamless handoffs for heterogeneous networks. Further to the use of specific link layer messages, we believe that the use of a router discovery method in a proper timing fashion enables MN to learn about necessary IP layer information and the prospective network ahead of time which results in lower handoff latencies together with smaller losses in packet stream. Hence, we introduce an improved access router discovery (i-ARD) method in this paper together with an improved link layer mechanism that assist FMIPv6 and perform seamless vertical handoffs. It is shown through

analysis that by enabling the proposed i-ARD method and the improved link layer event services, an MN can be well prepared for handoff and can perform faster movements. In order to evaluate the performance of the proposed method, we implemented our model and FMIPv6 through simulations and made a comparison in terms of latency and packet loss the two models cause with different types of packet streams. The rest of the paper is organized as follows: Section 2 introduces the structure of FMIPv6 standard and discusses the process IEEE802.21 media independent handoff, followed by a report on the other related researches in integrating these methods. Section 3 describes the proposed model and algorithms of i-ARD and improved layer-2 operations in details. In section 4, we report on the simulation implementations of the proposed method which is followed by the results achieved in the latter part. Section 6 presents an analytical performance inspection of the proposed model and comparisons made to FMIPv6 and finally, the conclusions make the last section.

## II. RELATED WORKS

This part gives a comprehensive explanation of the standards and ongoing works.

### A. FMIPv6

FMIPv6 [1] is a layer-3 solution which deals merely with IP-layer messages and initially intends to overcome the drawbacks of MIPv6 [2] basic handoff addressing the latencies introduced through the operations of movement detection, CoA stateless autoconfiguration including DAD procedure, and BU. The protocol mainly focuses on two problems: start of sending packets by MN immediately after new subnet detection, and sending packets by nAR immediately after MN is detected. This is performed during Handoff Initiation (HI) period while MN is connected to the network through old AR (oAR). During this period, MN sends Router Solicitation for Proxy Advertisement (RtSolPr) message to oAR and receives the advertised prefixes of nAR through Proxy Router Advertisement (PrRtAdv) message. This is a link layer mechanism and delivers the L3 information of the new

<sup>1</sup> Correspondent author email: vsolouk@ieee.org

network from oAR to MN. FMIPv6 protocol assumes the existence of a mapping table of L2 and L3 information in oAR by which neighboring MAC addresses are resolved to the corresponding AR prefixes.

Although FMIPv6 was designed to overcome the major drawbacks of MIPv6 handoff, it still leaves some deficiencies behind together with introducing other shortcomings. Primarily, due to the usage of limited L2 triggers in Handoff Initiation (HI) mode, it lacks a precise anticipation which may cause falsely-picked prospective ARs. While mapping table is supported by AR by exchanging neighboring information between ARs, FMIPv6 does not introduce any protocol or solution of implementing it in oAR. Furthermore, in order to overcome long DAD procedure problem, the whole operation is carried out during HI mode while the old connection is maintained. However, if DAD takes longer than normal, the connection to oAR might fail. This condition is a possibility and FMIPv6 suggests reactive mode of handoff which is equal to basic MIPv6 handoff in terms of the latencies occurred. Another process delay is introduced by FMIPv6 during neighbor discovery procedure during the exchange of NS and NA messages. This process in MN together with the message exchange duration might take several seconds and despite the use of Fast Neighbor Advertisement (FNA) in FMIPv6, the process is likely to take about 800 ms.

### B. IEEE802.21

IEEE802.21 standard [3] is being developed to enable handoff and interoperability in heterogeneous networks as Media Independent Handover (MIH). The proposed handoff procedure utilizes the information achieved from both MN and the network side. The link layer of this framework is focused on providing link intelligence information of the networks in neighborhood to the upper layers for an optimized handoff between heterogeneous networks. The link intelligence information includes network discovery and selection processes. IEEE802.21 introduces a new entity called MIH Function (MIHF) as a

shim layer between layer-2 and layer-3. The main functionality of MIHF is to provide three groups of services to upper layers or MIHF users from the area under the coverage of different networks. This is done by making use of a unified interface which is called Service Access Point (SAP). This unified interface is found in two modes: a Media Dependent mode that interfaces MIHF to heterogeneous link layers, and Media Independent mode which is the interface to upper layers and exposes services to MIHF users. The provided services reflect three groups of information and operations respectively.

The deployment of service primitives described above by IEEE802.21 is claimed to have the considerations of supporting various types of layer-3 mobility management protocols, especially MIP, MIPv6 and SIP. However as MIHF shim layer focuses mainly on solving media independency problem, it operates closer to layer-2 than dealing with mobility management protocols of layer-3. In order to reach an optimized seamless handoff in heterogeneous networks a fair interoperability between layer-2 operations and layer-3 mobility management protocols, particularly handoff management protocols seems to be inevitable.

### C. Integration of FMIPv6 and IEEE802.21

Despite the fact that FMIPv6 and IEEE802.21 are both aiming to improve handoff in different aspects, FMIPv6 merely deals with radio access heterogeneity and layer-2 mechanisms and focuses mostly on IP-layer messages. In contrast to FMIPv6, the aim of IEEE802.21 is to give a solution to vertical handoff while it deals mostly with media independency and improving layer-2 mechanisms. On one hand, FMIPv6 is claimed to be independent of the whole link-layer features and link specifications are considered to be customizable, on the other hand, while MIH services of IEEE802.21 are useful for link layer triggers, improving MIPv6-based vertical handoffs is very limited with the existing MIH primitives due to the fact that 802.21 is merely concerned with detecting layer-2 information.

Integrating these two protocols to optimize vertical handoff has been the concern of few proposals in this regard. Inadequacy of MIH primitives (MIES primitives as claimed) is the motivation of a work proposed in [4] where a new primitive, namely MIH-PrefixInfo including the prospective AR info was adjoined to L2 events and based on modified events, a similar mechanism to FMIPv6 for handoff is proposed. Although this work originally addresses the issues of anticipation and hesitant mobility in FMIPv6, a method was not indicated for AR discovery and information gathering from the neighborhood. In addition to the cost

Figure 1: MIHF shim layer interconnection

of improving L2 primitives, the proposed handoff mechanism leaves more deployment issues in AR.

Another solution was suggested in [5] and through a protocol for discovering AR information called Access Router Information Protocol (ARIP). This approach is based on IETF SEAMBOY working group project [6] defined as Candidate Access Router Discovery (CARD). The method uses Radio Access Network Discovery (RAND) protocol to propose a complete layer-2 solution while it still involves layer-3. The method is independent of the mobility management and can be applied to both homogeneous and heterogeneous environments as it does not rely on radio access technology. The information on neighboring ARs (ARIP) is provided at AR and sent to MN. However, the protocol suggests no method on how to collect ARIP info from AR and how the procedure should be initialized. In addition, the protocol still requires AR deployment which is a technology obstacle.

Improving MIIS services was also the concern of few other proposals. Information in MIIS is specified in common formats and as mentioned earlier these information aid handoff decision-making process. Selecting a higher layer mechanism of mobility management to obtain information of neighboring networks from different access technologies is how MIIS information primitives are utilized in [7] and [8]. The higher layer mobility management is a SIP-based mechanism and the method was tested with an MN having two neighboring subnets to select. These approaches suggest the MIH information be obtained by MN through several query/response messages to estimate the network. Once the network is chosen, MIH info reaches MN through request/response messages between MN and nAR. These works are mainly focused on improving SIP-based mobility management particularly handoff and the results were also compared accordingly.

### III. PROPOSED MODEL

As discussed previously, inefficiently performed access router discovery method in FMIPv6 results in considerable delay which contributes to the overall delay of handoff procedure. In addition, more problems such as hesitant mobility (causing ping-pong effect) are bound to happen when the actual target network is not selected precisely. Aiming to reduce the latencies in handoff initiation phase, we propose an improved access router discovery (i-ARD) method to achieve a precise prediction of the prospective serving network. Through this method, the message exchange between ARs is initiated using an established tunnel, whereby neighboring ARs are enquired for

necessary information, and the mapping table at AR is updated according to the MN needs. Consequently, we propose a handoff model in which i-ARD is responsible for acquiring neighboring ARs information as a replacement to MIIS. Therefore, the procedure of information service (MIIS) discovery which consumes much time due to DHCP server delay will be eliminated. For instance, the functionality of delivering the list of all available links which is usually performed through Link-List trigger is replaced by ARID-Info. In case of receiving the link details of candidate AR (cAR) from MN, the serving AR identifies this AR as a prospective network based on its network prefix. This means that the existing mapping table in AR is used for two purposes; the information availability for MN's on-demand requests and to further handoff preparations by AR as the candidate AR for handoff is determined. Based on these functionalities, by using i-ARD, no mapping table or local cache is needed to be maintained in MN since i-ARD protocol is applied mainly between ARs.

In our approach, we use specific service primitives in certain schedules aiming to deliver the necessary information to each node at proper time which in turn leads to fair handoff decision and execution with affordable latency and packet loss. Table 1 outlines the primitives and the related parameters we utilized in the protocol.

#### A. Proposed Algorithm

Figure 2 demonstrates the proposed handoff mechanism using the techniques explained earlier. Prior to any operation, the MN needs to register for MIH services. This can be done while MN has not yet detected its movement and therefore has not initiated any of handoff

process modes. The i-ARD procedure is the next operation which is usually performed at intervals or at any new AR activation. Unlike CARD protocol [6] that specifies the address resolution of ARs based on L2 IDs and initiated by MN, in i-ARD the address resolution procedure is performed in the oAR in which MN is currently served by. During i-ARD phase, the oAR enquires all candidate ARs using iARD-Req multicast

message and receives the information of active and potential ARs through iARD-Rpl reply message. The list of candidate ARs is a combination of two sources; the ARs reported to oAR by MN in certain intervals and the ARs in the vicinity of the reported candidate Access Routers (cAR) which is determined by oAR. Through this advance discovery method, a new entry for each discovered AR is created in oAR and the mapping table will be updated. These entries are available to MN on every request. Based on selected attributes of each network, ARs are classified and sorted in the mapping table by the technology in use.

TABLE 1: MIH PRIMITIVES AND RELATED PARAMETERS

| Primitive  | service | Parameters            |
|------------|---------|-----------------------|
| Link_Avail | ES      | AR prefix , Interface |
| Link_Goin  | ES      | Interface ID, oAR     |
| Link_Down  | ES      | Interface ID, nAR     |
| Link_Swite | CS      | HO mode, Interface ID |
| Link-Up    | ES      | Interface ID, nAR     |

Table 2 indicates the form that AR data are stored and sorted. The location ID code is used to identify the cARs in geographical vicinity which might be different from network neighborhood.

### B. Protocol Description

The actual handoff procedure starts as soon as MN senses an increase in one of the neighboring networks' signal strength. At such a situation, the MN sends ARID-Req message to oAR including L2 ID of the new network. By referring to the mapping table, the oAR specifies the candidate network which MN wants to handoff to. This cAR selection job is performed by oAR based on the information obtained through i-ARD. Since the prospective AR is already specified, the oAR then configures a new care-of address (nCoA) for MN using the new network prefix and MN link ID, initiates an FBU for the new address, and replies the MN with ARID-info including the information of the cAR which corresponds

to the existing L2 ID. These two messages replace router solicitation and advertisement messages (RtSolPr and PrRtAdv) introduced by FMIPv6 protocol indications. By this message, MN is informed of its nCoA together with the prospective AR. Referring to Link Type field included in ARID-info, the MN knows that it should configure its second interface with the nCoA it has received. At the time that MN moves toward the new network, a Link-Going-Down (LGD) trigger which is a result of signal degradation in the old interface will be issued from MIH to inform IP layer of the link degradation. As the signal indication reduces

Figure 2: Proposed handoff algorithm

TABLE 2: I-ARD INFORMATION FORMAT

| AR | Link Type | MAC | Prefix | Available BW | Location ID |
|----|-----------|-----|--------|--------------|-------------|
|----|-----------|-----|--------|--------------|-------------|

TABLE 3: SIGNIFICANT SIMULATION PARAMETERS

| Parameter                | Value             |                   |
|--------------------------|-------------------|-------------------|
|                          | Heavy Load        | Medium Load       |
| Inter-Request Time       | Exponential (360) | Exponential (720) |
| File Size (Bytes)        | Constant (50,000) | Constant (5,000)  |
| Start Time               | Uniform (100,110) | Uniform (5, 10)   |
| <b>Model Assumptions</b> |                   |                   |
| Beacon interval          | 0.01 s            |                   |
| AR trans. power          | 0.0005 w          |                   |
| MN rec. threshold        | -95 dBm           |                   |

simultaneously in oAR, an LGD trigger is also issued from MIH to IP layer in oAR and we specify this event as the start of handoff initiation (HI) and tunnel establishment between the two ARs. Since the tunnel establishment and binding update are the most time consuming processes, we introduce an overlapping operation allowing oAR to initiate HI/Hack operation during the waiting time for binding acknowledgement (FBack).

However, the packet forwarding to nAR starts right after the oAR receives and delivers FBack to both oAR and MN. Now that the MN received FBack, it activates the second interface and establishes a low layer connection to the nAR while disconnecting the old connection. This L2 handoff process is performed through a Link switch (LS) command event which is received by MIH layer at both oAR and MN. The events to issue LS command are the start of packet forwarding and receiving FBack at oAR

Figure 3: Network topology

and MN respectively.

As indicated in figure 2, there would be enough time for the MN to prepare for L2 handoff and link switch while shorter time is required at oAR for this operation. Thus, we show through simulation that these two events are properly scheduled.

When the Link Up (LU) trigger is received right after new connection establishment, the MN is fully attached to the new network and sends an Unsolicited Network advertisement (UNA) message to the nAR to ensure start of packet forwarding through the new connection. Now the MN can complete binding update with its home network.

#### IV. SIMULATION IMPLEMENTATIONS

In order to evaluate the performance of the proposed algorithm, we developed a model in which new modifications were applied to the current AR and MN modules. Using OPNET Modeler [9], three WLAN access routers together with a Serving GPRS Support Node (SGSN) build the ARs of our heterogeneous environment, while an FTP server plays the role of a Correspondent Node (CN). We also developed a special mobile node (MN) with WLAN and UMTS interfaces. The developed network model using OPNET is shown in figure 3 where the MN moves toward WLAN network through a predefined trajectory while communicating with its current point of attachment. The network condition is set to be free of any congestion so that the delays pertaining to long network access due to queue congestions in AR is eliminated.

The ARs are collocated with Access Points (AP) [10] as a true representation of real life situations while the Node\_b is apart from RNC and covers a large cell. The MN uses two interfaces to WLAN and UMTS networks with the related MAC layer in each interface. The MIH layer was created as a node model and placed before the MIP model. Figure 4 depicts the implemented mobile node model with two interfaces, MIP, and MIH layers. For the purpose of media homogeneity, a node level entity, so called MAC unifier has been created to recognize, specify, and deliver

the messages of each interface prior to entering the MIH module. The same MIH modules together with MIP layer were created on the standard implementation of AR to support MIH messages and triggers and FMIPv6 protocol. Alongside the implemented modules and node models, new process models which implement the new messages and procedures were also created. While ATM links were used between UMTS network entities; because of the nature of device connection in WLAN [11], the connection type between the gateway and AR in WLAN environment was 10Mbps Ethernet.

The radiuses of the areas under the coverage of ARs and the Node\_b were obtained through several simulation tests and were also based on the propagation and receiving parameters set for ARs and MN, respectively. The significant simulation parameters are based on [12] as summarized in Table 3.

#### V. NUMERICAL RESULTS

In order to measure the performance of the proposed protocol, two metrics of handoff latency and packet loss, were obtained from simulation runs based on the mobile node velocity. Roaming toward WLAN network implies the MN was assumed a pedestrian whose walking and running speeds are roughly 3 m/s and 7 m/s, respectively. Therefore, the simulations were run for the MN speeds of various intervals from 1 to 10 m/s for delay calculations and from 1 to 7 m/s for lost packets. Figures 5 and 6 depict the statistics obtained from the simulation runs. The vertical handoff model using i-ARD procedure is clearly comparable with FMIPv6 in terms of handoff delay and packet loss. For heavy FTP load conditions while FMIPv6 shows a latency of around 840 ms at walking speed of 2 m/s, handoff with i-ARD could complete in 372 ms. As a worst case we consider a running user at speed of 7 m/s and it could be seen that the handoff delay exceeds 1.2 s when using FMIPv6 while at the same situation handoff using i-ARD can still be tolerated with approximately 600 ms delay.

The difference is even more obvious with packet loss

Figure 5: Handoff latency at different node speeds

Figure 6: Packet loss

metric. At a walking speed of 2.5 m/s, handoff using i-ARD causes the loss of 8 packets in heavy load whereas, MN using FMIPv6 lost 61 packets which will affect real-time traffic. By increasing mobile moving speed, handoff using i-ARD barely causes 20 packet losses whereas FMIPv6 was measured to introduce over 100 packet loss. In the proposed algorithm, i-ARD procedure occurs prior to any trigger and handoff process therefore, the information is already prepared and ready to deliver to MN. This will omit the process cost in nAR. In reality, the total process of CARD is reported as 500 ms by several experiments [10] from which the major portion belongs to the processing portion of the algorithm. DAD procedure is reported to take around 1000 ms and each message exchange time between fixed nodes is 10 ms. Round-trip transmission between MN and each of the nodes could vary between 50 ms and 500 ms. Assuming equal situations in a comparative scenario for two methods, total handoff process in the proposed method is decreased by five transmission delay times between MN and either of ARs and additional 2 times process delay in oAR, which is a minimum of 300 ms and a worst case of 2500 ms. This difference range was also shown through simulation tests as reported earlier. As mentioned earlier, along with the protocol, one of the significant issues addressed here is process timing, especially while using i-ARD or any other alternative for access router discovery.

## VII. CONCLUSION

In this paper, a method for integrating layer-2 and layer-3 protocols to achieve seamless vertical handoff is proposed. The proposed algorithm improved link layer event services, applied an improved access router discovery mechanism for discovering neighboring access routers, and finally integrated the mechanisms with layer-3 mobility protocol to form a seamless handoff process. It was also shown that proper timing operation sequences can avoid significant processing delays. The proposed algorithm shows lower latency and affordable packet loss compared to FMIPv6. In order for the proposed approach to be applicable to UMTS systems, the event service primitives should be supported by UMTS link layer in real environment.

## ACKNOWLEDGEMENT

The authors wish to acknowledge the assistance and support of OPNET laboratory of University of Malaya and especially Professor Kaharudin Dimyati.

# BER Performance of Coded MSK/Multi-channel CDMA Fourth Generation Synchronous Downlink Cellular Systems in the Presence of MUI and FO

M. Abou El-Nasr

Arab Academy for Science and Technology (AAST), Alexandria, Egypt  
Department of Computer Engineering

**Abstract**—This paper studies the (BER) performance of synchronous coded Minimum Shift Keying/ Multi-channel Code Division Multiple Access (MSK/MC-CDMA) systems in the presence of Multi-access User Interference (MUI), and carrier Frequency Offset (FO). The theoretical effect of MUI on the BER performance was considered assuming the Standard Gaussian Approximation (GA) in AWGN channel. Furthermore, explicit simulations were carried out in AWGN and frequency selective Rayleigh fading channels for various parameters. The un-coded MSK/MC-CDMA system under investigation outperforms the corresponding system with BPSK modulation. Furthermore, a careful choice of coded MSK/MC-CDMA system parameters can achieve a better performance than the theoretical performance in AWGN channel for a single user and with no frequency offset or extra bandwidth requirements.

**Index Terms**—Algorithms, Downlink, Synchronous, Multi-access User Interference (MUI), Multi-Carrier, CDMA, Coding, and Minimum shift Keying (MSK) Modulation.

## I. INTRODUCTION

Multi-channel code division multiple access (MC-CDMA) scheme combines the high bandwidth efficiency in addition to the robustness against the distortion caused by multipath frequency selective fading channels. Moreover, MC-CDMA is an attractive candidate for future mobile communications. Specifically, it allows for low complexity receivers in the downlink, since the use of multi-carriers combats the effect of inter-symbol-interference (ISI) [1], [2]. However, the performance of this system is sensitive to both Multi-access User Interference (MUI), and frequency offset (FO) [3], [4].

A modulation scheme that is commonly considered for mobile communication systems is the Minimum shift keying (MSK) modulation scheme, as it is a power efficient modulation scheme with constant envelope and has a self synchronizing capability [5], [6].

The use of random spreading gives an upper bound on the bit error rate (BER) performance, and the exact analysis of the BER performance under these conditions seems to be significantly difficult. Hence, efficient approximations are desirable. The simplest well known approximation for the BER performance is the Standard Gaussian Approximation (GA), in which the overall effect of MUI in a

symbol interval is approximated by a Gaussian random variable. Moreover, it can be generalized to linear modulations and error control coding [7], [8], [9], [14], [15], [16], [17], [18].

Error control coding can be used with MC-CDMA systems with no extra bandwidth penalty due to the addition of redundant bits. This makes the application of error control coding very attractive in MC-CDMA systems. The error control coding technique considered in this paper is the cyclic block code, as it is an efficient coding scheme, and is easily implemented [13].

The organization of this paper is as follows. First, Section II includes a description of the system model. Then, Section III studies the BER performance in AWGN channel using GA. The simulation model is given in Section IV followed by numerical results obtained from simulations in AWGN channel and frequency selective fading channels for both un-coded and coded MSK/MC-CDMA synchronous downlink systems for a various number of interferers in Section V. Finally, conclusions are provided in Section VI.

## II. SYSTEM MODEL

The system under investigation, depicted in Fig. 1, has  $R$  users with corresponding  $R$  sequences of symbols. For the un-coded system, the  $R$  sequences are obtained after spreading each with spreading factor ( $S$ ) and MSK modulated. When coding is applied, the sequence is first coded and then MSK modulated after it is being spread. Without loss of generality, the spreading factor is assumed to be equivalent to the number of sub-carriers ( $M$ ). The effect of the  $R - 1$  interferers on the desired user is known as MUI [1]. Random spreading codes are applied under the assumption of perfect synchronization. Furthermore, the spreading codes are assumed to be dynamically changing from one bit to the other, and they are independent and identically distributed (*i.i.d*). All users are assumed to have equal powers  $P_r = P$ , under the assumption of perfect power control. The  $R$  users with MSK modulated symbols are spread and added.

The summation of the  $R$  users'  $m$ -th chip ( $m = 0, 1, \dots, M-1$ ) during the  $i$ -th bit interval is given by:

$$s_m(t) = \sum_{r=1}^R [b_i^r(t-t_0) \cdot c_{i,m}^r(t-t_0) - j b_i^{r-1}(t) \cdot c_{i,m}^{r-1}(t)] \cdot \exp(j\alpha^r) \quad (1)$$

Where,  $b_i^r$  represents the data bit of  $r$ -th user during  $i$ -th data bit, and  $c_{i,m}^r$  is the  $m$ -th chip in the  $i$ -th bit interval for the  $r$ -th user. The parameter represents  $r$ -th user carrier phase and  $t_0$  is the time offset required for MSK.

The baseband received signal impaired with frequency offset is given as [1]:

$$\hat{r} = \frac{1}{\sqrt{M}} \sum_{m=0}^{M-1} s_m \cdot \exp\left(j2\pi(m+\varepsilon)\frac{h}{M}\right) \quad (2)$$

Where,  $h = 0, 1, \dots, M-1$ , and  $\varepsilon$  is the normalized frequency offset.

### III. THEORETICAL BER PERFORMANCE

This section gives theoretical expressions for the BER performance of the system under study in AWGN channel, and it is compared to BPSK/MC-CDMA system. Moreover, the effect of the frequency offset on the BER performance is studied for both systems.

#### A. BER Performance of Un-coded MSK/MC-CDMA System

The effect of MUI on the BER performance in AWGN channel using GA for BPSK modulation with the assumption of chip and phase alignment for all users is as given in [5]:

$$P_b = Q\left(\sqrt{\frac{(2E_b/N_0)S}{R-1}}\right) \quad (3)$$

Where,  $E_b/N_0$  is the bit energy-to-noise ratio. For the case of MSK modulation, since it is a continuous phase frequency modulation technique, the effect of MUI is equivalent to the case where interfering signals are chip aligned with random phases. Thus, the probability of bit error is influenced by a factor of  $\sqrt{2S}$  instead of  $\sqrt{S}$  for the case of BPSK [5]. Hence, BER is expressed as:

$$P_b = Q\left(\sqrt{\frac{(2E_b/N_0)2S}{R-1}}\right) \quad (4)$$

This means that the BER performance of MSK/MC-CDMA systems outperform BPSK/MC-CDMA systems when the effect of MUI is considered, which is a critical factor that affects the performance of modern cellular systems.

The frequency offset has the same effect on both systems. The probability of bit error with frequency offset of the BPSK modulation case is expressed as [8]:

$$P_b = Q\left(\sqrt{\frac{\sin(\pi\varepsilon)^2(2E_b/N_0)S}{(\pi\varepsilon)^2(R-1)}}\right) \quad (5)$$

The probability of bit error with frequency offset assuming MSK modulation is expressed as:

$$P_b = Q\left(\sqrt{\frac{\sin(\pi\varepsilon)^2(2E_b/N_0)2S}{(\pi\varepsilon)^2(R-1)}}\right) \quad (6)$$

#### B. Performance of MSK/MC-CDMA System with Error Control Coding

Cyclic codes are linear block codes that have the advantage of being easy to encode, and have very efficient decoding schemes. Furthermore, cyclic codes are easy to implement using modern integrated circuit techniques [10], [11], [12], [13]. The codes considered in this paper are cyclic codes with code rates 7/15, 2/6, and 2/10.

The relation of the code-symbol energy per noise spectral density ( $E_c/N_0$ ), and the information bit energy per noise spectral density ( $E_b/N_0$ ) is given as [14]:

$$\frac{E_c}{N_0} = \left(\frac{k}{n}\right) \cdot \frac{E_b}{N_0} \quad (7)$$

Where,  $k$  is the number of message bits, and  $n$  is number of the codeword bits.

### IV. SIMULATION MODEL

A simulation model was carried out based on the parameters described in Section III-A. Moreover, computer simulations for the systems described in Section III-A were carried out in AWGN and frequency selective Rayleigh fading channels. The Frequency selective fading channel simulation was considered assuming that each sub-carrier experiences independent fading. A summary of simulation parameters is given in Table(1).

Fig. 1. MC-CDMA System Model.

TABLE I  
SUMMARY OF SYSTEM PARAMETERS

| Parameter                   | Value                                                                          |
|-----------------------------|--------------------------------------------------------------------------------|
| Modulation Schemes          | BPSK, MSK                                                                      |
| Spreading Factors           | $S= 32$ for un-coded system and $S= 16$ for coded system                       |
| Coding                      | Cyclic codes with code parameters $(n, k)$ of values (15,7), (6,2), and (10,2) |
| MUI                         | Synchronous users                                                              |
| Number of interfering users | $R=1, 3, 5$                                                                    |
| FO                          | $\varepsilon = 0, 0.2, \text{ and } 0.3$                                       |

## V. SIMULATION RESULTS

Figure 2 compares the BER performance of the system under study obtained via simulation in AWGN channel to the analytical form given by Eqn. (4), assuming 2, 4 and 6 users. As can be seen, the simulation results agree with the analytical expression. Next, Fig. 3 compares the BER performance of MSK/MC-CDMA and BPSK/MC-CDMA in frequency selective fading channel. As shown, the effect of MUI is less severe when MSK modulation is considered. Furthermore, simulation results assuming various values of the normalized frequency offset were considered in Fig. 4, where the effect of both the frequency offset and MUI on the BER performance is considered. Moreover, simulation results were compared to the theoretical expression defined by Eqn. (6). While increasing the frequency offset degrades the BER performance, its effect is independent of the number of multi-access users in the system. Figure 5 depicts the BER versus the number of users for various values of  $S$ .

Further simulations were carried out to investigate the performance of coded MSK/CDMA systems in AWGN and frequency selective fading channels. The linear block code employed is the cyclic coding with various code rates. Figure 7 compares the simulated BER performance of coded MSK/MC-CDMA to the theoretical performance of the un-coded case for the code (6,2). Moreover, Fig. 8 compares the simulated BER performance of coded MSK/MC-CDMA to the theoretical performance of the un-coded case for the code (10,2). As the code rate decreases, more enhancement is gained in the BER performance. It was noticed that the system with code (10,2) and 6 users outperforms the corresponding un-coded system with a single user.

In addition, simulations were carried out in frequency selective fading channels in order to investigate the effect of fading on the BER performance. Figure 9 compares the simulated BER performance of coded MSK/MC-CDMA to the theoretical performance of the un-coded case for the code (6,2). Moreover, Fig. 10 gives a comparison of the simulated BER performance of coded MSK/MC-CDMA and the theoretical performance of the un-coded case for

the code (10,2). The gain in the BER performance can be noticed with increasing the code rate without further increase in the bandwidth requirement.

Finally, the effect of frequency offset on coded MSK/MC-CDMA systems was investigated via simulation for various values of  $\varepsilon$  and  $R$  in AWGN and frequency selective fading channels. Figure ?? and Fig. 11 show the simulated BER of coded MSK/MC-CDMA using the code (15,7) in AWGN and frequency selective fading channel assuming various values of  $\varepsilon$  and  $R$  respectively. Figure 12 compares the BER performance of coded and un-coded MSK/MC-CDMA systems for the code (6,2) in AWGN channel for various values of  $\varepsilon$  and  $R$ . Furthermore, Fig. 13 and Fig. 14 show the simulated BER performance assuming the code (6,2) in AWGN and frequency fading channels for various values of  $\varepsilon$  and  $R$  respectively. Similarly, Fig. 15 and Fig. 16 depict the simulated BER performance assuming the code (10,2) in AWGN and frequency fading channels for various values of  $\varepsilon$  and  $R$  respectively. The effect of coding is clear in all results, specifically when increasing the code rate. Particular, in Fig. 16, the coded system with code (10,2),  $R = 2$ , and  $\varepsilon = 0.3$  gives a BER of  $1e-4$  at  $\text{SNR} = 8$  dB, whereas the un-coded system with  $R = 1$  and no frequency offset, given in Fig. 6 gives the same BER at  $\text{SNR} \approx 11$  dB in AWGN channel.

## VI. CONCLUSIONS

The effect of MUI on the BER performance of MC-CDMA systems with MSK modulation is less severe than the corresponding systems with BPSK modulation due to phase continuity. This applies in both AWGN and Rayleigh frequency selective fading channels. Nevertheless, the BER performance of these systems is sensitive to carrier frequency offset. However, the application of error control coding enhances the BER performance with no extra bandwidth penalty. A careful choice of the system parameters could result in a better BER performance of coded-MSK/CDMA systems with MUI and frequency offset in frequency selective fading channel than the corresponding un-coded systems with a single user in AWGN channel.

**Abstract** — This paper presents new Signaling System No. 7 (SS7) to IP based Signaling Transport (SIGTRAN) protocol interchanger software and related hardware to implement an improved distributed database based Automated Teller Machine (ATM) network where the countrywide existing IP network can be used. Currently the ATM network is based on fully centralized database environment. This leads to varying transaction time according to the ATM and central database. Moreover, link failure between central database and ATM leads to transaction failure. To overcome this problem, an improved distributed database system for ATM network is proposed. To deploy such network, a new software and related hardware is also presented which discards the need of costly new leased line or dial up connection. Using the software and hardware, the existing IP network can be used for expanding ATM network. Also the cost and benefits of the network is discussed by allocating fragment on different sites.

**Index Terms** — Automated Teller Machine (ATM), Distributed Database, SS7, SIGTRAN.

## I. INTRODUCTION

Currently all the ATM machines working around the world are based on the concept of centralized database system. Previously a distributed database base ATM network was proposed in [1]. In our paper, we have proposed an improved distributed database based ATM network. Cost and benefit of such network is discussed by allocating fragments on different ATM sites. And a new SS7 to SIGTRAN protocol interchanger software and related hardware is presented to deploy such ATM network using the existing countrywide SS7 network.

An ATM is simply a data terminal with two input and four output devices. Like any other data terminal, the ATM has to connect to, and communicate through, a host processor. The host processor is analogous to an Internet service provider (ISP) in that it is the gateway through which all the various ATM networks become available to the cardholder (the person wanting the cash).[2]

Fig. 1 ATM Connections

Most host processors can support either leased-line or dial-up machines. Leased-line machines connect directly to the host processor through a four-wire, point-to-point, dedicated telephone line. Dial-up ATMs connect to the host processor through a normal phone line using a modem and a toll-free number, or through an Internet service provider using a local access number dialed by modem. Leased-line ATMs are preferred for very high-volume locations because of their thru-put capability and dial-up ATMs are preferred for retail merchant locations where cost is a greater factor than thru-put. The initial cost for a dial-up machine is less than half that for a leased-line machine. The monthly operating costs for dial-up are only a fraction of the costs for leased-line. The host processor may be owned by a bank or financial institution, or it may be owned by an independent service provider.

If we could find a way to connect the leased line or dial up based ATM network to the countrywide existing IP network, then this would result a tremendous reduction of cost. Because leased-line or dial-up ATM network is much most costly than IP network. To use the IP network for ATM, we have designed the new software and hardware. The ATM machine has ports to communicate via lease line or dial up connection. We have designed E1 card that will be used to connect this ATM machine directly to an IP network. The E1 card performs the job of interfacing and the software performs the job of protocol interchanging e.g SS7 to SIGTRAN. An improved distributes database base ATM network is proposed in II, the software architecture is discussed in III while the hardware architecture is discussed in IV.

## II. DISTRIBUTED DATABASE BASED ATM NETWORK

According to current scenario, any request from a user is passed to the client's bank to the institution who issued the card. If a request is issued from a distant place then much time is required to send the request to the cardholder's bank or the institution who issued the card. A much convenient approach would be to store the client's information in multiple branches of the bank. This is done by dividing the global database into fragments. The fragments are allocated to one or more sites. The steps to apply the distributed concept in ATM network are,

- The first issue would be to inquire the client about the frequently accessed places. Then the client information is stored in all the branches those were identified by the client as frequently accessed places. Host processor is updated about which branches contain client information.
- The second issue deals with any request issued by the client to the ATM. The ATM forwards this information to the host processor. The host processor, on receiving the request determines which branch is nearest neighbor that stores information of that client from the place the request is issued. The nearest neighbor based on composite vectors can be determined with the help of the following equation [2]

$$Metric = K_1 * BW + \frac{K_2 * BW}{256 - Load} + K_3 * Delay \quad (1)$$

Where, Metric = factor that store a host processor in its database for its every neighbor.

K1, K2, K3 = Constant used to weight the effect of routing metrics. The default values for K1 and K3 are 1 and for K2 is 0. If we consider the default constant values, the basic metric calculation just reduces to

$$Metric = BW + Delay \quad (2)$$

Regardless of whether we used the default values, the result of the metric calculation is a composite metric that can fairly evaluate potential routes through a highly diverse network. The value of this composite metric is frequently described as the cost of a route. The route with the lowest cost is the best route.

- After determining the nearest neighbor, the host processor routes the transaction request to it and the transaction is performed. Transaction is all other branches at the same account us locked to ensure atomicity. All the other branches that contain the same client information are also updated at the same time by sending the transaction information by the host processor to maintain concurrency control.

So, in order to apply distributed concept, we need to consider two phases which is shown bellow,

Fig. 2 (a) Initial account opening procedure, (b) Transaction processing

A global relation can be split into several non-overlapping portions called fragments. There are several ways to split the global relation into fragments. The most common of them are Horizontal fragmentation and Vertical fragmentation. Fragments are physically located at one or several sites of the computer network. The allocation scheme defines at which site(s) a fragment is located. All the fragments, which correspond to the same global relation and are located at same site constitute the physical image of the global relation. For our proposed architecture we used horizontal fragmentation. To calculate the cost and benefits of the allocation of fragments of a global relation R, the following definitions are considered,

i is the fragment index, j is the site index, k is the application index,  $r_{ki}$  is the frequency of application k at site j,  $u_{ki}$  is the number of retrieval references of application k to fragment I,  $n_{ki}$  is the number of update references of application k to fragment i. Here,

$$n_{ki} = r_{ki} + u_{ki} \quad (3)$$

1. At first we determined the set of all sites where the benefit of allocating one copy of the fragment is higher than the cost, and allocate a copy of fragment to each element of this set. This method selects "all beneficial sites". We placed  $R_i$  at all sites j where the cost of retrieval of applications is larger than the cost of update references to  $R_i$  from applications at any other site.  $B_{ij}$  is evaluated as the differences:

$$B_{ij} = \sum_{i=1}^n f_{kj} r_{kj} - C * \sum_k \sum_{P \neq j} f_{kp} u_{ki} \quad (4)$$

C is a constant, which measures the ratio between the cost of an update and retrieval access.  $R_i$  is allocated at site j such that  $B_{ij}$  is positive. When all  $B_{ij}$  are negative, a single copy of  $R_i$  is placed at the site such that  $B_{ij}$  is maximum.

- Secondly, we determined the solution of the non replicated problem and then progressively introduced replicated copied starting from the most beneficial. The process is terminated when no additional replication is beneficial. We can measure the benefit by placing a new copy of  $R_i$  in terms of increased reliability and accessibility of the system. Let  $d_i$  denotes the degree of redundancy of  $R_i$  and let  $F_i$  denotes the benefit of having  $R_i$  fully replicated at each site. The function  $B(d_i)$  measures the benefit.

$$B(d_i) = (1 - 2^{-d_i}) F_i \quad (5)$$

Then we evaluated the benefit of introducing a new copy of  $R_i$  at each site j by modifying the previous formula as follows,

$$B_{ij} = \sum_{i=1}^n f_{kj} r_{kj} - C * \sum_k \sum_{P \neq j} f_{kp} u_{ki} + B(d_i) \quad (6)$$

For banking operation, we need to store particular client's information together. It is unusual to store client's name in one place and account number in another place. Rather all the information is kept together for easier access. For this reason we have avoided vertical fragmentation.

### III. PROPOSED SOFTWARE ARCHITECTURE

Protocol can be defined as the rules governing the syntax and synchronization of communication. We have worked with two protocols: SS7 and SIGTRAN.

Signaling System no. 7 (SS7) is a set of telephony signaling protocols [1], which are used in the telephone network. SS7 provides a universal structure for telephony network signaling, messaging, interfacing and network maintenance [2]. SIGTRAN is the name given to an IETF working group that produced specifications [3] for a family of protocols that provide reliable datagram service and user layer adaptations for SS7 and ISDN communications protocols. Our developed software along with our designed hardware is capable of taking data from telephone network and convert that to SIGTRAN protocol data defined by ITU-T [1][2][4]. Our developed software takes SS7

protocol data from SS7 network through designed USB E1 card then converts it to SIGTRAN data and transmits that data through Ethernet port. The working principle of our developed hardware and software is like,

Fig. 3 Working principle of the proposed system

The first part of the development of our software was to develop the protocol stack of SS7 and SIGTRAN protocol.

**SS7 Stack:** The SS7 protocol stack borrows partially from the OSI Model of a packetized digital protocol stack. OSI layers 1 to 3 are provided by the Message Transfer Part (MTP) of the SS7 protocol; for circuit related signaling, such as the Telephone User Part (TUP) or the ISDN User Part (ISUP), the User Part provides layers 4 to 7, whereas for non-circuit related signaling the Signaling Connection and Control Part (SCCP) provides layer 4 capabilities to the SCCP user [6].

The MTP[9] covers the transport protocols including network interface, information transfer, message handling and routing to the higher levels. SCCP is a sub-part of other L4 protocols, together with MTP 3 it can be called the Network Service Part (NSP). ISUP provides a circuit-based protocol to establish connections for calls. TCAP is used to create database queries and invoke advanced network functionality mobile services (MAP), etc. [7]

Fig. 4 SS7 protocol stack [8]

**SIGTRAN Stack:** The SIGTRAN protocols specify the means by which SS7 messages can be reliably transported over IP networks. The architecture identifies two components:

- A common transport protocol for the SS7 protocol layer being carried and
- An adaptation module to emulate lower layers of the protocol.

For example, if the native protocol is MTP (Message Transport Layer) Level 3, the sigtran protocols provide the equivalent functionality of MTP Level 2.

Fig. 5 SIGTRAN protocol stack [10]

The task of the data exchange between SS7 and SIGTRAN protocol is performed according to the following structure,

Fig. 6 SS7 and SIGTRAN protocol interconnection structure [11]

Our software exchanges SS7 protocol data via our designed USB E1 card and SIGTRAN protocol data from Ethernet port. This exchange of data between two different protocols takes place by analyzing the data [12] and maintaining the structure mentioned in figure 6. There are three part of the software which performs the data exchange operation. They are,

- Data reader
- Stack selector and
- Data exchanger

“Data Reader” window of our software is used to take SS7 data via E1 card or SIGTRAN data via Ethernet port. At first, the user has to specify the source to extract data for exchange. The selected source will be used as the base protocol which will be converted to the other protocol data. The software performing this task is shown bellow,

Fig.7 “Data reader” window of our developed software

“Stack Manager” window of our software lets the user to choose which message in the SS7 data is to be exchanged. It is very useful operation when the SS7 data length is very high. By choosing specific message, then user can reduce the number of exchanged messages so that only the desired message is transmitted. The software window of “Stack Manager” is shown bellow:

Fig.8 “Stack manager” window of our developed software

“Data Exchanger” is the last part of our software with which the selected portion of the base protocol is exchanged with other protocol. The software window performing data exchanging is shown bellow,

Fig.9 “Data exchanger” window of our developed software

#### IV. PROPOSED HARDWARE ARCHITECTURE

Our USB E1 card is an enhanced third-generation hardware that consolidates the essential pieces of industry-standard test equipment into a powerful, PC-Based USB E1 solution.

**PEF2256:** The PEF2256 is the latest addition to Infineon's FALC® family of sophisticated E1/T1/J1 framer and Line Interface Unit (LIU) transceivers which supports all standard E1/T1/J1 functions. [14]

**ATmega16:** ATmega16 is CMOS 8-bit microcontroller having 1 MIPS/MHz throughput. [15]

**FT245BM:** The FT245BM provides an easy cost-effective method of transferring data to / from a peripheral

and a host P.C. at up to 8 Million bits (1 Megabyte) per second. [16]

**74HC244:** These octal buffers are used to improve density of 3-state memory address drivers, clock drivers.

Using these ICs we have designed the USB E1 card. For avoiding complex PCB, we have designed the E1 card in two parts. They are,

1. Transceiver module: It includes transceiver IC, synchronizing clock, impedance matching transformer, transient voltage suppressor and connector for E1 link.

2. Controlling module: It includes microcontroller, USB interface, clock, serial and Parallel interface and power supply unit.

The schematics of the controlling and transceiver module are shown below:

Fig. 10 Transceiver module of the E1 card.

Fig. 11 Controlling part of the E1 card.

## V. RESULT

The hardware designing part is completed and currently it's working soundly.

Fig. 12 (a) Top and (b) Bottom layer of the designed PCB of the E1 card

SS7 and SIGTRAN data can be read [Figure 7] according to the selected structure [Figure 8] and exchanged using our hardware and software [Figure 9] successfully. This shows that the interfacing of ATM network and IP network is done successfully. One of the major achievements of our work is the tremendous reduction of the cost. The manufacturing cost of the hardware is very minute compared to the market price of similar range hardware. A PCI slot E1 card costs about 500\$ in the current market whereas our hardware costs only 35\$.

## VI. CONCLUSION

This paper presents new SS7 and IP based SIGTRAN protocol interchanger software and related hardware to implement an improved distributed database based Automated Teller Machine (ATM) network where the countrywide existing IP network can be used. The current growing demand of ATM machines makes it essential to increase the number of ATM booth and to make the transaction faster and reliable. At this point we believe that

our software and related hardware will be a feasible solution of current demand of increasing the ATM booth number at a very low cost using the existing IP network. Also the distributed database based ATM machines will be a perfect solution of providing faster and reliable service to the customers.

# Face Recognition using Gabor Filters

Md. Tajmilur Rahman and Md. Alamin Bhuiyan

Department of Computer Science and Engineering, Northern University Bangladesh and Department of Computer Science, Jahangir Nagar University, Shavar, Dhaka, Bangladesh.

**Abstract** — Gabor based face representation has achieved enormous success in face recognition. This paper addresses a novel algorithm for face recognition using neural networks trained by Gabor features. The system commences on convolving some morphed images of particular face with a series of Gabor filter co-efficient at different scales and orientations. Two novel contributions of this paper are: scaling of RMS contrast, and contribution of morphing as an advancement of image recognition perfection. The neural network employed for face recognition is based on the Multilayer Perceptron (MLP) architecture with back-propagation algorithm and incorporates the convolution filter response of Gabor jet. The effectiveness of the algorithm has been justified over a morphed facial image database with images captured in different illumination conditions.

**Index Terms** — Face Recognition, Gabor Filters, Morphing, RMS Contrast.

## I. INTRODUCTION

FACE representation using Gabor features has attracted considerable attention in computer vision, image processing, pattern recognition, and so on. The principal motivation to use Gabor filters is biological relevance that the receptive field profiles of neurons in the primary visual cortex of mammals are oriented and have characteristic spatial frequencies. Gabor filters can exploit salient visual properties such as spatial localization, orientation selectivity, and spatial frequency characteristics [1]-[2]. Considering these overwhelming capacities and its great success in face recognition, this paper addresses Gabor features to represent the face image and produces recognition task in tandem with neural network.

A fair amount of research works have been published in literature for Gabor based image recognition. Lades et al. developed a Gabor wavelet based face recognition system using dynamic link architecture (DLA) framework which recognizes faces by extracting Gabor jets at each node of a rectangular grid over the face image [3]. Wiskott et al. subsequently expanded on DLA and developed a Gabor wavelet-based elastic bunch graph matching (EBGM) method to label and recognize facial images [4]. In the EBGM algorithm, the face is represented as a graph, each node of which contains a group of coefficients, known as jets. However, both DLA and EBGM require extensive amounts of computational cost. Liu and Wechsler have developed a Gabor feature based classification protocol using the Fisher linear discriminate model for dimension reduction [5]. Shan et al. have developed an enhanced fisher

model using the AdaBoost strategy for face recognition [6]. Zhang et al proposed a face recognition method using histogram of Gabor phase pattern [7].

This paper proposes a Gabor filter coefficient based neural network approach for face recognition. Since rms contrast is sensible for image representation, attempts are focused on rms scaling. The scaling of rms contrast produces better recognition performance. Despite robustness, Gabor filter based feature selection methods are normally computationally expensive due to high dimensional Gabor features. To reduce feature dimension, this paper uses 15 Gabor filters; 3 for scaling and 5 for orientations.

The rest of the paper is organized as follows. Section II describes image pre-processing. Section III describes Gabor filter design. Section IV illustrates construction of the neural network with back-propagation algorithm. The experimental method and results are presented in Section V. Finally, in section VI, the results are discussed, conclusions are drawn and future works are proposed.

## II. IMAGE PRE-PROCESSING

The original images are first converted into gray scale images. Pointing the centers of two eyes on each face image, all images are properly rotated, translated, scaled and cropped into 100×100 pixels. Images are then subjected to some image pre-processing operations. The image pre-processing phase includes contrast and illumination equalization, histogram equalization, and morphing.

### A. Contrast and Illumination Equalization:

Contrast is a measure of the human visual system sensitivity. Although the role of contrast is significant in visual processing of computer displays, in almost all of the past literatures address the face recognition process in different lighting conditions with different illumination and contrast. To achieve an efficient and psychologically-meaningful representation, all images are processed with same illumination and RMS contrast. The RMS (root mean square) contrast metric, equivalent to the standard deviation of luminance, is given by [8]:

$$C_{rms} = \left[ \frac{1}{n} \sum_{i=1}^n (x_i - \bar{x})^2 \right]^{1/2} \quad (1)$$

Fig. 1 Illumination and RMS contrast equalization. Images were captured at illumination angles of  $-38.4^\circ$ ,  $-21.6^\circ$ ,  $-0.2^\circ$ ,  $20.6^\circ$ ,  $37^\circ$ , respectively.

Where  $x_i$  is a normalized gray-level value such that  $0 < x_i < 1$  and  $x$  is the mean normalized gray level. With this definition, images of different human faces have the same contrast if their RMS contrast is equal. The RMS contrast does not depend on spatial frequency contrast of the image or the spatial distribution of contrast in the image. All images are maintained with the same illumination and same RMS contrast using the following equation:

$$\mathbf{g} = \alpha \mathbf{f} + \beta \quad (2)$$

Where  $\alpha$  is the contrast and  $\beta$  is the brightness to be increased or decreased from the original image  $\mathbf{f}$  to the new image  $\mathbf{g}$ . The values of  $\alpha$  and  $\beta$  are chosen empirically. The illumination and RMS contrast equalization process is illustrated in Fig. 1.

### B. Histogram Equalization:

The face images may be of poor contrast because of the limitations of the lighting conditions. So histogram equalization is used to compensate for the lighting conditions and to improve the contrast of the image [9].

### C. Morphing the images:

Morphing is a special effect in motion pictures and animations that changes (or morphs) one image into another through a seamless transition. Most often it is used to depict one figure turning into another through some magical or technological means or as part of a fantasy or surreal sequence. We are using the pixel based morphing [10] technique to enhance the perfection of facial image recognition more. Morphing gives us some intermediate stages between the source and target image which we can consider as the intermediate poses if the two images are of a same person.

When a face is in motion; turning left to right or right to left or some other else, the image captured at that moment might have motion blur. In order to recognize images at different poses, five different rotated images of a particular face at angle of  $-20^\circ$ ,  $-10^\circ$ ,  $0^\circ$ ,  $10^\circ$  and  $20^\circ$  generates 12

intermediate changing moments from the four sequential pairs with 3 images from each pair. So we are getting 17 different rotated facial images for a particular face image.

## III. DESIGNING GABOR FILTERS

Gabor filter works as a band pass filter for the local spatial frequency distribution, achieving an optimal resolution in both spatial and frequency domains. The 2D Gabor filter  $\psi_{f,\theta}(x,y)$  can be represented as a complex sinusoidal signal modulated by a Gaussian kernel function as follows [11]:

$$\psi_{f,\theta}(x,y) = \exp\left[-\frac{1}{2}\left\{\frac{x_{\theta_n}^2}{\sigma_x^2} + \frac{y_{\theta_n}^2}{\sigma_y^2}\right\}\right] \exp(2\pi f x_{\theta_n}), \quad (3)$$

$$\text{where, } \begin{bmatrix} x_{\theta_n} \\ y_{\theta_n} \end{bmatrix} = \begin{bmatrix} \sin \theta_n & \cos \theta_n \\ -\cos \theta_n & \sin \theta_n \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} \quad (4)$$

$\sigma_x, \sigma_y$  are the standard deviations of the Gaussian envelope along the  $x$ - and  $y$ - directions,  $f$  is the central frequency of the sinusoidal plane wave, and  $\theta_n$  the orientation. The rotation of the  $x$ - $y$  plane by an angle  $\theta_n$  will result in a Gabor filter at the orientation  $\theta_n$ . The angle  $\theta_n$  is defined by:

$$\theta_n = \frac{\pi}{p}(n-1) \quad (5)$$

For  $n=1, 2, p$  and  $p \in \mathbf{N}$ , where  $p$  denotes the number of orientations.

Design of Gabor filters is accomplished by tuning the filter with a specific band of spatial frequency and orientation by appropriately selecting the filter parameters; the spread of the filter  $\sigma_x, \sigma_y$ , radial frequency  $f$ , and the orientation of the filter  $\theta_n$ . The important issue in the design of Gabor filters for face recognition is the choice of filter parameters. This research organizes 15 Gabor channels consisting of five orientation parameters  $\theta \in \left\{0, \frac{\pi}{5}, \frac{2\pi}{5}, \frac{3\pi}{5}, \frac{4\pi}{5}\right\}$  and three spatial frequencies,  $f \in \{0.6, 1.0, 1.4\}$  respectively.

The Gabor representation of a face image is computed by convolving the face image with the Gabor filters [12]. Let  $f(x,y)$  be the intensity at the coordinate  $(x,y)$  in a gray scale face image, its convolution with a Gabor filter  $\psi_{f,\theta}(x,y)$  is defined as:

$$g_{f,\theta}(x,y) = f(x,y) \otimes \psi_{f,\theta}(x,y) \quad (6)$$

where  $\otimes$  denotes the convolution operator. Fig. 2 illustrates the convolution result of a face image with a Gabor filter. The response to each Gabor kernel filter representation is a complex function with a real part  $\Re\{g_{f,\theta}(x,y)\}$  and an imaginary part  $\Im\{g_{f,\theta}(x,y)\}$  the magnitude response  $\|g_{f,\theta}(x,y)\|$  is expressed as:

$$\|g_{f,\theta}(x,y)\| = \sqrt{\Re^2\{g_{f,\theta}(x,y)\} + \Im^2\{g_{f,\theta}(x,y)\}} \quad (7)$$

This research uses the magnitude response  $\|g_{f,\theta}(x,y)\|$  to represent the features. To reduce the influence of the lighting conditions, the output of Gabor filter about each direction has been normalized. In the sequel, a transformation  $Q_{f,\theta}(x,y)$  to which  $\|g_{f,\theta}(x,y)\|$  is subjected is given by Fig. 3.

Fig. 3 Network architecture of Gabor based multi-layer Perceptron.

$$Q_{f,\theta}(x,y) = \frac{\|g_{f,\theta}(x,y)\|}{\sum_{\theta \in \Theta} \|g_{f,\theta}(x,y)\|} \quad (8)$$

The function  $Q_{f,\theta}(x,y)$  takes the value in the range  $[0, 1]$

and the parameter  $\theta$  is in  $\Theta \equiv \left\{0, \frac{\pi}{5}, \frac{2\pi}{5}, \frac{3\pi}{5}, \frac{4\pi}{5}\right\}$

#### IV. GABOR FILTER BASED NEURAL-NETWORK

Face recognition is achieved by employing a multilayer Perceptron with back-propagation algorithm. The architecture of the neural network is illustrated in Fig. 3.

Fig. 3 Network architecture of Gabor based multi-layer Perceptron.

The first layer, called Gabor layer, receives the Gabor features. The number of nodes in this layer is, obviously equal to the dimension of the feature vector incorporating the Gabor features. The number of nodes in the output layer equals to the number of individual faces the network is required to recognize. The number of epochs for this experiment was 10,000 and the goal was to reduce the error margin up to 0.01. The recognition algorithm is illustrated in a flowchart as shown in Fig. 4.

In order to evaluate the effectiveness of the proposed method, experiments were carried out for real images at different illumination conditions and different orientations.

We used CMU Pose, Illumination, and Expression (PIE) database [13] and selected 200 images of 40 individual subjects with 2 different poses and 5 different illumination conditions. Half of the images in the database were taken for the morphing process. Three intermediate images of the morphing process for each of the images of were used as a training dataset and the remaining images were used as probe images in the recognition test.

Fig. 4 Flow-chart of interactive image recognition for Human-Machine Interfacing.

All images were subjected to Gabor filters and were convolved with 15 Gabor filters. To each face image, the outputs were 15 images which record the magnitudes of the Gabor filter responses. Fig. 5 shows a typical face image being morphed and we took three different intermediate positions of morphing. Thus these three images (Fig. 5 i, ii, iii) were put into the database to train by Gabor filter. Fig. 6 shows the results for a typical face image.

Fig. 5 (a) Source image for morphing. (i) 30° pos (ii) 60° pos (iii) 90° pose of intermediate steps of morphing.

Fig. 6 Gabor filters response of a typical face image.

The output of the Gabor filters was used to train the neural network. The training curve, indicating the gradual reduction in error over several epochs due to back propagation learning algorithm, is shown in Fig. 7.

Fig. 7 Error versus iteration.

Fig. 8 Error Vs Iteration Graph for the image database without any morphed samples.

TABLE I  
RECOGNITION PERFORMANCE OF THE PROPOSED  
ALGORITHM

| Method                         | Correct Recognition (%) | Correct Rejection (%) |
|--------------------------------|-------------------------|-----------------------|
| EBGM                           | 75.29                   | 78.32                 |
| Log-polar                      | 77.38                   | 82.33                 |
| rms scaling Gabor              | 84.50                   | 87.75                 |
| Without any<br>Morphed Samples |                         |                       |
| rms scaling Gabor              | 96.07                   | 98.65                 |
| With Morphed<br>Samples        |                         |                       |

The graphical analysis implies that the training set of morphed images advances the learning and recognition process as well. This method can successfully trace the mutinous snapshots in between two different poses and increases the probability of recognition.

Finally, the effect of the proposed algorithm on the performance of face recognition has been analyzed. In order to evaluate the method for contrast equalization, we performed a comparison among our proposed system (rms scaling Gabor), the Elastic Bunch Graph Matching (EBGM), and the log-polar Gabor methods. The comparison results for the average recognition rates using different methods are furnished in Table I. The performance of the morphing process was evaluated for different images keeping the size of the source and target images same. To test the performance of using morphed intermediate poses for training set and image database we applied the gabor features to the image database not having any morphed samples. Two different image databases were created for the recognition of the face images. And trained for the process at a seed value of 0.5 and we got two different error vs. iteration graphs as shown in Fig. 7 and Fig. 8 respectively. For recognition we supplied same set of samples containing both images with motion blurs and without motion blurs to both the trained sets and the success rate of recognition was extensively high of our proposed method. Experimental results demonstrate that our method is capable of recognizing faces in gloomy environments also, with significant margin.

## VII. CONCLUSION

This paper presents a neural network based face recognition system using Gabor filter coefficients that can cope with illumination changes. The recognition performance has been improved substantially due to implication of contrast equalization using the rms value of the image pixels and adding the intermediate mutinous snapshots between two different poses by employing image morphing in the processing step.

A face recognition system should identify a face from a new image despite the variations between images of the same face. A common approach to surmount the impediments in image variations due to changes in the illumination conditions is to use image representations that are relatively insensitive to these variations. Examples of such representations are edge maps, image intensity derivatives, and images convolved with Gabor-like filters. This paper focuses on a pragmatic study that evaluates the effectiveness of the proposed method for facial images at different illuminations and different view angles. The processing time of Gabor transformation is reduced to less than one second with the image size of 100×100 pixels on a PC with a 1.2 GHz processor. From now on, the effectiveness of the method will be justified by testing it with face images of more persons and of some common databases. Since each pixel of the magnitude response of Gabor filter corresponds to a Gabor feature, the number of Gabor features for each sample is  $100 \times 100 \times 15 = 150,000$ . Therefore, our next step will be to improve the algorithm which would be able to employ more complex classifiers and distance measures to represent Gabor faces with spatial and frequency features.

# High-speed distance measurement between moving vehicles with NIR-LED markers

M. Fukuzawa, H. Hama, N. Nakamori, and M. Yamada

Graduation School of Science and Technology, Kyoto Institute of Technology,  
Matsugasaki, Sakyo-ku, Kyoto 606-8585, Japan

**Abstract** — An image-based technique with high measurement rate has been proposed to measure the distance between two moving vehicles. By combining several near-infrared (NIR) LED markers mounted on the forward vehicle with an NIR-filtered CMOS camera mounted on the backward vehicle, one can clearly recognize the marker shape and positions without any adjusting the focus lens of camera, and hence he can extremely reduce the time of digital preprocessing such as noise elimination and marker segmentation. The distance may be easily calculated from the geometrical transformation of the marker positions obtained in sub-pixel resolution from the gravity center of the pixel value. The image-based technique proposed here is actually examined in the vehicles moving on linear and curved tracks. It is experimentally confirmed that the measurement rate attains to 1000 frames/sec in the windowed image of 752×34 pixels, with a small processor with the clock of 600MHz, including the capture time of the image, the calculation time of the gravity center, and the geometrical transformation time. The measurement error is less than 1 % for the distance range of 0.5 to 3 m.

**Index Terms** — distance measurement, image processing, infrared imaging, motion control, moving vehicles

## I. INTRODUCTION

Distance measurement is one of important applications in the vision system for industrial use such as nondestructive testing of products and motion control of vehicles and robots. The high-speed measurement in the wide field of vision is strongly demanded for the high-speed motion control of cargo vehicles which are moving on a common track in production facilities.

In order to cover the wide field of vision, several techniques of distance measurement were developed. In the case using active light source, several laser range-finding techniques such as optical triangulation, time-of-flight, phase shift measurements and frequency modulated continuous wave (FMCW) method were proposed [1]. In the case of passive measurement, several stereo vision techniques and the depth-of-focus techniques were proposed [2-4]. Those techniques mentioned above took a time for image capturing and digital preprocessing such as laser scanning, focus adjustment, noise elimination, marker segmentation and stereo matching, although there was an advantage that a priori knowledge of shape and position concerning on target was not needed. Therefore, a

new technique is desired to develop for the high-speed measurement of distance in the wide field of vision.

In this paper, we proposed an image-based technique to measure the distance between two vehicles at the high measurement rate in the wide field of vision. Here, we assume that the forward vehicle on which several luminous markers are mounted and the backward vehicle on which a single camera is mounted to take the image of markers are moving on a curved rail track. All the backgrounds except markers are effectively eliminated by combining NIR-LED markers and NIR-filtered camera and hence the time of digital preprocessing may be extremely reduced. Then, the distance can be numerically calculated from a straightforward technique of image processing: that is, the geometrical transformation of the marker positions obtained in sub-pixel resolution from the gravity center of the pixel value. The formulation of the geometrical transformation is given below. Also, experimental results are shown for confirming the performance of proposed technique.

## II. A DISTANCE MEASUREMENT TECHNIQUE BASED ON A PROJECTION OF LUMINOUS MARKERS

Figure 1 shows our arrangement of two vehicles moving on a curved track, in which the vehicles are drawn as cube by solid lines. The center of rear panel of the forward vehicle is defined as the origin of a local coordinate system  $(x, y, z)$ , and the forward, left and upper directions are represented as  $x$ -,  $y$ -, and  $z$ -axes, respectively. The other local coordinate system  $(x', y', z')$  is linked to the backward vehicle in the similar manner to the forward vehicle. A distance between the origins of two coordinates is defined as  $d$ . An angle between the  $x$ - and  $x'$ -axes is defined as  $\phi$ . The other angle between  $x'$ -axis and the direction of  $d$  is defined as  $\theta$ . The  $d$ ,  $\phi$ , and  $\theta$  are the values to be measured in our study. In the forward vehicle, eight luminous markers are attached at the corner and the center on the front, rear and side panels, which are noted as white circles in the Fig.1. In the backward vehicle, a single camera is mounted at the origin so that the optical axis of the camera should be similar to the  $x$ -axis.

Fig. 1. Arrangement of two vehicles moving on a curved track.

In order to simplify the geometrical transformation from the marker positions to the vehicle distance, we assume that the  $x$ - $y$  plane is similar to the  $x'$ - $y'$  one. This assumption is reasonable when the track is flat without up and down slopes and the vehicles are not tilted. In this case, the markers are lined up along the  $y'$ -axis in the image surface of the camera. Then, the distance can be transformed only from the  $y'$ -coordinate of the marker positions in the image. Under the vehicle arrangement shown in the Fig. 1, the image reveals five markers on the rear and right-side panels because three markers on the front and left-side panels are hidden behind the vehicle itself. If the vehicles are moving on a linear track, the image reveals only three markers on the rear panel. In this study, we formulate the transformations only from the  $y'$ -coordinate of the marker positions in those two cases of three and five markers. However, it should be noted that the distance can also be transformed from the  $y'$ - and  $z'$ -coordinates of the marker positions even if the  $x$ - $y$  plane is not similar to the  $x'$ - $y'$  one, relating to the track slope or vehicle tilts.

Figure 2 shows  $x$ - $y$  in-plane arrangement of three markers on the rear panel of the forward vehicle and the camera on the backward vehicle. The markers are noted as  $p_0, p_1, p_2$ . The center of the camera lens with the focal length  $f$  is placed at  $p_c(x_c, y_c)$  and its vision field is assumed to be enough wide to cover the three markers. Strictly speaking, only three markers are revealed in the image if  $-S \leq y_c \leq S$  or  $-2S \leq x_c \leq 0$ . The  $y'$ -coordinate of the marker projected on the  $y'$ - $z'$  image surface is defined as  $p'_0, p'_1, p'_2$ . In this case,  $d, \phi$ , and  $\theta$  are obtained from  $p'_0, p'_1, p'_2, f$  and  $S$  by solving following equations:

$$\tan \phi = -\frac{(r_1 - r_0) + (r_1 - r_2)}{r_2(r_1 - r_0) + r_0(r_1 - r_2)},$$

$$r_k = \frac{p'_k}{f}, \quad (1)$$

$$d = \sqrt{x_c^2 + y_c^2}, \quad (2)$$

$$\begin{aligned} x_c &= -\frac{(r_1 \tan \phi + 1)y_c}{r_1 - \tan \phi} \\ &= -\frac{(r_0 \tan \phi + 1)(y_c - S)}{r_0 - \tan \phi} \\ &= -\frac{(r_2 \tan \phi + 1)(y_c + S)}{r_2 - \tan \phi} \end{aligned} \quad (3)$$

$$\begin{aligned} y_c &= \frac{(r_1 - \tan \phi)(r_2 \tan \phi + 1)S}{(r_2 - \tan \phi)(r_1 \tan \phi + 1) - (r_1 - \tan \phi)(r_2 \tan \phi + 1)}, \quad (4) \\ &= \frac{-(r_1 - \tan \phi)(r_0 \tan \phi + 1)S}{(r_0 - \tan \phi)(r_1 \tan \phi + 1) - (r_1 - \tan \phi)(r_0 \tan \phi + 1)} \end{aligned}$$

$$\theta = \tan^{-1}\left(\frac{y_c}{x_c}\right) - \phi. \quad (5)$$

Fig. 2. In-plane arrangement of three markers on the rear panel of the forward vehicle and the camera on the backward vehicle.

Figure 3 shows  $x$ - $y$  in-plane arrangement of five markers on the rear and right-side panels of the forward vehicle and the camera on the backward vehicle. In addition to the  $p_0, p_1, p_2$ , the markers on the right-side panel are noted as  $p_3$  and  $p_4$  together with their projected positions as  $p'_3$  and  $p'_4$  in the Fig. 3. For convenience of the calculation, the marker  $p_2$  is placed at the origin and then, a distance between  $p_2$  and  $p_c$  and an angle between  $x'$ -axis and the  $p_2$ - $p_c$  direction are defined as  $d'$  and  $\theta'$ , respectively. In this case,  $d', \theta'$ , and  $\phi'$  are obtained from  $p'_0, p'_2, p'_4, f$  and  $S$  by solving following equations:

$$\tan \phi = \frac{r_4(r_2 - r_0) - (r_2 - r_4)}{(r_2 - r_0) + r_0(r_2 - r_4)},$$

$$r_k = \frac{p'_k}{f}, \quad (6)$$

$$d' = \sqrt{x_c^2 + y_c^2}, \quad (7)$$

$$\begin{aligned} x_c &= -\frac{(r_2 \tan \phi + 1)y_c}{r_2 - \tan \phi} \\ &= -\frac{(r_0 \tan \phi + 1)(y_c - 2S)}{r_0 - \tan \phi}, \quad (8) \\ &= -\frac{(r_4 \tan \phi + 1)y_c - 2S(r_4 - \tan \phi)}{r_4 - \tan \phi} \end{aligned}$$

$$\begin{aligned} y_c &= \frac{-2S(r_2 - \tan \phi)(r_4 - \tan \phi)}{(r_4 - \tan \phi)(r_2 \tan \phi + 1) - (r_2 - \tan \phi)(r_4 \tan \phi + 1)}, \quad (9) \\ &= \frac{-2S(r_2 - \tan \phi)(r_0 \tan \phi + 1)}{(r_0 - \tan \phi)(r_2 \tan \phi + 1) - (r_2 - \tan \phi)(r_0 \tan \phi + 1)} \end{aligned}$$

$$\theta' = \tan^{-1} \left( \frac{y_c}{x_c} \right) - \phi. \quad (10)$$

The  $d$ ,  $\phi$ , and  $\theta$  can also be derived from  $d'$ ,  $\theta'$ , and  $\phi$  by translation of the  $y$ -axis. Finally, the  $d$ ,  $\phi$ , and  $\theta$  for any arrangement of the vehicles are determined by using either eqs.(1) to (5) or eqs.(6) to (10) according to the number of markers revealed in the image.

Fig. 3. In-plane arrangement of five markers on the rear and right-side panels of the forward vehicle and the camera on the backward vehicle.

### III. EXPERIMENTAL RESULTS

The distance measurement was performed with a horizontal flat track including linear and curved parts from

which two metal cages are vertically hanged as vehicles. The NIR-LED markers were attached to the forward vehicle and their image was taken by a NIR-filtered CMOS camera (752×480 pixels) mounted on the backward vehicle while varying the relative position of the vehicles. In order to reduce the processing time, a windowed image (752×34 pixels) including all the markers near the  $x'$ - $y'$  plane was captured and processed by a small signal processor. The windowed image was divided into several regions including a single marker based on their approximate position estimated from the profile along the  $y'$ -coordinate of the image. Consequently, the precise position of the marker  $p_k'$  was obtained by calculating the  $y'$ -coordinate of the gravity center in every region. In order to confirm the performance of our proposed technique, the distances and directions from the camera center to each marker were also measured as  $d_L$  or  $d'_L$  by a laser-distancemeter (Leica DISTO D3) with a precise rotary stage mounted on the backward vehicle.

Figure 4 shows the measurement results of the  $d$  on the linear track: (a) experimental arrangement, (b) windowed images, and (c) comparison between  $d$  and  $d_L$ . The windowed images clearly revealed three markers lined up along the  $y'$ -axis. The marker intervals in the image were decreased with the increase of the distance between the vehicles. The calculated values of  $d$  revealed very good agreement with those of  $d_L$ . The maximum error of  $d$  was less than 1 % for the distance range of 0.5 to 3 m.

Figure 5 shows the results of the  $d'$  on the curved track measured in the same manner as shown in the Fig. 4. The windowed images revealed that the marker positions were moved to the right and their intervals were decreased with the increase of the vehicle distance. The calculated values of  $d'$  also agreed with those of  $d'_L$ . The error of  $d'$  was similar extent to that in the linear track. Because of the fixed curvature of the track, the variable range of the  $\theta'$  was less than 4 degrees in this experiment. Further measurements of  $\theta'$  for error analysis is still in progress. However, the error of  $\phi'$  in the range of 20 to 80 degrees was less than 2 %, which is enough to identify the vehicle position on the curved track.

The measurement rate was examined by evaluating the execution time of image capture, calculation of the gravity center, and geometrical transformation. In the case of the signal processor with the clock of 600MHz, it attained to 1000 frames/sec for the windowed image of 752×32 pixels. It was very lower processing-cost than that of the versatile techniques with complex algorithms of digital preprocessing such as stereo visions. Therefore, we can conclude that the proposed technique is useful for high-speed motion control of the cargo vehicles.

Fig. 4. Measurement results of  $d$  on the linear track: (a) experimental arrangement, (b) windowed images, and (c) comparison between  $d$  and  $d_L$ .

Fig. 5. Measurement results of  $d'$  on the curved track: (a) experimental arrangement, (b) windowed images, and (c) comparison between  $d'$  and  $d_L'$ .

## VI. CONCLUSION

High-speed distance measurement between two vehicles has been successfully performed by processing the image of the forward vehicle with NIR-LED markers taken by a NIR-filtered CMOS camera mounted on the backward vehicle. It was experimentally confirmed that the measurement rate attains to 1000 frames/sec in a windowed image of 752×34 pixels, with a small processor with the clock of 600MHz, including the capture time of the image, calculation time of the gravity center, and geometrical transformation time. The measurement error was less than 1 % for the distance range of 0.5 to 3 m. Therefore, we can conclude that the proposed technique is useful for high-speed motion control of the cargo vehicles.

# SEI and SHI Representations for Human Movement Recognition

Mohiuddin Ahmad and Md. Zulfikar Hossain\*

Dept. of Electrical and Electronic Engineering, Khulna University of Engineering and Technology,  
Khulna-9203, Bangladesh

\*Dept. of Electronics and Communication Engineering, Khulna University of Engineering and  
Technology, Khulna-9203, Bangladesh

**Abstract** — In this paper, we propose spatio-temporal silhouette representations, called silhouette energy image (SEI) and silhouette history image (SHI) to characterize motion and shape properties for recognition of human movements such as human actions, activities in daily life. The SEI and SHI are constructed by using the silhouette image sequence of an action. The span or difference of the end time and start time is used to make the SHI. For addressing the human shape variability, we used the variation of the anthropometry of the person. We extract the features based on geometric shape moments. We tested our approach successfully in the indoor and outdoor environment. Our experimental results show that the proposed method of human action recognition is robust, flexible and efficient.

**Index Terms**—Anthropometry, human action recognition, shape variability, silhouette energy image, silhouette history image.

## I. INTRODUCTION

Recognition of human actions from multiple views by the classification of image sequences has the applications in video surveillance and monitoring, human-computer interactions, model-based compressions, video retrieval in various situations. Typical situations include scenes with moving or clutter backgrounds, stationary or non-stationary camera, scale variation, starting and ending state variation, individual variations in appearance and cloths of people, changes in light and view-point, and so on. These situations make the human action recognition a challenging task.

The standard approach for human action recognition is to extract a set of features from each image sequence frame and use these features to train classifiers and to perform recognition. Therefore, it is important to consider the appropriateness and robustness of features of action recognition in varying environment. Actually, there is no rigid syntax and well-defined structure for human action recognition available. Moreover, there are several sources of variability that can affect human action recognition, such as variation in speed, viewpoint, size and shape of performer, phase change of action, scaling of persons, and so on. In addition, the motion of the human body is non-rigid in nature. These characteristics make human action recognition a sophisticated task. Considering the above circumstances, we consider some issues that affect the development of models of actions and classifications, which are as follows: (i) An action can be characterized by the local motion of

human body parts, (ii) an action can be illustrated by the silhouette image sequence of the human body, which can be regarded as global motion flow, (iii) the trajectory of an action from different viewing directions is different; some of the body parts (part of hand, lower part of leg, part of body, etc) are occluded due to view changes, and (iv) human actions depend on several variability, such as anthropometry, method of performing the action, speed, phase variation (starting and ending time of the action), and camera view variations such as zooming, tilting, and rotating.

Among various features, the motion of the body parts and human body shape play the most significant roles for recognition. Motion based features can represent the approximation of the moving direction of the human body and human action can be effectively characterized by motion rather than other cues, such as color, depth, and spatial features. In the motion-based approach, the motion information of the human such as optic flows, affine variation, filters, gradients, spatial-temporal words, and motion blobs are used for recognizing actions. Motion-based action recognition had been performed by several researchers; a few of them are [3, 11, 12, 14]. However, motion-based techniques are not always robust in capturing velocity when motions of the actions are similar for the same body parts. On the other hand, the human body silhouette represents the pose of the human body at any instant in time, and a series of body silhouette images can be used to recognize human action correctly, regardless of the speed of movement. Different descriptors of shape information of motion regions such as points, boxes, silhouettes, and blobs are used for recognizing or classifying actions. Several researchers performed action recognition using shapes or silhouettes, such as [1, 2]. Bobick and Davis [1] proposed the motion energy image (MEI) and motion history image (MHI) for human movement representation and recognition and were constructed from the cumulative binary motion images. We propose silhouette energy image (SEI) and silhouette history image (SHI) which gives shape information with global motion information but MEI and MHI give only motion information.

In addition of shape and motion, several variabilities that occurred frequently are also responsible for human action recognition. Sheikh and Shah [15] explicitly identified three sources of variability in action recognition, such as viewpoint, execution rate, and anthropometry of actors and

they used the 3D space with thirteen anatomical landmarks for each image. In contrast to their work, we explicitly define and employ the anthropometry variation, camera observations (zooming of a person, slanting body, and rotation of human body), phase variation, speed variations and multiple views variation of the action. Related works have typically concentrated on the variability in viewpoint [13] by deriving view invariant features or proposing a view invariant algorithm.

During the action recognition of persons, we utilize the global shape motion features in addition to several variabilities for recognizing the periodic as well as non-periodic actions. The global shape motions are extracted from geometric shape of models. Therefore, based on the combined information of global motion, sources of variability's, and multiple views, human action recognition is more robust and flexible. We propose to recognize several actions of humans in the daily life from multiple views learning of local and global motion features using the multiclass support vector machine (MCSVM).

In our system, we assume that silhouettes of an image sequence are correctly captured. From the silhouette image sequence, we estimate the temporal boundary (i.e. period or duration) of each action. Depending on the temporal boundary, an action model (i.e. SHI) is constructed by the silhouette image sequence. Using the variability parameters and the SHI, variability models (adaptable models) are generated. The models are characterized by various geometric shape motions. We learn an action for multiple views global motion descriptors by using a MCSVM, and generate SVM models for specified actions. For recognizing actions, we classify (using the similarity of features) descriptions using SVM models. The actions modelling and classification in this work involve both the Korea university full body gesture database (FBGDB) [4] and the KTH database (KTHDB) [10]. Of particular interest is the detection method, which we use for the recognition of several daily actions of elderly people for human-robot interaction (HRI) or similar applications.

This paper is organized as follows: Section II presents action representation and variability generation in our system. Section III discusses global motion descriptors of combined models. Section IV presents experimental results and discussions of the selected approaches. Finally, conclusions are drawn in Section V.

## II. SEI, SHI, AND HUMAN SHAPE VARIABILITY

The silhouette history image represents the shape history information of an image sequence. This history information represents the time history for performing an action. SEI and SHI gives the idea of motion and action recognition by watching silhouettes.

### A. Human Action

Human action is the movement of humans for performing a task within a short period of time. The action may be simple or complex depending on the number of body limbs involved in the action. Many actions performed by humans have cyclic nature and they show periodicity of short duration. Besides, many actions show single occurrence or non-periodic with time frame of specific length (i.e. duration). We consider human actions daily performed which are almost cyclic in nature, either multiple cyclic (period= $nT$ ) or periodic actions (different types of walking, running, jogging, etc), and single occurrence (duration= $p$ ) or non-periodic actions (bowing, raising the hand, sitting on the floor, etc). Under the above circumstances, it is possible to transform a human action in the spatio-temporal space or 3D space, into a 2D spatial space, where the 2D space contains spatial information with temporal information.

### B. Silhouette Energy Image (SEI)

We define the silhouette history image as the image where the time variation of an action is represented by the body shape information. Let us assume  $x_t = f(x, y, t)$  is the silhouette image in a sequence at time  $t$ , which includes an action under duration or a period as shown in fig. 1. Therefore, SEI ( $SEI = S(x, y)$ ) is defined by Eq. (1): Moreover, the standard deviation image as well as motion variation image is shown in fig. 1(b) and 1(c) respectively.

$$A_{2D} = S(x, y) = \frac{1}{t_e - t_s} \int_{t_s}^{t_e} x_t dt \quad (1)$$

$$\sigma(x, y) = \sqrt{\frac{\int_{t_s}^{t_e} f^2(x, y, t) dt}{t_e - t_s} - \left( \frac{1}{t_e - t_s} \int_{t_s}^{t_e} f(x, y, t) dt \right)^2} \quad (2)$$

$$COV(x, y) = \frac{\sigma(x, y)}{S(x, y)} \quad (3)$$

Here,  $t_s$  and  $t_e$  are the starting and ending states of an action. Since the average 2D image stores the global motion distribution and orientation of the silhouette images, we can designate this as a SEI. The number of frames in the action depends on the person, time, and type of action. Since, we use the average of the time sequence silhouette images; the normalized variation affects are very low. Figure 1 shows the sample silhouette images with the SEI of the "bowing" action along with the variation of motion. This representation shows the shape as well as motion changes of an action.

Fig. 1. Human action model representation. (a) Silhouette image sequence of sitting on the floor action. (b) SEI. (c) Standard deviation image. (d) Covariation image

The SEI represents an action model (AT), due to the following reason: (1) The energy of a pixel at every point is a result of an action formation; (2) Each silhouette represents the unit energy of a human action at any instance; (3) It determines the energy distribution of an action.

### C. Silhouette History Image (SHI)

Silhouette history image (SHI) refers to the shape variation of the image sequence in time. By SHI, we represent how the silhouette of an image sequence is moving. It does not show only the motion image representation as [1] but also it represents the global motion orientation of an action at any instant of time. The shape of the person at present state as well as the person's global motion orientation is visualized by the SHI.

Fig. 2. Silhouette energy image (SEI) and silhouette history image (SHI) of human actions

From the image sequences of some actions, we show the SEI as well as SHI as shown in Fig. 2. Figure 2 shows several key frames of an action and the formation of both SEI and SHI. We construct these representations by using plastic model of human. From both SHI, we can show the action orientation or simply the direction of the action. From the MHI representation in [1], SHI represents both body shape and global motion change. The brighter region represents the recency of the human body shape.

### D. Variability of Body Shape

To consider the diversity of modeling (learning) and classifying actions, we consider multiple human body shape, and the produced models are known variability models (VTs). The anthropometry variation of an action represents the width and height variation of a person. Due to these variations, human action recognition should adapt anthropometry. We define basic eight sets of anthropometric variations by Eq. (4).

$$S(x, y)|_a = \begin{cases} S(x-a, y), & Hg \\ S(x, y-b), & Hh \\ S(x+a, y), & Lg \\ S(x, y+b), & Lh \\ S(x-a, y+b), & HgLh \\ S(x+a, y-b), & LgHh \\ S(x-a, y-b), & HgHh \\ S(x+a, y+b), & LgLh \end{cases} \quad (4)$$

Where,  $H$ =Higher  $g$ =girth,  $L$ =Lower, and  $h$ =height.

Fig. 3. Anthropometric variation images with different body width and height

where,  $a$  &  $b$  are width and height variation parameters with  $a \approx 0.067R \sim 0.1R$  and  $b \approx 0.067C \sim 0.1C$ . The variability models can be constructed by resizing the human body using bilinear interpolation method. We can generate a set of anthropometric images which are shown in Fig. 3.

### III. GLOBAL GEOMETRIC SHAPE & MOTION DESCRIPTION

We express the global shape motion description by the model orientation, span and elevation of motions, geometric and orthogonal moments. Therefore, we express the geometric shape motions by  $\{S_g, S_z, S_d\}$ . The symbols are defined in the following subsections.

#### A. Geometric Moments

Moments and function of moments have been utilized as pattern feature in pattern recognition applications. Such features capture global information about the image and do not require close boundaries as required by Fourier descriptors. By positioning the center of mass (COM), we can differentiate the motions for each action. Since this feature should be independent of the location of a person, then we consider the relative appropriate position for each action. Hu [6] introduced seven nonlinear functions,  $h_i$ , where  $i = 1, 2, \dots, 7$  defined on regular moments using central moments that are translation, scale, and rotation invariant. To achieve the consistent camera observations, we used non-orthogonal features, namely Hu moments,  $h = (h_1, h_2, \dots, h_7)$  [6] which are slightly modified to extract specific characteristics.

$$\eta_{pq} = \frac{\mu_{pq}}{m_{00}^\gamma} = \frac{1}{m_{00}^\gamma} \sum_{x=0}^{N-1} \sum_{y=0}^{N-1} (x - \bar{x})^p (y - \bar{y})^q S(x, y) \quad (5)$$

$$\text{where, } m_{pq} = \sum_{x=0}^{M-1} \sum_{y=0}^{N-1} x^p y^q S(x, y),$$

$(\bar{x}, \bar{y}) = (m_{10}/m_{00}, m_{01}/m_{00})$  and  $\gamma = (p + q + 2)/2$   $\forall (p + q) \geq 2$ . The advantage of a moment's methods is that they are mathematically concise and for the intensity image of action models, they reflect both shape and global motion distribution within it.

#### B. Zernike Moments

The geometric moment shows highly inaccurate results when the image is noisy. Zernike polynomials provide very useful moment kernels, present native rotational invariance and are far more robust to noise. Scale and translation invariance can be implemented using moment normalization. The magnitude of Zernike moments has been treated as shape features because they are rotation invariant. The two-dimensional Zernike moments of an image intensity function  $f(\rho, \theta)$  with order  $n$  and repetition  $m$  is expressed as follows [9]:

$$Z_{nm} = \frac{n+1}{\pi} \int_0^{2\pi} \int_0^1 R_{nm}(\rho) e^{-jm\theta} f(\rho, \theta) \rho d\rho d\theta \quad (6)$$

$$R_{nm}(\rho) = \sum_{s=0}^{(n-|m|)/2} (-1)^s \frac{(n-s)!}{s!((n+|m|)/2-s)!(n-|m|/2)!} \rho^{n-2s} \quad (7)$$

$$\text{where, } \rho = \frac{\sqrt{(2x - N + 1)^2 + (N - 1 - 2y)^2}}{N},$$

$$\theta = \tan^{-1} \frac{N - 1 - 2y}{2x - N + 1} \quad \text{and } 0 \leq \rho \leq 1. \quad \text{For each action}$$

model and one given value  $\rho$ , we obtain the Zernike moments value. We used the absolute Zernike moment, which is given by

$$Z_{nm} = \frac{n+1}{\lambda_N} \sum_{x=0}^{N-1} \sum_{y=0}^{N-1} f(x, y) R_{nm}(\rho_{xy}) \exp(-jm\theta_{xy}) \quad (8)$$

as the global motion features.

#### C. Direction of Actions (Overall Width or Height)

The 2D orientation (direction of major axis, or minor axis) of the motion distribution for every action is different. Thus the relative differences in magnitude of the eigenvalues are an indication of the elongation of the image (action model). The global motion orientation is obtained from the eigenvalue  $\lambda_i$ , of the covariance matrix of the action models. The eigenvalue is given by

$$\lambda_i = \frac{\mu'_{20} + \mu'_{02}}{2} \pm \frac{\sqrt{4\mu'^2_{11} + (\mu'_{20} - \mu'_{02})^2}}{2} \quad (9)$$

where,  $\mu'_{pq} = \mu_{pq} / m_{00}$  and the covariance matrix is  $COV[S(x, y)] = \begin{pmatrix} \mu'_{20} & \mu'_{11} \\ \mu'_{11} & \mu'_{02} \end{pmatrix}$ . We have considered the projection of major and minor axis orientation and the direction of the major axis as global features for action models.

## IV. EXPERIMENTAL RESULTS & DISCUSSION

#### A. Databases

The FBGDB [4] contains 14 representative full body actions in the daily life of 20 performers. In the database, all the performers are elderly persons (both male and female) with ages ranging from 60 to 80. The database contains 3D motion data and 2D data. The 2D data consists of both video data and 2D silhouette data. As an example, the sample images for left view are shown in fig. 4.

The KTHDB is one of the largest databases with sequences of human actions taken over different scenarios [10]. The database contains six types of human actions, performed several times by 25 subjects in four scenarios: outdoors (s1), outdoors with scale variation (s2), outdoor with different cloths (s3), and indoor (s4). The database contains 2391 sequences. The sample images are shown in

Fig. 5. The image sequences have the spatial resolution of 160×120 pixels and have a length of four seconds in average.

Fig. 4. Korea University Gesture database on all specified actions in three different views

Fig. 5. KTH database on all specified actions in different scenarios

## B. Classification Results

Support vector machines (SVM) have high generalization capabilities in many tasks, especially in terms of object recognition. In applying MCSVM [5, 16], the training data of the global shape motions of the image sequences are divided into defined classes manually. The MCSVM predicts the class label information for arbitrary action. Before applying MCSVM, we normalized each component. Table I shows the action recognition results of FBGDB using MCSVM where we use components and global motions for each view. We use 9 subjects, 9 actions, and 4 views variation for testing (vA represents arbitrary view). The correct recognition rate (CRR) for any action is calculated as follows:

$$\text{CRR} (\%) = (N_c / N_a) \times 100 \quad (9)$$

Where,  $N_c$  is the total number of correct recognition sequences while  $N_a$  is the number of total action sequences. As can be seen, there is a clear separation among different kinds of actions. The overall CRRs of v1, v2, v3, and vA are 79.34, 84.12, 89.47 and 81.53 respectively, of FBGDB. We use combined models (AATs = ATs + VTs) to evaluate the performance.

TABEL I  
CRRS OF EACH ACTION AND VIEW OF FBGDB

|    | SC  | WP  | RH   | BW   | SF  | GF   | LF   | RF  | WF  |
|----|-----|-----|------|------|-----|------|------|-----|-----|
| v1 | .98 | .57 | 0.86 | 1.00 | .71 | 0.57 | 1.00 | .57 | .86 |
| v2 | .85 | .44 | 1.00 | 0.86 | .86 | 0.86 | 1.00 | .86 | .86 |
| v3 | .97 | .86 | 1.00 | 1.00 | .86 | 1.00 | 1.00 | .57 | .72 |
| vA | .94 | .57 | 0.94 | 0.99 | .76 | 0.76 | 0.90 | .76 | .76 |

We also have tested our approach by using the KTHDB, since it is one of the largest human action databases and several researchers used this database. We have tested 8 subjects, 6 actions, and 4 scenarios and each scenario contains 2 or 3 action sequences. Table II shows the recognition of each action in various scenarios for global shape motions. The CRRs of s1, s2, s3, s4, sA are 89.33, 83.17, 87.50, 88.3, 87.50 respectively for KTHDB, where sA is arbitrary scenario.

TABEL II  
RECOGNITION OF ACTIONS OF KTHDB

| Scenario | BP   | HC   | HW   | JP   | RP   | WP    |
|----------|------|------|------|------|------|-------|
| s1       | 0.98 | 0.97 | 0.97 | 0.91 | 0.74 | 0.82. |
| s2       | 0.98 | 0.88 | 0.94 | 0.83 | 0.61 | 0.78  |
| s3       | 1.00 | 0.96 | 0.97 | 0.74 | 0.81 | 0.81  |
| s4       | 0.95 | 0.94 | 0.93 | 0.81 | 0.67 | 0.80  |

We use 21 image sequences for classification of each action and each view in case of FBGDB. For arbitrary view recognition, we use more than 60 sequences for each action. It is important to mention that in some cases, the motion of

the elderly persons is similar. In our method, it is shown that by using the 2D action model with variability selection, the action recognition is more robust, since we use the natural actions of humans, with emphasis on elderly persons (FBGDB). The movement of elderly person's is significantly different than that of young people. For example, the speed and style of walking and running of elderly people are very similar.

We test the system performance without generating adaptable models, and we make a comparison of performance among AT, VT, and AAT. As an example, the performance (in CRR) of AT, VT, and AATs are 80%, 84.33%, and 89.33% respectively. The performance of AAT is significantly better than AT.

We compare our works with some state-of-art action recognition approaches by using the same database and similar test sequences but different methods. For example, we compare our method with [3, 7, 8, 12, 14] using KTHDB. Our results by global shape motions flow are compared with their results by spatio-temporal filters, volumetric features, spatio-temporal words, and local space time features. The overall comparison of different methods is listed in Table III. Compared to the mentioned researches, our approach yields better recognition results.

TABLE III  
COMPARISON RESULTS OF ACTION RECOGNITION

| Method              | CRR   | Scenario      |
|---------------------|-------|---------------|
| Dollar et al. [3]   | 81.17 | $sI+s2+s3+s4$ |
| Jiang et al. [7]    | 84.43 | $sI+s2+s3+s4$ |
| Ke et al. [8]       | 62.96 | $sI+s2+s3+s4$ |
| Niebles et al. [12] | 81.50 | $sI+s2+s3+s4$ |
| Schuldt et al. [14] | 71.72 | $sI+s2+s3+s4$ |
| Our method          | 87.50 | $sI+s2+s3+s4$ |

## V. CONCLUSION

We proposed a novel method for recognizing human action using the silhouette energy image and silhouette history image with the variation of anthropometric models. The SEI represented the energy content of the action model and SHI represented the energy history of the action model. The anthropometry variation provided a more natural and robust environment for human action recognition, using an advanced human-machine interface. Moreover, by adapting the shape variation, incomplete actions and partial occluded

actions were recognized successfully. We recognized human actions in individual and arbitrary views. With global motion features, the action recognition became sparse and flexible and it can be adapted to practical applications of human movement, human action recognition, and so on. Our future work will include the precise detection and recognition of action in complicated situations.

# Generation of Mountain Ranges by Modifying a Controlled Terrain Generation Approach

K. Raiyan Kamal # and Dr. M. Kaykobad \*

Department of Computer Science and Engineering,  
Bangladesh University of Engineering and Technology  
#raiyan.kamal@gmail.com \*kaykobad@cse.buet.ac.bd

**Abstract**—The terrain generation approach proposed in ‘Parametrically Controlled Terrain Generation, (Proceedings of GRAPHITE 2007)’ focuses on generation of terrains having mountains of prespecified heights and spreads of base regions and peaks nearly at prespecified locations. However, inability to produce mountain ranges is a shortcoming of the algorithm. In this paper, we present a modification to the original algorithm that will enable generation of whole mountain ranges while preserving the similar parametric control over the resulting terrain. Experimental results of our algorithm have also been compared with results of existing algorithms.

**Index Terms**—Physically based modeling, procedural modeling, terrain generation.

## I. INTRODUCTION

Generation and rendering of artificial terrains has been extensively studied in computer graphics. The need for studying effective and efficient terrain generation and rendering techniques rises from the fact that artificially generated terrain models are useful across a broad range of application including geography, geology, climatology and other related fields. In recent years, the field of A.I. has also found artificially generated terrains useful in experiments due to growing interest in research for automatic trajectory generation for mobile robots [1]. Terrain models are also useful in military tactical decision making [2]. Besides scientific research and planning, artificial terrains are important part of many art and entertainment forms like computer or video games and animation movies.

Earlier terrain generation algorithms, consisting mostly of fractal techniques, are indeed able to generate sufficiently natural looking terrains but lack the control over the resulting terrains due to their unpredictable nature. Recent works have concentrated on controlled terrain generation providing significant control over the resulting terrain while preserving the randomness. Like any other procedural modeling, the randomness is a vital part in artificial terrain generation due to its responsibility to produce seemingly realistic yet unpredictable artifacts for the unspecified parts of the model.

The terrain generation approach presented in [3] offers control through a set of parameters, hence the name Parametrically Controlled Terrain Generation. A significant

drawback of the algorithm is its inability to produce mountain ranges or an entire landscape having several mountains. A possible solution to this problem would be to produce different terrain models with mountains at different location and features and then combine them to produce an entire landscape or mountain range. But the overhead of storing the intermediate results and combining them later on is significant. Thus the goal here for a better terrain generation approach is to provide means of producing mountain ranges or landscape with multiple mountains with low time and memory overhead while preserving the parametric controls provided by the original algorithm.

This paper presents Polyline Walk, a modified version of the Probing Algorithm. This extended version of the algorithm focuses on generation of mountain ranges according to prior specifications. Alongside the original set of features describing a single mountain peak, we introduce the following additional features which are vital for describing a mountain range.

- 1) Shape of the mountain range, e.g. linear shaped or zig-zag
- 2) Key mountain peaks, i.e. the significant mountain peaks characterizing the mountain range
- 3) Point of discontinuity, if any on the mountain range

The paper is organized as follows. Section 2 reviews in short the literature on terrain generation. Our proposed technique is presented in section 3. Section 4 depicts the observations and experimental results followed by future research directions and conclusion in Section 5.

## II. BACKGROUND AND PREVIOUS WORKS

### A. Data Structure

A widely used data structure for terrain representation is the height field. A height field is a mapping of two dimensional coordinates along X and Z axis with an elevation value along Y axis.

$$y = field(x, z) \begin{cases} min_x \leq x < max_x \\ min_z \leq z < max_z \end{cases}$$

This formulation leads to the implementation of height fields as a two dimensional rectangular grid of elevation

values. Triangular and hexagonal grid versions are also possible. Despite its drawbacks, height field is the most favorable data structure owing to ease of manipulation and other advantages including highly optimized rendering [4] and collision detection.

### B. Previous Works

Based on the degree of control offered, the known terrain generation algorithms can be classified into two categories. The ones providing explicit control over the result and the ones that do not. Most of the earlier works can be put into the second category while the recent works are of the first category.

1) *Early Terrain Generation Algorithms:* The Mid-Point Displacement Algorithm, a recursive subdivision algorithm introduced by Fournier et al [5], offers control over the resulting terrain through a roughness parameter  $H \in [0, 1]$ . Although roughness of the resulting terrain is controllable, the location and structure of resulting mountains and valleys are entirely unpredictable. Fault algorithm by Krten [6], basically mimicking the effect of earthquake, offers a similar type of control through specifying the amount by which one portion of the terrain to elevate at each iteration and thereby controlling the steepness of the resulting terrain. The erosion techniques introduced by Musgrave et al [7] simulate effects of thermal erosion, water-flow, air-flow, rain-fall or other geophysical phenomena on a supplied base terrain. Control over the result is achieved by tuning a set of parameters defining the nature and intensity of erosion. However, the influence of this action over the resulting terrain is indirect and the overall shape and structure of the result depend solely on the base terrain.

Results of these algorithms can be seen in figure 1.

Fig. 1: results of early terrain generation algorithms

2) *Controlled Terrain Generation Algorithms:* Parry proposes a controlled terrain generation technique [8] offering control over the number of hills/mountains, their

average height with a certain standard deviation and slopes of the mountains. Based on the Modified Bivariate normal(MBVN) model [9], this Extended MBVN technique models each mountain as a bivariate normal distribution surface in the three dimensional space, possibly made unsymmetrical by tuning its parameters. Drawbacks of this technique are lack of reality and non-exact modeling.

Fig. 2: Terrain generated by Genetic algorithm

Ong et al. proposed a method for controlled terrain generation [10] that uses genetic algorithm approach in two passes. The first pass refines an user provided rough sketch of terrain region boundaries using a genetic algorithm. Then this result is coupled with a database of given terrain data to generate an artificial terrain, which is again optimized using a second genetic algorithm. A limitation of the system is that in order to have realistic results the terrain database has to be populated with realistic terrain data, possibly GIS(Geographical Information System) information of real life locations, which are not always readily available. Terrain generated using this approach is seen in figure 2.

### C. The Original Probing Algorithm

The probing algorithm [3] is capable of generating a single mountain peak of given height at a given location of the terrain with spread of the base of the mountain also being controlled by algorithmic parameters. With advanced tuning of parameters, the algorithm can produce craters and other unusual artifacts as well. Result of this algorithm can be seen in figure 3.

The algorithmic parameters are

- $n$  : number of iterations to perform, integer
- $l$  : number of cutting lines drawn in each iteration, integer
- $r$  : probing depth, integer

The basic idea is to draw several random straight lines across the base terrain cutting the height-field into a number of polygons, hence the name *cutting line*. A set of polygons among the resulting ones is chosen by performing a probing through neighboring polygons starting from the polygon containing the prespecified location of the mountain peak and these polygonal regions are elevated by a constant amount. Two polygons are considered to be neighbors during the probing if they share a common side. This process is repeated several times.

Fig. 3: Terrain generated by Probing algorithm

In advanced tuning of the algorithmic parameters, the elevation to be applied to the  $i$ th polygon found in course of probing is looked up from a deterministic function or from a vector initialized with precalculated values. This vector is referred to as *delta*,  $delta[i]$  holds a real value by which the  $i$ th polygon is to be elevated. Mountains of certain amount of steepness or flatness and unusual artifacts such as cavity and volcanic craters are also possible to produce using this technique.

### III. THE PROPOSED TECHNIQUE

#### A. Basic Notations

For convenience of discussion, let  $P$  denote a poly line, an ordered sequence of vertices. Let  $v_i = (x_i, z_i)$  be a vertex of the poly line where  $x_i$  and  $z_i$  are the coordinates of the vertex on the height field along  $X$  and  $Z$  axis respectively. Let  $a_i$  and  $r_i$  denote altitude values of the  $i$ th peak in the mountain range and span of its base respectively. A line segment connecting the vertices  $v_i$  and  $v_j$  is denoted by  $\langle v_i, v_j \rangle$ .

#### B. Modifications to the Original Algorithm

The following modifications and new features are introduced to the original algorithm in order to facilitate the generation of mountain ranges.

- Shape of the target mountain range is provided as an input parameter in the form of a polyline with  $N \geq 3$  vertices. Each vertex represent location of a key mountain peak.
- Instead of drawing  $l$  random lines,  $n - 1$  pairs of random lines are drawn as cutting lines. Thus the parameter  $l$  is made obsolete as it is not needed anymore. The details of drawing these lines are discussed later.
- Instead of randomly selecting the polygons to be elevated, only the polygons containing one of the

vertices of the polyline is elevated. Thus the parameter  $r$  is effectively replaced by  $N$ .

A more detailed discussion of the algorithm as a whole follows.

#### C. Generating a Mountain Range

Our algorithm generates a mountain range whose shape is specified as a poly-line having  $N \geq 3$  vertices. Each of the vertices represent location of a key mountain peak. The algorithm is of iterative nature. The number of iterations to be performed, denoted by  $n$ , is provided as an algorithmic parameter and the following operations are performed on each iteration. For each of the  $N - 1$  line segments that comprises the poly line, a random point  $p_i$  is chosen, which we choose to call pivot point, lying on the  $i$ th segment of the poly line. Through each of these pivot points, a pair of random straight lines is drawn in a fashion similar to drawing fault lines across the terrain in the fault algorithm [6]. These lines cut the terrain into several polygons from which, the set of polygons containing the key mountain peaks are chosen to be elevated by a constant amount, say 1. Figure 4 presents an illustration of this process. The resulting terrain after  $n$  iteration contains a mountain range with shape matching the given poly line and the key mountain peaks having the same altitude which is proportional to  $n$ . Pseudocode reflecting the procedure follows. Figure 5 depicts steps of generating a mountain range using this procedure.

#### **procedure** *MtRangeBasic*( $N, P, n$ )

```

1: for j=1 to n do
2: for i=2 to N do
3: $p_i \leftarrow \text{randomPointOn}(\langle v_{i-1}, v_i \rangle)$
4: $\text{draw2lines}(p_i)$
5: end for
6: for i=1 to N do
7: $\text{elevate}(v_i, 1)$
8: end for
9: end for
```

#### **procedure** *randomPointOn*( $\langle v_i, v_j \rangle$ )

```

1: returns a random point on the line segment $\langle v_i, v_j \rangle$
```

#### **procedure** *elevate*( $v, k$ )

```

1: elevates the polygon containing the vertex v by amount k using a flood-fill technique
```

#### **procedure** *draw2lines*( $v$ )

```

1: draws two random lines across the height-field through the vertex v
```

For drawing the cutting lines and erasing them at the end of the iteration, a procedure same as that of the original

algorithm is followed.

Fig. 4: Illustration of the process followed in one iteration of the algorithm. The filled circles, outlined circles, dashed lines and gray polygons denote locations of key mountain peaks, pivot points, cutting lines and elevated polygons respectively.

Two important parameters defining a mountain range are the altitude values of its key mountain peaks and span of the individual mountain bases. These parameters are considered next. Altitude of each of the key mountain peaks can be controlled by specifying their relative altitude  $a_i$  with respect to the highest peak in the range. Modifying the basic mountain range generating algorithm to elevate the polygon containing  $v_i$  by a value of  $a_i$  enables control over the altitude of each key mountain peak separately. A negative value for  $a_i$  produces a crater instead of mountain peak at the same location and negative value for all key mountain peaks produces a canyon instead of a mountain range. A farther modification in the algorithm to choose two pivot points within  $r_i$  distance from  $v_i$ , one from the line segments  $\langle v_{i-1}, v_i \rangle$  and  $\langle v_i, v_{i+1} \rangle$  for each vertex  $v_i$ ,  $2 \leq i \leq n-1$  of  $P$  instead of choosing one pivot point per line segment enables control over the span of the base of the mountains as well. The final algorithm enriched with these modifications is reflected in the following pseudocode.

```

procedure MtRagne(N, P, n)
1: for $j=1$ to n do
2: for $i=2$ to N do
3: $p_{ia} \leftarrow \text{RandomPointWithin}(\langle v_{i-1}, v_i \rangle, r_i)$
4: $p_{ib} \leftarrow \text{RandomPointWithin}(\langle v_i, v_{i+1} \rangle, r_i)$
5: $\text{draw2lines}(p_{ia})$
6: $\text{draw2lines}(p_{ib})$
7: end for
8: for $i=1$ to N do
9: $\text{elevate}(v_i, a_i)$
10: end for
11: end for

```

Fig. 5: Steps of generating a mountain range.

**procedure**  $\text{randomPointWithin}(\langle v_i, v_j \rangle)$

1: returns a random point on the line segment  $\langle v_i, v_j \rangle$  and within  $r$  distance from  $v_i$

Figure 6 demonstrates the effect of specifying maximum allowed base span,  $r_i$  on the resulting terrain. For a particular mountain peak, small value of  $r_i$  would cause that particular mountain to have a small base span making it somewhat detached from rest of the mountain range, creating a point of discontinuity on the mountain range. For larger values of  $r_i$ , the mountain base grows up to the point where it eventually merges with the rest of the range.

#### IV. EXPERIMENTAL RESULTS AND OBSERVATIONS

##### A. Generation of Simple Mountain Ranges

Figure 7 shows terrains containing simple mountain ranges generated using the basic procedure. The defining

(a)  $r_2 = 30$

(b)  $r_2 = 40$

(c)  $r_2 = 50$

(d)  $r_2 = 60$

Fig. 6: Effect of maximum allowed base span,  $r_i$  on individual peaks. Base span of the mountain in the middle is being varied keeping all other parameters constant. For smaller values of  $r_i$ , smaller base span makes this particular mountain somewhat detached from rest of the range. With increasing allowed base span, the mountain base grows larger and eventually merges with the rest of the range.

polygons of the two mountain ranges are linear and zig-zag shaped respectively and so are the resulting mountain ranges.

### B. Generation of Complex Terrains

Further control of the resulting terrain is required to produce mountain ranges with complex attributes. Such a terrain consisting of a peak surrounded by two craters on both sides can be seen in figure 8. The defining polygon is a simple linear one and relative altitude values for the three peaks here are  $-0.8$ ,  $1.0$  and  $-0.7$  respectively. Note that the negative value for altitude has turned the first and third peak into craters effectively.

(a) Simple linear shaped mountain range.

(b) Zig-zag shaped mountain range.

Fig. 7: Simple terrains generated by the basic procedure.

Fig. 8: Generating mountain range with unusual characteristics. White dots on the poly line indicates vertices representing spots of negative altitude, i.e. craters.

Figure 6 demonstrates the effect of specifying  $r_i$ , maximum allowed base span on individual peaks, as discussed earlier.

### C. Experimentation with MPD Algorithm

MPD(Mid-Point Displacement) algorithm has the property that if the initial height field is biased with some seed value at a certain location before running the algorithm, the seeded location retains that height in the resulting terrain as well. Apparently this property is favorable in generating mountain ranges by seeding the coordinates of vertices from the defining poly line with relative altitude values. In effect, the resulting terrain indeed contains desired altitude at the desired points but the remaining part of the terrain stays still beyond control obscuring the distinctive elongated high altitude region of the mountain range if any be created at all. Results of such experimentation can be seen in figure 9. In this experiment, attempts were taken to produce a simple linear shaped mountain range, but as can be seen from the experimental results, the generated terrain does not show any convincing mountain range with distinctive features. Moreover, the results differ widely from one run of the algorithm to another making this approach inappropriate for serving this purpose.

Fig. 9: Limitation of MPD algorithm at producing simple linear shaped mountain ranges by biasing.

#### D. Experimentation with Fault Algorithm

Crude height fields resembling mountain ranges of intended shape (linear in this case) and altitude attributes were provided as seed terrains to the Fault algorithm. As can be seen in figure 10, the resulting terrain indeed contains a linear shaped mountain range. But the lack of realistic features and uncontrolled altitude along the length of the range is evident. Results of another experiment in figure 11, aiming a mountain range with two distinct peaks of same height. Altitude of the same mountain peak differs greatly between two runs of the procedure.

Fig. 10: Experimenting with Fault algorithm. Attempting to produce a simple linear shaped mountain range.

#### V. CONCLUSION AND FUTURE WORKS

The presented modification to the algorithm described in [3] effectively eliminates the drawback discussed earlier in this paper. Additional advantages of the proposed technique are low additional overhead and reduction of user inputs. Currently the algorithm can work with mountain ranges without branching. Future works would focus on adapting the algorithm to accept more complex mountain ranges with branching and loops, i.e. trees or planar graph structures with cycles as well.

(a) The seed terrain of a mountain range containing two distinct peaks.

Fig. 11: Drawback of Fault algorithm on a seed terrain method. Mountain peaks on the resulting terrain does not always have same altitude and shape.

# A Machine Vision Based Automatic System for Real Time Recognition and Sorting of Bangladeshi Bank Notes.

Raihan Ferdous Sajal, Mohammed Kamruzzaman, Faruq Ahmed Jewel.

Visual Magic Corporation Limited, House # 13/1, Road # 12, Baridhara, Dhaka-1212.

**Abstract** — This paper presents an efficient machine vision algorithm for real time image analysis and recognition of different features of Bangladeshi bank notes by using an automatic banknotes sorting system. The features recognized by this algorithm include denominations, orientations and sides of the bank notes. In a mechatronic system the Bangladeshi bank notes are fed together. The system draws the notes one by one and gets their images using a CCD sensor from a specific side. Then the system determines the denomination, orientation and side of the bank notes by analyzing the images grabbed by the CCD sensor. The average recognition speed is 8 to 9 bank notes per second and the rate of success is 100% for the banknotes having no extremely fatal damage.

**Index Terms** — Machine vision, Banknotes sorting, Image processing, Neural networks, Simplified Bi-directional associative memory.

## I. INTRODUCTION

Automatic banknotes recognition and sorting systems have become mandatory in the current fast going world. In the banks where a large transaction of money is an everyday reality, the officials find it tedious to count and sort the notes manually.

This paper presents a real-time machine vision based algorithm for recognizing and sorting the Bangladeshi banknotes. The algorithm is implemented and dumped in a banknotes sorting system, in which the notes are placed upon a feeding tray and the system draws them one by one and grabs the images of a specific side of the banknotes with a CCD sensor. The images are then analyzed with a microcontroller, LPC-H2106, where the implementation of this algorithm is housed. The image analysis and recognition is performed in real time and the notes are dispatched to two different terminal pockets according to their denominations, orientations and side.

## II. BACKGROUND

Number of researches have been conducted throughout the world for paper currency identification, sorting and recognizing the counterfeit notes. William J. Jones et al [1] developed an automatic currency processing system that uses the digital signal processing method for identifying the denomination of the notes. Danek and

Menelly [2] patented an idea for currency paper verification and denomination finding device that uses a linear array of photo-emitters and photo-detectors in one side of the banknotes and determines the authenticity of the banknotes from the reflected and transmitted light. Paul A. Jones et al [3] contributed another document processing system that analyzed the full image.

Joshi et al [4] developed a method for determination of the validity of the bills by visual and reflective spectral response. Rhodes and Gustafson [5] developed a system for checking the genuineness of the notes by verifying the watermarks in them.

## III. METHODOLOGY

### A) Image Acquisition:

When the banknotes are placed upon the system tray, an optical sensor issues an interrupt to the system notifying the banknote's arrival. The system then draws the note with its first roller. When the note moves inside the system, it slides on a long and slender CCD sensor array. The sensor array is one dimensional, and it can take the image of a single line of the note at any particular instance. But when the entire note slides on the sensor, the complete image of the note is grabbed.

### B) Determination of the denomination, orientation and side:

The banknotes images are obtained in grayscale. The monochrome images are then filtered by using a high-pass filter mask. These filtered images are then converted to binary images by using a histogram based thresholding technique. Since the threshold value is determined by analyzing the histogram of the image, the binary images remain almost the same irrespective to the new, old, blurred or faded notes.

These binary images are divided into equal sized rectangles and the average gray-levels of each rectangle is computed. These average values constitute the feature vectors of the banknotes. Since the notes cannot rotate inside the system, and the images are taken from a fixed distance, the size and direction of the notes in their images remain the same in all cases. It facilitates the design of the algorithm, because the effects of scaling and rotation of

the notes images are almost completely absent. The feature vectors obtained from the banknotes are first used to train an artificial neural network, and then it is used to classify the notes.

Figure 1: The grayscale image of a 50 taka note.

Figure 2: The filtered image.

Figure 3: The binary image after thresholding.

The neural network used in this research for classifying the notes is known as Simplified Bi-Directional Associative Memory (sBAM) [7]. First proposed by S. Rajasekaran and V. Pai in 1998, this associative memory can manipulate real-number data while the conventional associative memory can manipulate the binary data only. But since it is an associative memory, it has a major drawback: it must associate any input pattern with an output pattern although the input pattern is absolutely absurd. That means, an associative memory cannot classify a pattern as indeterminate while other sorts of neural network like the multilayer feed-forward network has the capability to do it. For example, if an associative memory is trained with the patterns of Bangladeshi 500, and 100 taka images, and then if any other arbitrary image is given as input, the associative memory cannot classify it as an indeterminate pattern. Rather it classifies it as one of the aforementioned input patterns of 500 and 100

Bangladeshi taka. It implies that, if an associative memory is trained with the Bangladeshi banknotes images, and if any arbitrary piece of paper is placed on the system's input tray, the program will definitely recognize that vague piece of paper as one of the Bangladeshi banknotes.

In order to get around this problem, first the feature vector extracted from an input image is given to sBAM. The sBAM then classifies that as a Bangladeshi banknote with a particular denomination, orientation and side. Then a particular portion of the testing banknote is cropped and compared with the portion in the same location of the respective banknote image. If both the cropped portions are found substantially similar, the banknote is considered to be classified successfully. Otherwise, the algorithm classifies the input image as an indeterminate one and the therefore the microcontroller notifies the system about this problem.

C) The Simplified Bi-Directional Associative Memory (sBAM):

For both the training and recognition of the patterns, the Simplified Bi-Directional Associative Memory (sBAM) follows a twofold approach: The input normalization and evaluation.

Given a set of N training pairs  $(A_i, B_i)$ ,  $i=1,2,3,\dots,N$  where  $A_i = (a_{i_1}, a_{i_2}, \dots, a_{i_n})$  and  $B_i = (b_{i_1}, b_{i_2}, \dots, b_{i_p})$ ,  $a_{i_j}, b_{i_j} \in \mathbb{R}$ , the normalized input pattern  $(\hat{A}_i)$  is given by

$$(\hat{A}_i) = \frac{A_i}{\|A_i\|},$$

$$\text{where } \|A_i\| = \sqrt{\sum_{j=1}^n (a_{ij})^2}$$

Clearly, the vector  $(\hat{A}_i)$  is a unit vector.

Now, let,  $\alpha$  be the vector to be submitted to retrieve the associated pair  $\beta$ . Now,  $\alpha$  could represent a stored pattern or a noisy pattern. Irrespective of the case, the general system of equation is given as:

Frame the co-relation vector

$$M_{n \times 1} = [m_j], [m_j] = \phi(\langle \alpha, \hat{A}_j \rangle), j = 1, 2, \dots, N.$$

where,  $\phi(x) = 1$  when  $x = \max(\langle \alpha, \hat{A}_j \rangle)$  and 0 otherwise.

Now,  $\beta$  can be retrieved as,

$$\beta_k = \sum_{i=1}^N (\hat{a}_{ik} m_k), k = 1, 2, \dots, p$$

Where  $\beta_k$  is the k-th component of the vector  $\beta$  and  $\hat{a}_{ik}$  is the k-th component of  $\hat{A}_i$ . It is to be observed that the computation of  $\beta_k$  is unnecessary since for some  $d$ , when

TABLE I  
THE RESULT OF DENOMINATION AND ORIENTATION RECOGNITION

| Denomination | Orientation | Number of notes | Successful recognition | Wrong recognition | Recognition as indeterminate | Average time per note (in milliseconds) |
|--------------|-------------|-----------------|------------------------|-------------------|------------------------------|-----------------------------------------|
| 500          | Forward     | 20              | 20                     | 0                 | 0                            | 115                                     |
| 500          | Reverse     | 20              | 20                     | 0                 | 0                            | 115                                     |
| 100          | Forward     | 50              | 48                     | 0                 | 2                            | 105                                     |
| 100          | Reverse     | 50              | 47                     | 0                 | 3                            | 105                                     |
| 50           | Forward     | 100             | 97                     | 0                 | 3                            | 97                                      |
| 50           | Reverse     | 100             | 97                     | 0                 | 3                            | 97                                      |
| 20           | Forward     | 100             | 95                     | 0                 | 5                            | 100                                     |
| 20           | Reverse     | 100             | 97                     | 0                 | 3                            | 101                                     |
| 10           | Forward     | 100             | 96                     | 0                 | 4                            | 80                                      |
| 10           | Forward     | 100             | 94                     | 0                 | 6                            | 84                                      |

$m_d = \phi(\langle \alpha, \hat{A}_d \rangle) = 1$ , the corresponding  $\hat{B}_d$  is the vector to be retrieved.

#### IV. EXPERIMENTAL RESULTS

The overall system has been tested using numbers of banknotes ranging from Bangladeshi 10 taka to 500 taka. While recognizing the denomination and the orientation or side of the banknotes, the system could determine the appropriate values for 96.08% of the given banknotes images. In the remaining 3.92% cases the system could declare the banknotes as the indeterminate ones because they were too much old, irregularly torn, or violently corrupted by different noises. But there was no such case that the system mistakenly determined a wrong denomination or orientation. The result is shown in the table 1.

#### V. CONCLUSION

The automatic banknotes recognition and sorting systems are used allover the developed countries of the world. But in Bangladesh it is not available yet. However, in order to make the monetary transactions more dynamic such systems capable to recognize and sort the Bangladeshi banknotes must be introduced in the banking sectors and different business centers properly. This research is probably the first attempt to develop machine vision based practical banknotes manipulation systems in Bangladesh. The primary results shown in this paper are certainly promising. Nevertheless the authors believe that there is still a long way to go to make the methods more accurate, fast and efficient.

#### ACKNOWLEDGEMENT

The authors wish to acknowledge the strong enthusiasm and support of Dr. Kenji Yoshida, the chairman of Visual Magic Corporation Limited, and professor of Hosei University, Japan.

# An Efficient Implementation Scheme for Multidimensional Online Analytical Processing

Nilufar Easmin, K. M. Azharul Hasan, Nilufa Parvin

Department of Computer Science and Engineering, Khulna University of Engineering and Technology, Khulna 9203, Bangladesh

**Abstract**— Multidimensional online analytical processing (MOLAP) processes data that is already stored in a multidimensional array in which all possible combinations of data are reflected. It employs multidimensional array as their basic data structure. The intent of this paper is to develop a MOLAP model based on the scheme called Extended Karnaugh Map Representation (EKMR) and evaluate it. The basic idea of EKMR scheme is to present multidimensional array by a set of two dimensional arrays. This reduces data access time from secondary storage if the tuple of subscripts are known. Effectiveness of this scheme over traditional multidimensional array is shown with sufficient analysis and experimental results.

**Index Terms**— MOLAP, Dice, Slice, Multidimensional Array, EKMR.

## I. INTRODUCTION

Decision support systems are rapidly becoming a key to gaining competitive advantage for businesses. Many corporations are building decision-support databases, called *data warehouses*, from operational databases. Users of data warehouses typically carry out on-line analytical processing (OLAP) for decision making. Multidimensional aggregation plays an important role in OLAP technology in providing decision support environment for the users. In order to present this multidimensional view, the data is usually stored in the form of “summary tables”. This approach of storing data cube is known as ROLAP (relational OLAP) [1][2]. The other approach which the data cube is stored as a multidimensional array is known as MOLAP [3].

ROLAPs are built on top of standard relational database systems. MOLAPs are based on multidimensional database systems. A MOLAP is a set of *multidimensional datasets* and is designed to allow for the efficient and convenient storage and retrieval of large volumes of data that is closely related, viewed and analyzed from different perspectives. These perspectives are called *dimensions*. It is realized in the database technology that there is no single best data structure for all applications within an enterprise [4]. In a simple MOLAP model, a multidimensional dataset consists of *dimensions* and *measures*, represented by  $R(D_1, D_2, \dots, D_n; M_1, M_2, \dots, M_k)$ , where  $D_i$ 's are dimensions and  $M_j$ 's are measures. The data structures in which ROLAPs and MOLAPs store datasets

are fundamentally different[5]. ROLAPs use relational tables as their basic data structure on the hand MOLAPs store their datasets as multidimensional arrays. MOLAPs only store the values of measures in a multidimensional array. The position of the measure values within the array can be calculated by the dimension values. The latest step in the evolution of databases is the MOLAP database and this technology has matured into the database engine for data analysis applications. The MOLAPs are designed for analyzing large groups of records whereas relational databases make it easy to work with individual records. The advantages of wide acceptance of the MOLAP includes ease of data presentation and navigation, ease of maintenance and high performance for storage and retrieval costs [4] [6].

From the data model point of view, the multidimensional data model is one of the paradigms which can assist the data analysis and data summarization from multiple attribute values of database [11]. Many multidimensional data structures have been proposed [8]-[11]. Most of the MOLAP implementation use traditional multidimensional array as their basic data structure[1]-[3]. [12][13] Used multidimensional extendible array [8] as their basic data structure for MOLAP and multidimensional database implementation. Here in this paper a new representation scheme for multidimensional array is used for the implementation. The representation scheme is named as Extended Karnaugh map Representation[14][5]. In EKMR, an  $n$  dimensional array is represented by a set of 2 dimensional arrays. The superiority of the scheme over the traditional array for matrix operations is shown in [14].

## II. THE NOTION OF EKMR

In the EKMR scheme, a multidimensional array is represented by a set of two-dimensional arrays. The idea of the EKMR scheme is based on the Karnaugh map. Consider the 3 input K-map and its corresponding EKMR(3) in Fig. 1. Let  $A[k][i][j]$  denote a three-dimensional array based on Traditional Multidimensional Array TMA(3) with a size of  $3 \times 4 \times 5$ . The corresponding EKMR(3) of array  $A[3][4][5]$  is shown in Fig.1. The analogy between the EKMR(3) and the 3-input Karnaugh map is that the index variables  $i$ ,  $j$ , and  $k$  are

corresponding to the variables X, Y, and Z, respectively (Fig.1(a) and Fig.1 (b) ). According to the 3-input Karnaugh map, a three dimensional array based on the TMA(3) can be presented by a two-dimensional array based on the EKMR(3). The EKMR(3) is represented by a two-dimensional array with the size of  $4 \times (3 \times 5)$ . Here index variable  $i$  is used to indicate the row direction and the index variable  $j$  is used to indicate the column direction. The index variable  $i$  is the same as the index variable  $i$  and the index variable  $j$  is a combination of the index variables  $j$  and  $k$ .

Fig. 1: 3-input K-map and its corresponding EKMR(3)

### III. EMPLOYING MULTIDIMENSIONAL ARRAY

The records stored in the relational table are the gathering of the column values to each dimension of the multidimensional array. The example representing in Fig. 2 is a representation of a 3 column relation in a 3 dimensional array. Making each column each dimension of 3 dimensional array each column value is being corresponded with the subscript of each dimension. Also, each cube of array shows the position inside the array of each record. The subscript of the dimension is assigned name to 1, location to 2, and age to 3. Due to this, each record can stand for as an element of 3 dimensional array. For example, the record whose *Name* column value is “Yesmin”, *Location* column value is “Kushtia” and *Age* column value is 22 can be expressed as the subscript values (2,2,1) of the three dimensional array; these subscript values(i.e., coordinate) stand for the corresponding position in the array. The column values

need to be transformed into the subscript of the array to express the relation with the multidimensional array.

Fig. 2: Relational table implementations using multidimensional array

### IV. AN EFFICIENT MOLAP IMPLEMENTATION MODEL

In this Section the proposed MOLAP Implementation model and its operations are described. In the following, the EKMR based implementation is called as EI and the Traditional Multidimensional (TMA) based implementation is called as TI.

In Traditional Multidimensional Array (TMA) based implementation of MOLAP scheme each of the  $k$ th column of a  $n$  column relational table is mapped to the  $k$ th dimension of the multidimensional array. Each column value is mapped to a unique subscript and the measure value (i.e. sales value) of the relational table is inserted into the corresponding cell in the multidimensional array. Figure 3(b) represents the TI based MOLAP model for the relational table of the Figure 3(a). Hence for a  $n$  column relational table the corresponding multidimensional array is  $n-1$  dimensional array.

Fig. 3: MOLAP implementation scheme by TMA and EKMR.

Consider a simple multidimensional model in Figure 3, in which we have the column names product, store, time, and sales ( Figure 3(a)). There are three dimensions in Figure 3(b) product, store, and time respectively. The sales value

is stored in the corresponding cell of the array as fact data. For example the sales value 400 in TI (Figure 3(b)(c) ) indicates the fact that this is the sales value for the product P4 in store S4 at the time T3 which corresponds to the coordinate  $\langle 4,4,3 \rangle$ .

The similar approach of mapping is also considered for EI approach as shown in Figure 3(c) for MOLAP implementation. From Figure 3(b) and 3(c) we see that the representation scheme for MOLAP is fundamentally different in EI and TI. The 4 dimensional array is replaced by a 2 dimensional array. Hence the location of the sales value or array cell number will be different for TI and EI. And for the same reason, the same relational table implementation for MOLAP will be different.

## V. MOLAP OPERATIONS

The slice and dice operation for different situation is described in this section. We are taking a 5 column relational table as an example.

### A. Slice Operation

The slice operation for a 4 dimensional array implemented as MOLAP is the basis for answering the following questions

- Q1) Find the sales value of product P4
- Q2) Find the sales value of store S3
- Q3) Find the sales value at time T2
- Q2) Find the sales value for model M1

In slice operation the number of known dimension is only one and on the basis of the value of this dimension expected sales value is found. The physical organization of these situations is explained in Figure 4 using row major order of array organization. In Figure 4(a), the candidate array cells are shown for the case Q1. We can see all the candidate values are linear and can be accessed very easily if the array is stored in the secondary storage. All the candidate sales values are collected and added to produce the result for Q1. For this case the retrieval for slice operation will be advantageous for EI.

In Figure 4(b), we see that, the candidate array cells are organized in three different streams having 9 values are in the same stream. It will be necessary to access the streams to collect and produce the result for Q2. In Figure 4(c), (for Q3) the candidate values are organized in 9 different streams 3 values for each stream. And finally, In Figure 4(d), all the values are organized different stream. These values are collected and added to get the result of the slice operation.

Fig. 4: Different situation for Slice operation for 4 dimension case ( $\rightarrow$  indicates those values which can be accessed linearly because of row major order).

### B. Dice Operation

The dice operation is similar to that of the slice operation. Dice operation is the basis for answering of the questions like

- Q1) Find the sales value of product P2 at store S2  
Q2) Find the sales value of product P2 for store S3 at time T2, and so on.

The number of known dimension in slice operation is only one on the other hand number of known dimension for dice operation is more than one. For example in the Q1 above the known dimension is product dimension and

Fig. 5: Different situations for Dice operation( $\rightarrow$  indicates those values which can be accessed linearly)

store dimension. Figure 5(a) shows the situation for the case Q1 and Figure 5(b) shows the situation for case Q2. All the values are collected and added to get the sales value for dice operation.

## VI. EXPERIMENTAL RESULTS AND ANALYSIS

In this Section the experimental result for both EI and TI are described and compared. The parameters that are considered are as follows.

### A. Parameters

| Parameter | Description                                                                                                                                                                                           |
|-----------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $N$       | Total number of dimensions                                                                                                                                                                            |
| NR        | Total no. of records in the relational table.                                                                                                                                                         |
| $D_i$     | Length of dimension of dimensions $i(i \leq N)$ . We assumed all the lengths of dimension $D_i$ is equal for all $i$ ( $1 < i < n$ ). Hence we write $D$ to indicate the lengths of dimension $D_i$ . |
| $\rho$    | Density of records in the Array $\rho = NR / IID_i$ . We assumed the records are uniformly distributed in EI and TI.                                                                                  |

### B. Comparison between EI and TI for Slice Operation

We have taken executing time for dice and slice operation for MOLAP at different length of dimension and at different density of records for each dimension for the case of EI and TI scheme. The retrieval time for slice and dice operation at  $\rho=0.3$  for  $N=65$  are shown in Table 1. In Table1  $D_1$ ,  $D_2$ ,  $D_3$  and  $D_4$  are dimension 1, 2, 3 and 4 respectively for which the slice operation is done. From table1 we see that for slice operation if dimension 4 is known then executing time is 90 ms this is the situation pointed out in Figure 4(a). This is because when

Table1: Processing time for slice and dice operation

|                 |          |           |             |        |
|-----------------|----------|-----------|-------------|--------|
| Slice operation | D1       | D2        | D3          | D4     |
|                 | 6990 ms  | 199627 ms | 15703 ms    | 90 ms  |
| Dice operation  | D1,D4    | D1,D3     | D1,D2       | D2,D3  |
|                 | 3974 ms  | 210 ms    | 81 ms       | 250 ms |
|                 | D1,D2,D3 | D2,D3,D4  | D1,D2,D3,D4 |        |
|                 | 20 ms    | 20 ms     | 0 ms        |        |

(a)

(b)

(c)

Fig. 6: Slice operation comparison for EI and TI for different values of known dimension

dimension 4 is known then more data are linear and can be collected easily. If dimension 1 is known then executing time is 6990ms this corresponds to the situation pointed out in Figure 4(b), if dimension 3 and dimension 2 corresponds to the situation described in Figure 4(c) and 4(d) respectively.

(a)

(b)

Fig. 7: Dice operation comparison for EI and TI for different values of known dimension

Comparison between EI and TI for slice operation at  $\rho = 0.25$  density for length of dimension 70, 75, 80 and 85 are shown Fig. 6 which shows the retrieval time for slice operation for different known value of dimension for varying length of dimension for EI and TI having  $\rho = 0.25$ . We see that, the time required to perform slice operation EI scheme is superior over TI for different known value of dimension. Some of the results have unexpected value as shown in the figure. This is because the uniform distribution that is used to generate the data automatically we put one dimension as reference dimension. So when the query that is adopted is not reference dimension it might cause less data because the data placement idea in EI is completely different than that of TI. One more important point is that the same array location for TI and EI does not refer to same record in a relational table. Hence some unexpected result for a query may occur. The superiority of EI scheme will be well understood by the

Figure 6(c) which shows the average execution time for TI and EI. We can see all the length of dimension values the EI scheme has advantages over TI. The average is calculated using the values resulted for the Q1 to Q4 (Section V).

### C. Comparison between EI and TI for Dice Operation

Fig. 7(a) and (b) show the dice operation comparison for different combination of known dimensions for EI and TI. EI has advantages in most of the cases of the experiment in EI over TI. Finally it can be concluded that the EI scheme proposed in this paper has advantages over TI. Although both are multidimensional arrays but due to the organization difference the EI scheme is superior over TI scheme for large volume MOLAP design and implementation.

## VI. CONCLUSION AND FUTURE WORKS

We propose and evaluate an efficient MOLAP implementation scheme using a new array representation scheme as opposed to the conventional multidimensional arrays. Our performance result shows that the proposed scheme is superior in most of the cases of slice and dice operations. We believe our scheme can also be applied to the multidimensional database implementations effectively specially for data warehousing applications for multidimensional analysis.

The future direction of this paper is to proceed for compressed data warehouse design and implementation using this scheme. The large number of array cells that are empty should be ignored and that's why compression is important. One more direction is to apply for parallel data warehouse design because many operations described in this paper can be done independently that will make efficient the structure to be applied in parallel environment.

**Abstract** — Mining data from a database using classification algorithm is not an innovative technique. This paper presents a technique namely Decision Tree based Routine Generation (DRG) algorithm to create an academic routine. The concept of open credit course registration system (after completion of pre-requisite courses any student may choose any course in any semester) makes the research more challenging and complex to accomplish. This is an NP-Hard Problem and hence unsolvable to satisfy all students and teachers at the same time. A level of tolerance has to be added to make the evaluation efficient and effective to achieve the goal, a conflict free routine. OLAP representation helps to classify the courses along with the proposed algorithm to eliminate some constraints. Day-based pattern, minimum Manhattan Distance between courses of same teacher, minimum conflicted course distribution has been stage-managed to classify the courses. To alleviate the algorithm, decision tree based models and sequential search methods are espoused with computational results.

**Index Terms** — OLAP, Crosstable, Conflict List, Favorite Slot, Faculty Choice, Course Color, Day-time slot pattern.

## I. INTRODUCTION

In this paper the proposed Decision Tree based Routine Generation (DRG) algorithm describes how to generate a university class routine within a tolerable range of some constraints. A decision-tree based classification algorithm has been introduced to solve this NP-Hard Problem. CPL (constraint logic programming) is a respected technology for solving hard problems which include many (non-linear) constraints [1]. Constraint propagation technique has been applied to overcome the preferential requirements for slots of teachers, courses from pre-advising by students and class room allocation. Versatile choices for courses may lead to a deadlock situation. Golz used priorities heuristic ordering [2] where Abdennadher introduced an optimized cost-based rule mining [3,4] to solve these type of problems. On the other hand, knowledge based in a hyper heuristic course scheduling using case based reasoning is used to maximize the rule covering area [5]. DRG presents key features of generating class routine with minimum computational time. Heterogeneous distribution of courses is classified with maximum satisfaction of all

constraints. Section II describes about previous related works and preliminaries in details. Section III illustrates the problem dimensions with the data filtering technique used in the paper to summarize for further manipulation; pursued by the proposed algorithm, DRG, and the classification procedure to find the feasible solution in Section IV. Section V explains the computational results and the performance analysis.

## II. PRELIMINARIES AND RELATED WORK

A university class routine generation problem – as considered in this work – consists of assigning each course in a set of slots (classes) in a limited class rooms within the teachers' favorite time slots. This highly constrained problem is optimized by simulated annealing and genetic algorithm [6,7]. Seven different major and minor objectives are discovered and deadlock situation is overcome by randomly exploring the composite neighborhood [8]. The most closely related attempt with this work appears to be the constraint programming approach used by Boizumault [9] and the simulated annealing approaches explored by Dowsland and Thompson [10,11]. The principal innovation in DRG is the sequential use of these two methods. DRG may select some poor slots, with respect to teachers or students, under a tolerable conflict range. A similar sequential approach has been taken in DRG on other problems: White and Zhang [12] used constraint programming to second a starting point for tabu search in solving course timetabling problems. For a high school timetabling Yoshikawa tested several combinations of two stage algorithms, including a greedy algorithm followed by simulated annealing and a constraint programming phase followed by a randomized greedy hill climbing algorithm (which is deemed to be the best combination of those used). In a similar vein, Burke, Newell and Weare [13] used their work on sequential construction heuristics [14] to generate initial solutions for their memetic algorithm [15].

### III. PROBLEM DESCRIPTION AND DATA FILTERING

The routine maps a set of courses chosen by students and teachers to a specific room and time-slot. A major objective, in developing an automated system, is to minimize the hassle of separating conflicted courses from choices by students. In this paper the major identified problems are (a) Number of lectures per week for each course are fixed, (b) Room overlapping is prohibited, (c) Fitting the routine with teacher's favorite timeslots, and (d) trying to assert different timeslots to same level of courses. On the other hand, the minor objectives are day-timeslots pattern for the course, room capacity, avoiding gaps between classes of same teacher, if possible, single class for student per day and ensuring compactness of interclass time difference.

The required scattered data contains total courses (course choices from pre-advising by students)  $C = \{c_1, c_2, c_3, \dots, c_n\}$  where the dependencies between courses are also maintained. Here course dependency can be defined as  $\exists C_i, C_i \rightarrow C_j$  where  $C_i, C_j \subset C$ . For this paper the students',  $S = \{S_1, S_2, S_3, \dots, S_z\}$ , course choices can be derived as  $S_j = \{c_i\}$  where  $\exists i, c_i \in C$  and  $1 \leq i \leq n$  and  $|S_j| = \max\_course\_choice$  for the student as shown in Fig. 1. Teachers' favorite timeslots are grouped according to day-timeslots pattern. Here group A and B is formed for the teacher  $t_k$ , where  $T = \{t_1, t_2, t_3, \dots, t_m\}$ ,  $A(t_k) = \{\text{favorite time\_slots of } t_k \mid \text{sequential time slots for Saturday, Monday and Wednesday}\}$  and  $B(t_k) = \{\text{favorite time slots of } t_k \mid \text{sequential time slots for Sunday, Tuesday and Thursday}\}$ , whereas  $\text{time\_slots} = \{1, 2, \dots, 30\}$  contains 5 sequential slots per day starting from Saturday. Here Friday is considered as an off-day. Priority of the teacher has been introduced by  $P(t_k) = \{1, 2, \dots, 10\}$  where a higher value represents higher priority. An exceptional priority is also introduced as 11 reflecting part-time faculty, whose projected time cannot be changed. Fig. 2. and Fig. 3. shows the teachers' wish-list and the course distribution among the teachers'. Target of this work is to find the values of the "class slot routine" field of the Fig. 3. The resultant routine vector,  $V = \{\{c_i\}_q\} \forall i, c_i \in C$  and  $1 \leq i \leq n$  and  $1 \leq q \leq 30$ , consists of the course classification as per day required for each course and class room availability.

In this paper, this huge dimensionality of dataset is reduced by initiating an OLAP (On-Line Analytical Processing) representation [16]. Here a *Crosstable* (Cr) of  $(n \times n)$  courses are initialized.  $Cr(n \times n) = \{\text{conflict}_{i,j}\}$  where  $1 \leq i,j \leq n$  and 'n' is the total number of courses requested by the student (or is 'n' number of courses offered by the department). Here the conflict of  $Cr_{i,j}$  is a positive integer that reflects the common students between

$c_i$  and  $c_j$ . The diagonal values of  $Cr_{i,i}$  show the total number of students requesting for the course  $c_i$ .

| Student ID     | Course ID      | Semester ID |
|----------------|----------------|-------------|
| S <sub>1</sub> | c <sub>1</sub> | 1           |
| S <sub>1</sub> | c <sub>3</sub> | 1           |
| S <sub>2</sub> | c <sub>1</sub> | 1           |
| S <sub>2</sub> | c <sub>3</sub> | 1           |
| S <sub>3</sub> | c <sub>2</sub> | 1           |
| S <sub>3</sub> | c <sub>4</sub> | 1           |
| S <sub>3</sub> | c <sub>5</sub> | 1           |
| S <sub>4</sub> | c <sub>4</sub> | 1           |

Fig. 1. Courses Pre-Advised by the Students.

$\sum Cr_{i,j}$ ,  $[1 \leq j \leq n]$  is the total conflict for the course  $c_i$   $[\forall i, i \neq j]$ . Maximum "chaos" (conflict) courses can be easily sorted out from this two dimensional conflict distribution (*Crosstable*).

| Teacher ID     | Favorite Slots             | Priority |
|----------------|----------------------------|----------|

Fig. 3. Courses and Classes Distribution for the Teachers.

To minimize the potential for time conflict, an admissible heuristic ( $h$ ) is imposed to regroup the courses according to their dissimilarity. Graph Coloring algorithm is used to cluster where the conflict in *Crosstable* confirms the weights of the edges in the graph. Here the admissible heuristic is applied as the maximum number of colors needed to find the minimum number of groups of courses. Here faculty redundancy is also considered as weight, that is, same faculty of different courses cannot be in the same group. The output of Graph Coloring Algorithm assigns a color to all courses individually (same colored courses are treated as a group). Fig. 4. shows the resultant *Crosstable*. Each group may consist more than the threshold limit

members with tolerable conflict range. Here the number of the rooms is considered as the threshold value. In this work the tolerable conflict range is set to 0.

| Course ID      | c <sub>1</sub> | c <sub>2</sub> | c <sub>3</sub> | c <sub>4</sub> | Total Conflict |
|----------------|----------------|----------------|----------------|----------------|----------------|
| c <sub>1</sub> | 40             | 5              | 7              | 0              | 12             |
| c <sub>2</sub> | 5              | 50             | 0              | 2              | 7              |
| c <sub>3</sub> | 7              | 0              | 35             | 5              | 12             |
| c <sub>4</sub> | 0              | 2              | 5              | 40             | 7              |
|                | t <sub>1</sub> | t <sub>2</sub> | t <sub>3</sub> | t <sub>1</sub> |                |

Fig. 4. Crosstable for  $n \times n$  Courses.

This easy formation of coloring may lead to a measure of the undesirability of having classes overlapped in the routine. It will be effective to try to fit the most “chaos” courses of high priority teachers in the routine first. Random selection may be used to select teacher having same priority. The data used in this work to test the algorithm is real.

#### IV. THE DECISION TREE BASED ROUTINE GENERATION (DRG) ALGORITHM

The aim of the proposed DRG algorithm is to classify all the courses with a degree of satisfaction. Enormous permutation of courses may lead to a time consuming process. So a standardized branch & bound condition may be applied to reduce the problem surface area. The DRG sequentially follows 4 sets of cascading decision trees. Depending upon the emergence and success rate, the result of one tree is propagated to another tree. These transitions may lead to a solution but also may degrade the satisfaction threshold. A control portion helps to justify the problem solution needed to be more explored or not.

##### A. Priority regulated DRG (PDRG)

The first decision tree accumulates the high prioritized teacher  $t_k$  and most conflicted course  $c_i$  of  $t_k$  to the routine vector with maximum fitness value. The *max\_fit* function tries to discover the day-time pattern for the course. If the consequential day-time slots are already occupied by other courses, it checks the corresponding course color. If the color of the courses is same it classifies the course  $c_i$  with a degree. Here the fitness value of a course is referred as degree. The highest returned degree of a day-time slot, as maximum fitness value, is selected as the course class for  $c_i$ . This operation provides a pattern-based course distribution,  $A(t_k)$  or  $B(t_k)$ , in the routine although some courses may be placed partially as per their *class\_per\_week* and *max\_class\_per\_slot* constraints. In this manner, the low priority teachers may suffer by not getting the classes in a sequential manner. But in practice

26% of the total courses can be placed with zero conflict and with a high level of satisfaction. The level of satisfaction is a quantitative measure of placement for a course with respect to the teachers’ favorite slots. The definitive PDRG tree is shown in Fig. 5. The partially placed and not yet placed courses then elected as cascaded input to second level of exploration. The computational time of this operation requires  $O(n \times m)$  where the maximum number of courses per teacher is ‘n’ and the number of faculties is ‘m’.

##### B. Chaos eradication DRG (CDRG)

In this decision tree, the less demanded time slots (with respect to number of rooms) are labeled as “cold” whereas high demanded ones are labeled as “hot”. Among the remaining most conflicted courses (may not or partially placed) with low frequent time slots of the corresponding teacher are chosen for the second decision tree. If the considerable slot is empty then the course is placed in that

Fig. 5. Decision Tree of PDRG

slot, otherwise the colors have to be matched. If the color of the courses placed in the slot matches with the concerning course, the latter course is classified, and if not other options are taken into consideration for the teacher. The considerable courses in CDRG are the overlooked courses from PDRG, where PDRG confirms the day-time pattern is not possible for the courses due to color and the scattered choice of slots by the teachers. So day-time slots pattern are ignored in this operation. After using this second decision tree few courses may remain unchanged. Nevertheless this time the number of remaining courses is much less than the previous one. Around 32% of the remaining courses are placed successfully by CDRG. The

combined effort of decision trees still provides high confidence. Fig. 6. demonstrates the Chaos eradication DRG. Now this tree holds time complexity of  $O((n - d) \times (m - l))$  where the maximum number of courses per teacher is 'n', the number of faculties is 'm' and 'd' is the already classified courses of each teacher by the PDRG and 'l' is the number teacher whose all courses were placed in the routine by PDRG.

Fig. 6. Decision Tree of CDRG

### C. Tolerable DRG (TDRG)

The first two decision trees are aimed at automated generations of a better assignment. The second approach seeks to find an assignment of vector which may be more difficult to locate in the search space using the already assigned vector. The third decision tree allows the remaining courses according to the priority of the teachers to find a place into the routine within a tolerable conflict range of the subsequent teachers' favorite slots. Here the course color is overlooked. This classification now introduces errors into the system by considering the tolerable students conflicts only. Important issue is that, this manipulation may iterate several times to include as many courses possible to place in to the routine. 22% of the unclassified and partially classified courses are labeled with a tolerable error. The flowchart presentation of this decision tree is shown in Fig. 7. The average time complexity of TDRG is approximately  $O(t \times (n - (d + o)) \times (m - (l + p)))$  where the maximum number of courses per teacher is 'n', the number of faculties is 'm' and 'd' is the already classified courses of each teacher by the PDRG and 'l' is the number teacher whose all courses were placed in the routine by PDRG. 'o' is the number of

courses placed by CDRG and 'p' is the number of teachers whose courses are completely placed by CDRG. Here 't' is the number of TDRG iterates.

Fig. 7. Decision Tree of TDRG

### D. Neighboring Tour DRG (NTDRG)

The fourth possibility search allows the courses to look over the contour of the teachers' favorite slots to find the least conflicted slots. Although the students' scattered choices is overlooked in TDRG but the placed courses do not displease teachers' preference. The final decision tree is modeled in such a manner so that the rest of unplaced courses are going to be graded into the routine vector within a minimum distance of the teachers' choice. Manhattan Distance is calculated for this placement of courses. Manhattan Distance for a teacher is a vital performance measuring tool to find the slot gaps per day for an individual teacher. The optimization can be done by keeping cumulative Manhattan Distance for the teachers as low as possible. It is assured that the courses were not placed on that day. From the remaining courses, a course is selected according to the priority of the teacher. Complement of the intersection between the classification value of that course and the corresponding teachers' used slots are considered as new host slots. The neighboring slots of the new hosts are the most likely candidates. Among the candidates the most "cold" (less desired slots) slots are considered as candidates. Considerable issues in this placement are tolerable conflict range, allocable number of rooms and day-time misjudgment. Fig. 8. demonstrates the overall scenario of Neighboring Tour DRG (NTDRG). The approximate time complexity is  $O(2 \times (n - (d + o + u)) \times (m - (l + p + v))) \approx O((n - (d + o + u)) \times (m - (l + p + v)))$  where the maximum number of courses per teacher is 'n', the number of faculties is 'm'

and 'd' is the already classified courses of each teacher by the PDRG and 'l' is the number of teacher whose all courses were placed in the routine by PDRG. 'o' is the number of courses placed by CDRG and 'p' is the number of teachers whose courses are completely placed by CDRG. 'u' is the number of courses placed by TDRG and 'v' is the number of teachers whose courses are completely placed by TDRG.

Fig. 8. Decision Tree of NTDRG

These four sequential decision trees feed forward to an acceptable solution. The cumulative time complexity of DRG is  $O(A.mn + B.m + C.n)$ , where A, B and C are constants depending upon the number of iterations of TDRG algorithm and number of courses placed by each and every algorithm. The algorithm degrades due to the fact that the students have a freedom to choose any course (assuming that the prerequisite course is completed). First search PDRG faces problem if same prioritized teacher focus into same favorite time slots. By using CDRG this situation may prevail over considering a level of discontinuity into the day-time pattern for the courses.

In second run, if the low “chaos” course holds high prioritized teacher then the classification may dissatisfy the teacher. For the third rotation the conflict may arise for the students for not considering the color. For NTDRG if the host slot is elected as the first and last class of the day then the previous and the next consecutive slot are from

different days. So, this day jump increases huge distance for the teacher which may lead to an unfeasible classification.

## V. EXPERIMENTAL RESULTS

Test results for DRG algorithm are carried out on a PC with Pentium IV/1.6 GHz processor and 256 MB of memory. Table I. shows the computational results for semester 1 and semester 2 with 66 and 61 courses correspondingly. Where for semester 1, around 24 teachers, with minimum 10 classes per week and at least 3 courses and 120 students with 430 combinations of choices of courses are considered as input. For semester 2, around 23 teachers, with minimum 10 classes per week and at least 3 courses and 106 students with 414 combinations of choices of courses are considered as input.

In Table I. *unclassified courses* refers to the number of courses that were not classified by any decision trees, *partially classified courses* gives the number of courses partially classified (the number classes already placed into the routine is less then the required classes). *Day-time pattern* shows the numbers of courses that followed the day-time pattern. *student conflict* estimates the percentage of unsatisfied requirements for courses by students. *Unsatisfied time* refers the number of time slots automatically generated beyond teachers' favorite choice. Randomization or prediction on classification is not used. So the output of this  $O(A.mn + B.m + C.n)$  based deterministic algorithm strictly depends upon the input.

## VI. CONCLUSION

This paper presents an algorithm that generates a promising result. It should be noted that the proposed Decision Tree based Routine Generation (DRG) algorithm using OLAP representation, to construct a university class routine, brings the complexity to a considerable level. This solution classifies 96% - 97% of the courses as well 93% - 95% satisfaction for teacher. For this data set, students' satisfaction is 100% but in general 90% - 93% satisfaction may be achievable by using DRG. Preferential requirements on time variables are met around 93%.

## ACKNOWLEDGEMENT

The proposed algorithm is employed to construct a class routine for a reputed university in Bangladesh. Author(s) of the paper express gratitude to the university authority for providing indispensable information.

# Extended Algorithm for Spatial Characterization and Discrimination Rules

Md. Rashidul Hasan, Md. Zakir Hossain, Fahim Md. Chowdhury, Mohammad Khalad Hasan

Department of Computer Science & Engineering, Shah Jalal University of Science & Technology, Sylhet, Bangladesh. {shaikot\_cse, zakir\_01913, tanim\_csesust}@yahoo.com, khalad-cse@sust.edu.

**Abstract** — Spatial data mining, i.e., mining knowledge from large amounts of spatial data, is a demanding field since huge amounts of spatial data have been collected in various applications, ranging from remote sensing to geographical information systems (GIS), computer cartography, environmental assessment and planning. The collected data far exceed people's ability to analyze it. The number and the size of spatial databases are rapidly growing which results in an increasing need for spatial data mining. In this paper, we have presented a new spatial data mining algorithm for spatial characterization and discrimination rules. For spatial data mining algorithm, it is important that class membership of a database object is not only determined by its non-spatial attributes but also by the attributes of objects in its neighborhood. We have implemented the algorithm within a general framework for spatial data mining providing a small set of database primitives on top of a commercial spatial database management system. At the end, performance analysis using a real geographic database demonstrates the effectiveness of the proposed algorithms.

**Index Terms** — Characterization, data mining algorithm, discrimination, spatial database primitives, spatial data mining.

## I. INTRODUCTION

Knowledge discovery in databases (KDD) has been defined as the non-trivial process of discovering valid, novel, potentially useful and ultimately understandable patterns from data; a pattern is an expression in some language describing a subset of the data or a model applicable to that subset [1]. The process of KDD is interactive and iterative, involving several steps such as data selection, data reduction, data mining, and the evaluation of the data mining results [2]. The heart of the process, however, is the data mining step which consists of the application of data analysis and discovery algorithms that, under acceptable computational efficiency limitations, produce a particular enumeration of patterns over the data [1].

Spatial Database Systems (SDBS) [3] are database systems contain spatial objects representing natural objects like mountain or rivers, infrastructure like railroad, location, highways and/or extension as well as by several non-spatial attributes. Figure 1 illustrates a spatial database named Branches where the location of the branch has stored as spatial object.

Fig. 1. Spatial and Non-spatial attribute of a data set.

Spatial data mining algorithms are used to find implicit regularities, rules or patterns hidden in large spatial databases, e.g. for geo-marketing, traffic control or environmental studies. A variety of data mining algorithms for mining in relational as well as spatial databases have been proposed in the literature [4][5][6].

The discovery process for spatial data is more complex than for relational data. This applies to both the efficiency of algorithms as well to the complexity of possible patterns that can be found in a spatial database. The reason is that, in contrast to mining in relational databases, spatial data mining algorithms have to consider the neighbors of objects in order to extract useful knowledge. This is necessary because the attributes of the neighbors of some object of interest may have a significant influence on the object itself [2].

In this paper, we present a new spatial data mining algorithm for both characterization and discrimination rules which extends current spatial characterization algorithm [4]. These tasks, especially characterization and discrimination rules in spatial databases were also studied in [6, 7, 8] and [12] respectively. A characterization rule is an assertion which characterizes a concept satisfied by all

or a majority number of the examples in the class undergoing learning (called the target class). For example, the symptoms of a specific disease can be summarized by a characterization rule. A discrimination rule is an assertion which discriminates a concept of the class being learned (the target class) from other classes (called contrasting classes) [12]. For example, to distinguish one disease from others, a discrimination rule should summarize the symptoms that discriminate this disease from others. We have developed an algorithm that can characterize target class and find out the concepts by which it is discriminated from other classes. For example, the algorithm can summarize the symptoms of a specific disease as well as it also can summarize the symptoms that discriminate this disease from others. Our algorithm for spatial characterization and discrimination are presented within a general framework based on database primitives [9] for spatial data mining.

## II. DATABASE PRIMITIVES FOR SPATIAL DATA MINING

For the efficient support of the spatial data mining algorithms one should analyze typical operations and data structures that can support different types of knowledge discovery queries. Martin Ester, Alexander Frommelt, Hans-Peter Kriegel and Jörg Sander have presented the concepts of neighborhood graphs, neighborhood paths and neighborhood indices [9]. The neighborhood concept covers different type of spatial relations including topological relations (meet, overlap etc.), distance relations (close to), and direction relations (north, west, under, etc.). The neighborhood graph for a relation neighbor is a graph where nodes are objects in the database and edges between nodes  $n_1$  and  $n_2$  represent the fact that the relationship neighbor ( $n_1, n_2$ ) holds. The neighborhood path in the neighborhood graph  $G$  is a set of nodes directly connected through the edges of the graph. The authors presented basic operations for the construction of graphs and for browsing and expansion of paths. Some important definition and basic operation has been described which are used in our algorithm.

### A. Neighborhood graphs and paths

Let *neighbor* be a neighborhood relation and  $DB$  be a database of spatial objects. A *neighborhood* graph  $G_{neighbor}^{DB} = (N, E)$  is a graph with nodes  $N = DB$  and edges  $E \subseteq N \times N$  where an edge  $e = (n_1, n_2)$  exists iff *neighbor*( $n_1, n_2$ ) holds. A *neighborhood* path of length  $k$  is defined as a sequence of nodes  $[n_1, n_2, \dots, n_k]$  where *neighbor* holds for all  $(n_i, n_{i+1})$ . The following basic operations are briefly described.

- *neighbors*:  $Graphs \times Objects \times Predicate \rightarrow Sets\_of\_objects$
- *paths*:  $Sets\_of\_objects \rightarrow Sets\_of\_paths$
- *extensions*:  $Graphs \times Sets\_of\_paths \times Integer \times Predicates \rightarrow Sets\_of\_paths$

The operation *neighbors*(*graph*, *object*, *predicate*) returns the set of all objects connected to object in graph satisfying the conditions expressed by the predicate *predicate*. The operation *paths*(*objects*) creates all paths of length 1 formed by a single element of objects and the operation *extensions*(*graph*, *paths*, *length*, *predicate*) returns the set of all paths of the specified length in graph extending one of the elements of paths. The extended paths must satisfy the predicate *predicate*. The elements of paths are not contained in the result implying that an empty result indicates that none of the elements of paths could be extended.

Because the number of neighborhood paths may become very large, the argument *predicate* in the operations *neighbors* and *extensions* acts as a filter to restrict the number of neighbors and paths to certain types of neighbors or paths. The definition of predicate may use spatial as well as non-spatial attributes of the objects or paths.

The techniques of implementing these basic operations (which is described above) in commercial spatial database system have been described here [2]. Typically, spatial index structures, e.g. R-trees, are used in a spatial DBMS (such as oracle 11g spatial) to speed up the processing of spatial queries such as region queries or nearest neighbor queries. Using the spatial index structures, a neighbor algorithm (which has signature *neighbors* (*Graph*, *object*, *predicate*)) [2] have presented which returns neighbor of a spatial object for some predicates in a graph. We have used the algorithm in the implementation of our proposed algorithm.

## III. CONCEPTS OF THE ALGORITHM

Spatial characterization of a set of target objects with respect to the database containing them as a description of the spatial and non-spatial properties which are typical for the target objects but not for the whole database. To obtain a spatial characterization, not only the properties of the target objects should be considered, but also the properties of their neighbors up to a given maximum number of edges in the neighborhood graph [4].

A spatial discrimination is a general description of the features discriminating or contrasting a class of spatial data (target objects) from other class (contrast objects),

like the comparison of price ranges of houses in different geographic regions. The relative frequencies of non-spatial attributes and the relative frequencies of different object types can be used as interesting properties for describing spatial characterization and spatial discrimination rules [2]. Figure 2 illustrates relative frequencies in the database as well as in the target regions and the ratio of these frequencies in comparison with the specified level of significance.

A *property* of some spatial object by a tuple of one of the two following formats: either *(attribute, value)* or

Fig. 2. Sample frequencies and differences [2].

*(“type”, type)* where “type” denotes the special “attribute” representing the object type such as community, mountain or river [2].

The task of spatial characterization is to discover the set of all properties for which the relative frequency in a set of target objects, extended by its neighbors, is significantly different from the relative frequency in DB [4]. The task of spatial discrimination is to discover the values of that set of properties in a set of contrast objects, extended by its neighbors and compare them with the values of the set of the properties for the target region. For spatial discrimination, it is important to find out properties which are significant with the properties of target objects and their neighbors, not with total databases because only same property values can be comparable.

So, to obtain spatial discrimination, the following steps are required:

1) First find the properties of target class which are significant from the properties of total database with expansion to maximum neighbors.

2) Find the values of the properties of the characterized target class in contrast objects with expansion to maximum neighbors. The values of these properties should have the maximum frequency in contrast region.

3) Compare the target and contrast objects using these properties.

#### IV. PROPOSED ALGORITHM

The current spatial characterization algorithm [2] is suitable for characterizing some spatial objects like finding characteristics of weather pattern in a certain region. We think the comparison of characteristics of weather pattern among two or more different regions is also necessary for business and real life purposes. In comparison, it is important to ensure that the relevant properties of two classes have been compared so that comparison makes valid sense. So, we have extended the current spatial characterization algorithm and make it compatible for finding both spatial characterization and discrimination rule. Using our proposed algorithm, the characteristics of some spatial objects (selected by some predicates) can be found as well as what the characteristics of that spatial objects discriminate from other contrast spatial objects can also be found. We have used in our algorithm same basic notations of current existing spatial characterization algorithm [2].

Let  $G_{neighbor}^{DB}$  be a neighborhood graph and *targets*, *contrasts* are subset of DB. Let frequency  $^s(prop)$  denote the number of occurrences of the property *prop* in the set *s* and let  $card(s)$  denote the cardinality of *s*. The *frequency factor* of *prop* with respect to set of spatial objects *objects* and *DB*, denoted by, is defined as follows [4]:

$$f_{objects}^{DB}(prop) \Rightarrow \frac{freq_{objects}(prop)}{card(objects)} \bigg/ \frac{freq^{DB}(prop)}{card(DB)}$$

Let *significance* and *proportion* be real numbers and let *max-neighbors* be a natural number. Let  $Neighbors_G^i(s)$  denote the set of all objects reachable from one of the elements of *s* by traversing at most *i* of the edges of the neighborhood graph *G*. Then, the task of *spatial characterization* is to discover each property *prop* and each natural number  $n \leq max-neighbors$  such that (1) the set  $objects = Neighbors_G^n(targets)$  as well as (2) the sets  $objects = Neighbors_G^n(\{t\})$  for at least *proportion* many  $t \in targets$  satisfy the condition:

**Discover-Spatial-Characterization-Discrimination** (graph  $Gr_r^{DB}$ , set of objects *targets*, set of objects *contrasts*, real *significance*, real *proportion*, integer *max-neighbors*)

initialize the set of (*targets\_characterizations*, *contrast\_characterizations*, *final\_targets\_characterizations*, *final\_contrast\_characterizations*, *final\_contrast\_characterizations\_nonspatial*, *final\_contrast\_characterizations\_spatial*) as empty.

Initialize the set of *target\_regions* to *targets*, the set of *contrast\_regions* to *contrasts*.

initialize integer *n* to 0, real *contrast\_region\_frequency\_factor* to 0, property *maximum\_frequency\_property* as empty ;

calculate  $frequency^{DB}(prop)$  for all properties *prop* = (attribute, value) in DB;

**while**  $n \leq \text{max-neighbors}$  **do**

**for** each attribute of DB and for the spatial attribute object type **do**

*contrast\_region\_frequency\_factor* = 0;

**for** each value of attribute **do**

            calculate  $frequency^{target\_regions}(prop)$  for property *prop* = (attribute, value);

            calculate  $frequency^{contrast\_regions}(prop)$  for property *prop* = (attribute, value);

**if**  $frequency_{target\_regions}^{DB}(prop) \geq \text{significance}$  or  $frequency_{target\_regions}^{DB}(prop) < \frac{1}{\text{significance}}$  **then**

**add** (*prop*, *n*,  $frequency_{target\_regions}^{DB}(prop)$ ) to the set of *targets\_characterization*;

**if**  $frequency_{contrast\_regions}^{DB}(prop) > \text{contrast\_region\_frequency\_factor}$

*contrast\_region\_frequency\_factor* =  $frequency_{contrast\_regions}^{DB}(prop)$  ;

                    replace *maximum\_frequency\_property* by *prop*;

**end of for.**

**add** (*maximum\_frequency\_property*, *n*,  $frequency_{contrast\_regions}^{DB}(prop)$ ) to the set of *contrast\_characterizations*;

**end of for**

**if**  $n < \text{max\_neighbors}$  **then**

**for** each object in *target\_regions* **do**

**add** neighbors( $Gr_r^{DB}$ , object, true) to *target\_regions*;

**for** each object in *contrast\_regions* **do**

**add** neighbors( $Gr_r^{DB}$ , object, true) to *contrast\_regions*;

    increment *n* by 1;

**end of while.**

*final\_targets\_characterizations* = extract all tuples (*prop*, *n*, *factor*) from *targets\_characterizations* which are significant in at least proportion of the regions with *n* extensions;

**for** each non-spatial attribute in *final\_targets\_characterizations* **do**

*final\_characterizations-nonspatial* = extract all tuples (*prop*(non spatial attribute, value), *n*, *factor*) from *contrast\_characterizations* set for that nonspatial-attribute which has maximum frequency-factor with *n* extensions;

**end of for.**

*final\_contrast\_characterizations\_spatial* = extract all tuples (*prop* (spatial-attribute, value)) from *contrast\_characterizations* set which are significant in at least proportion of the regions with *n* extensions;

**add** (*final\_contrast-characterizations-nonspatial*, *final\_contrast-characterizations-spatial*) to *final contrast-characterizations*.

**return** *final\_target\_characterization* set and the rule generated from these discriminations;

Fig. 3. Algorithm for discovering spatial characterization and discrimination rules

$$frequency_{Objects}^{DB}(prop) \leq \text{significance}$$

$$\text{Or } frequency_{Objects}^{DB}(prop) < \frac{1}{\text{significance}}$$

In point (1) the union of the neighborhood of all target objects is considered simultaneously, whereas in point (2) the neighborhood of each target is considered separately.

The parameter *proportion* specifies the minimum confidence required for the characterization rules and the frequency factors of the properties provide a measure of their interestingness with respect to the target objects. The parameter *proportion* is relevant only for the last step of the algorithm, i.e. for the generation of a rule. Figure 3 presents the algorithm for discovering spatial characterizations and discriminations.

In this algorithm, If the relative frequency of the property (attribute, value) in target region differ significantly (either grater or smaller) from relative

[11], an application server for Oracle spatial database for the visualization purpose of those spatial data.

Target Objects

Maximally Expanded Region

Fig. 4. Target objects and after expansion with maximum neighbors.

frequency of the property (attribute, value) in DB then the property is added to set of target characterization. If frequency factor of a property for current value of the attribute is grater than the previous value of that property in the contrast region, then the property is stored and added into the set of contrast characterization. After traversing up to maximum neighbor, for each non-spatial attribute in the actual set of target characterization, we extract same non-spatial attribute tuples from the set of contrast characterization and for spatial attributes, extract all tuples of spatial attribute which are significant at least proportion in the contrast regions with n extensions. Then we evaluate the discrimination rules by using by comparing the characterization sets of two regions.

## V. EXPERIMENTAL SETUP

We have implemented the database primitives on commercial spatial database Oracle 11g using its 2D spatial data which offers R trees in the spatial index structure. A geographical datasets was collected from sample spatial datasets [10] which contain three datasets (Customers, Branches and Competitor Branches). Each datasets contains several non-spatial attributes (such as name, category, city etc.) and one spatial object named Location which specifies their locations in the geodetic co-ordinate system. The total amount of spatial data among all the datasets is 3944. We have used Map Viewer

## VI. EXPERIMENTAL RESULT

The algorithm usually starts with small set of target and contrast objects, selected for instance by a predicate on some non-spatial attribute(s) such as 'city = Sun Francisco' for target objects and 'city = Washington DC' contrast objects in a dataset (such as Branches). You can also select target and contrast objects from different datasets (such as, target objects from Branches datasets and contrast objects from Competitors Branches). Here, we describe a testing result from our algorithm where target objects are selected from Branches datasets and contrast objects are selected from the Competitor Branches using predicate for both objects "city = Sun Francisco " so that these two types of branch (Branches and Competitors Branches) characteristics and their customers behavior can be analyzed. Then, the algorithms expands region around the target objects, simultaneously selecting those attributes of the regions for which the distribution of values differs significantly from the distribution in the whole database [Figure 4]. In the same way, it also expands region around contrast objects and selects those attributes for contrast region.

In the last step of the algorithm, characterization rules are generated for describing the target regions and discrimination rules are generated by comparing both target and contrast objects characteristics.

TABLE I. CHARACTERISTICS VALUES FOR TARGET AND CONTRAST OBJECTS.

| Attribute Name    | Target Attribute Value | Target Value Frequency Factor | Contrast Attribute Value | Contrast Value Frequency Factor |
|-------------------|------------------------|-------------------------------|--------------------------|---------------------------------|
| Customer Category | Hotel                  | 1.6962                        | Hotel                    | 1.3374                          |
| Street Number     | 301                    | 1.602                         | 502                      | 1.421                           |
| Street Name       | Mission ST             | 2.0007                        | Montgomery ST            | 1.801                           |
| City              | Sun Francisco          | 1.744                         | Sun Francisco            | 1.7105                          |
| Customer Grade    | Silver                 | 0.8488                        | Gold                     | 0.5432                          |

TABLE II. PERFORMANCE OF SPATIAL CHARACTERIZATION AND DISCRIMINATION ALGORITHM

| No. of Test Case | No. of objects in target region | No. of objects in contrast region | Run time for the algorithm (seconds) |
|------------------|---------------------------------|-----------------------------------|--------------------------------------|
| 1                | 1214                            | 627                               | 86.312                               |
| 2                | 1475                            | 516                               | 88.714                               |
| 3                | 1752                            | 547                               | 94.183                               |
| 4                | 1832                            | 841                               | 101.714                              |

Table 1 show the results of algorithm and specifies the characteristics of target objects which are most significant from the total database and values for the same properties in the contrast objects. We can informally say the characterization rules for target objects “Maximum branches in Sun Francisco are situated besides in the Mission Street and their maximum customers are normally hotels and silver graded”. The discrimination rule can be “Maximum branches in the city Sun Francisco are situated besides in the Mission Street and their customers are silver graded whether their competitor branches are situated in the Montgomery Street and their customers are gold graded”.

Table 2 reports the efficiency of our spatial characterization and discrimination algorithm. As the algorithm efficiency of the algorithm depends on the neighbors operation, so we provide here number of spatial objects have been manipulated in each test case after expansion neighbors in both target and contrast objects. Target and contrast objects have selected using various non-spatial predicates in different datasets.

## VII. CONCLUSION

In this paper, we have presented a new spatial data mining algorithm for both spatial characterization and

discrimination rules. In this algorithm, we consider not only the properties of target and contrast objects but also the properties of their neighbors as they impact on the characteristics of them. The algorithms were implemented successfully within a general framework for spatial data mining providing a small set of database primitives on top of a commercial spatial database management system Oracle 11g and performance analysis using a real geographic data show the effectiveness of the proposed algorithm.

# Isolating Significant Phrases in Common Natural Language Queries to Databases

Mohammad Moinul Hoque, Md. Shahriar Mahbub, and S.M. Abdullah Al-Mamun

Department of Computer Science and Engineering, Ahsanullah University of Science and Technology, Tejgaon, Dhaka, 1208, Bangladesh

**Abstract** — This paper describes a novel methodology for extracting significant phrases from common natural language queries to databases. We show the usability of the methodology for developing database front ends, and propose it as an acceptable alternative to developers of databases that are supposed to be subject to massive interaction by non-technical people. Here we localize the matching procedures by isolating the phrases that are important for mapping the queries to database details, and propose to use heuristics and soft computing techniques for inexact matching of the phrases.

**Index Terms** — Natural Language Query, Database Interface, Attribute Value Phrase, Object Identification.

## I. INTRODUCTION

To face the multifaceted problem of ambiguity present in natural language texts, usual NL (Natural Language) query processing limits its scope within finding key words or their synonyms in the queries [1]. Others like Microsoft English Query, much talked about over the Internet, propose extensive use of English grammar. We rather opted to go for an approach that emphasizes structural analysis of queries. This one supposes cashing on the facts that most common queries addressed to databases have a comparatively small number of strictly formulated structures. These structures can be outlined by marking the boundaries or delimiters of phrases significant for formulating expressions in a form that is widely used, like SQL (Structured Query Language). Our basic assumptions are as follows.

- The problem of creating a Natural Language Interface (NLI) to database remains open as far as accuracy, ease of implementation and generality of a solution is concerned.
- Unlike an arbitrary NL sentence, an NL query remains, as always, provocative to search for a technique to map it automatically to a SQL query that demands no effort for a commoner once placed for execution in a computer system.
- Finally, database developers, who are expected to know the domain as well as the users of the database they are going to develop, can incorporate an extension to the data dictionary along with a few algorithms for providing a good NLI to the database without much effort.

Very common aspects of Natural language processing like dealing with phrase structures are emphasized in the proposed methodology and it gives, we think, the fragrance of some sort of generality. Although the earlier works claimed to be portable [3], those were, as correctly observed in [1], basically not so natural language oriented but mostly check-box based. Later works claimed achieving reliability [8], but at the cost of scope of functionality. Recent works claim of no generality at all [10], [11]. With this background we propose our methodology, and as of today, we restrict our investigation to common queries, but we believe that the methodology will turn out to be significantly accommodative due to the generality of approach. Our work is closer in principle to the theory proposed in [8], where exhaustive tokenization of a limited type of queries and mapping tokens to database features are proposed, and closer to some ideas like semantic structure extraction referred to in [2], [5], [6], [7], [9].

Experimental encounters of the proposed methodology were designed keeping in front three of a very much common type but heavy duty database systems. The first one was the Result Processing System (RPS) of the University we work at and the other two, Air Travel Information System (ATIS) and Employee Information Management System (EIMS), had typical design and data that many can think of at ease. We analyzed queries that are common, but most significant in number like ‘What is the CGPA of the student 04020032?’, ‘List the students who are from Dhaka.’, ‘Show the total number of female employees who joined before 2007.’, ‘What is the type of the Thai airways plane that flies from Dhaka on Sunday evening for London?’

And for this type of queries we have found common phrase structures belonging to the set of a very limited number of predefined ones that are very simply traced down to SQL queries.

## II. SIGNIFICANT PHRASES

As our assumptions go, significant phrases are those that help to map an NL query to various components of an information repository for effective retrieval of the

information addressed to. We restrict our investigation by considering a relational database as a possible repository of information on one hand and restricted types of English Interrogative and Imperative sentences on the other. This implies that significant phrases are related to different aspects of object descriptions that are explicitly or implicitly presented in a relational database. It also implies that the phrases can be isolated using a limited number of syntactic and semantic rules.

First of all we can take into account Attribute Phrases (APs). By an AP we mean a phrase that denotes an 'attribute' in a 'relation' or 'table' which is most common, but obvious of the parameters used in a formal query language for information retrieval. 'student ID number' or 'roll' may simply denote the attribute 'id' in a possible 'student' relation.

Next come Attribute Value Phrases (AVPs). Specifying the values associated to the attributes described within a query is very much likely. This leads to identification of phrases that contain concrete values of the attributes specified in a query. We eventually come to the concept of Attribute Value Phrases or AVPs. In the query 'What is the CGPA of the student bearing identification number 050204003?', the phrase 'identification number 050204003' is a simple AVP, while 'newly enrolled' in 'Display the rolls and names of newly enrolled students in the department of CSE.' may pose to be a difficult one.

The concept of Object Identifying Phrases or OIPs is to be introduced for coping up with those nuances of NL queries that essentially include pointers to specific relations of the database in terms of typical descriptors common to the multiple relations of the same database. Distinguishing 'male patient' and 'male doctor' in a Hospital Information System is a must. More simple use of OIPs can be demonstrated in the query 'List the students of third year 1st semester', where no AP is specified. Here records of students are to be fetched although it is unlikely that an ordinary Data Dictionary allows a relation to be accessed bypassing the attributes. In a better situation when 'all' is added after 'List' it becomes easier to match to a predefined structure.

We have to be aware of the presence of Aggregate Function Phrases (AFPs) in common queries as well. There is no doubt that we are going to have phrases containing words like average, total, best, last, sum, lowest, etc. It also comes out interesting to isolate AFPs and recognize them in combination with APs, AVPs and OIPs present in a query.

Let's consider the query, Q1 given below.

Q1: What are the names and resident addresses of the students bearing id numbers 050402001 and 050204009?

Analysis of this query can be depicted using the diagram at Fig. 1 and it turns into a grammar rule like the one below.

Query  $\rightarrow$  HW1 AP and AP of OIP [oip\_del1] AVP avp\_del1 AVP

Fig. 1. Structure of the query, Q1

Here HW1 may stand for What, Who, etc. and oip\_del1 is a delimiter that may possibly appear after an OIP, like bearing, whose etc., and so on. Let's look into another example that begins with List.

Q2: List the students who got A+ in CSE203.

The pictorial representation of the sentence is shown in Fig. 2 followed by the grammatical representation.

Fig. 2. Structure of the query, Q2

Query  $\rightarrow$  HW2 OIP [oip\_del2] AVP

Here HW2 may stand for List, Display, etc. and oip\_del2 is a delimiter that may possibly appear after an OIP, like of, bearing, who, etc. We present another example to illustrate aggregate function queries.

Q3: Show the average grade points of 1st year 1st semester CSE students in CSE103.

In case of this query, the representations look like the ones below.

Fig. 3. Structure of the query, Q3

Query  $\rightarrow$  HW3 AFP AP [of] AVP [in] AVP

Here HW3 may stand for average, total, sum, etc.

### III. MARKING PHRASE BOUNDARIES

For marking the phrase boundaries, we propose that the NL query be preprocessed (filtered) first. The preprocessed NL query (PNLQ) is then used as input to the Algorithm1, the output of which is a phrase structure (PS). A PS is a sequence of pairs containing Non-delimiter phrases (NDPs) and NDP classes. Important features of the algorithm are that it uses a set of DFAs to recognize the delimiter structure and a set of Moore Machines (MMs) to generate the structure consisting of the NDP-NDP class pairs. The machines ensure efficient search by providing a strict formalism.

In the typical queries we specified in the scope of our investigation we have observed that a number of words do not play any role in formation of an executable query. It is in line with the idea of ‘words not semantically important’ in [8]. We have marked them as ‘insignificant’. The words ‘is’ and ‘the’ may be marked insignificant in the NLQ ‘What is the CGPA of the 3rd year student Abdul Karim?’. The sequence is supposed to undergo further refinement that frees it from words that may come into conflict with predefined phrase delimiters. While ‘of’ is a very important phrase delimiter in our objects of investigation, this very ‘of’ in the phrase ‘department of CSE’ will be a misleading delimiter. We have included the filtering processes above in the ‘Preprocessing’ part of our proposed system, for which correctly written specific NL queries are inputs and PNLQs are outputs.

Further processing for demarcation is performed using an algorithm that is specified below in Algorithm1. A set of rules is assumed that exhaustively describes the possible structures of queries each of which is numbered. A DFA with the same index recognizes the sequence of delimiters of each structure.

A possible DFA that can be used to recognize the delimiters of the extended version of Q1, Q1’: ‘What are the roll numbers, names, resident addresses and CGPAs of the students bearing id numbers 050102001, 060204034 and 050204009?’ is depicted below (Fig. 4).

Fig. 4. DFA that recognizes the delimiters of Q1’

Then the relevant Moore Machine from the predefined set classifies the phrases isolated from the query may look like the following (Fig. 5).

Fig. 5. Moore Machine that generates PS of Q1’

*Major steps of Algorithm 1:*

- Take a PNLQ as input.
- Isolate Delimiter Structure (DS) from the PNLQ and store the NDPs in the Buffer.
- If any DFA, DFA<sub>i</sub> of the DFA Set accepts the DS, then return the corresponding Rule number, R<sub>i</sub>, else return ‘Query unrecognized’ and terminate with ‘Unsuccessful’ notice.
- Find the Moore Machine, MM<sub>i</sub> from the MM Set using R<sub>i</sub>.
- Generate the structure consisting of the sequence of NDP-NDP class pairs, and the rule number.

Final processing supposes understanding the phrases in the PS returned by Algorithm 1, that is to say, mapping each phrase isolated in the PS to appropriate database details. It will include the Extended Data Dictionary (EDD). Algorithm 2 described in the next section is assigned the job.

### IV. ASSOCIATING PHRASES WITH DATABASE DETAILS

We propose an algorithm, Algorithm 2 to associate database details to the previously isolated phrases. The algorithm takes as input the set of phrase structures (PS) returned by the Algorithm 1 and itself returns the PS associated to the database object descriptors. The output has been abbreviated as PSO.

An extension of Data Dictionary in line with the idea temporal phrase affixes associated to concrete presented in [4], is referred here which has been proposed to have a number of relations (tables), such as a table with known APs associated to concrete attributes of the database tables, a table with known OIPs associated to concrete database tables and so on. A special table called Typical Value Table (TVT) is also proposed that would contain frequently used values of certain attributes, patterns of such values and common attributes of database tables.

*Major steps of Algorithm 2:*

**Begin Procedure**

For each element of the sequence of NDP-NDP class from the PS do

IF the NDP class is AP then  
 Try to match the NDP with the APs of the EDD.  
 In case the NDP sufficiently matches to an AP,  
 place the corresponding object-attribute details  
 along with the NDP class in the PSO accordingly;  
 Otherwise place the NDP marked 'Unrecognized'  
 along with the NDP class.  
 ELSE IF the NDP class is OIP then  
 Try to match the NDP with the OIPs of the EDD.  
 In case the NDP sufficiently matches to an OIP,  
 place the corresponding object details along  
 with the NDP class in the PSO accordingly;  
 Otherwise place the NDP marked  
 'Unrecognized' along with the NDP class.  
 ELSE IF the NDP class is AVP then  
 Try to match the NDP with the APs of the EDD.  
 IF the NDP sufficiently matches to an AP  
 Separate the AP portion of the NDP and take  
 the remaining part as the value of the AP,  
 incase this is a suffix or prefix of the NDP,  
 and place the corresponding object-attribute  
 details along with the value portion and NDP  
 class in the PSO accordingly; In case it is not,  
 place the NDP marked 'Unrecognized' along  
 with the NDP class.  
 ELSE  
 Try to establish that value + OIP = AVP in a  
 similar way.  
 ELSE  
 Try to match the NDP with the values in  
 TVT (Typical Value Table).  
 IF a match is found then  
 Place the corresponding object  
 attribute details along with the NDP as its  
 value in the PSO accordingly.  
 ELSE  
 Analyze the element inserted in the PSO  
 immediately before. In case it is an  
 AVP, treat the current NDP as an AVP  
 also; In case not, place the NDP

marked 'Unrecognized' along with the  
 NDP class.  
 END IF  
 END IF  
 END IF  
 End Procedure

## V. EXPERIMENTAL VERIFICATION

We have verified our algorithms over three different databases named earlier. For experimentation, commonly used database systems like RPS, ATIS and EIMS were chosen to diversely test our system using different level of queries in terms of complexity. Various types of possible queries were formulated based on these systems. We have manually extracted different phrases from these queries and compared these phrases with the recorded output of the algorithms. Although the system showed near 100% accuracy in some cases, it also showed some average performance for some complex and not well formulated queries. From a sample set of NLQs, 15 versatile queries were selected for the experimental purpose and the following table (Table 1) depicts a comparison between actual significant phrases and detected significant phrases presented in those NLQs. The resulting graphs for detecting APs, AVPs and OIPs are shown in Fig. 6, Fig.7 and in Fig. 8.

Fig. 6. Identification of APs.

TABLE 1  
 COMPARISON OF ACTUAL SIGNIFICANT PHRASES AND DETECTED SIGNIFICANT PHRASES IN NLQS

| Query Number    | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | 15 |
|-----------------|---|---|---|---|---|---|---|---|---|----|----|----|----|----|----|
| Actual APs      | 1 | 2 | 1 | 1 | 2 | 1 | 3 | 1 | 2 | 2  | 1  | 2  | 2  | 4  | 5  |
| Identified APs  | 1 | 2 | 1 | 1 | 2 | 1 | 3 | 1 | 1 | 2  | 1  | 1  | 2  | 4  | 5  |
| Actual AVPs     | 3 | 2 | 5 | 2 | 2 | 1 | 2 | 6 | 2 | 3  | 1  | 2  | 1  | 2  | 3  |
| Identified AVPs | 2 | 2 | 4 | 3 | 2 | 1 | 2 | 5 | 2 | 3  | 1  | 2  | 1  | 2  | 3  |
| Actual OIPs     | 1 | 2 | 2 | 2 | 2 | 1 | 1 | 2 | 2 | 2  | 2  | 1  | 1  | 1  | 1  |
| Identified OIPs | 1 | 1 | 2 | 1 | 1 | 1 | 1 | 1 | 2 | 2  | 2  | 1  | 0  | 1  | 1  |

Fig. 7. Identification of AVPs.

Fig. 9. Error detection rate in different NLQs.

Fig. 8. Identification of OIPs.

Fig. 10. Overall performance of the system.

The rate of errors that occurred in various queries while detecting APs, AVPs and OIPs are given in Table 2 and the pictorial representation is also shown in Fig. 9.

Comparing over three different database systems, we have found that, on an average, a maximum of 20% error occurred in identifying OIPs and the error rate in indentifying APs and AVPs were below 10% which was quite satisfactory.

We have used over two hundred of possible NLQs taken from three different database systems and on an average the system showed around 88.5% success rate in indentifying significant phrases as depicted in Fig. 10.

## VI. DISCUSSION AND FUTURE WORKS

Evidences present in the related publications urge to believe a few things which we tried to address in our work. First of all, it is evident that a relatively small number of basic structures involving significant phrases are there in NL queries. And this directed us to make one of our basic assumptions for the current investigation.

Secondly, we come to the fact that extensive use of NL grammars may be avoided. That means we need to handle less ambiguity, which is much easier to implement in contrast. Further, portability across natural languages

TABLE 2  
ERROR RATE IN IDENTIFYING DIFFERENT SIGNIFICANT PHRASES

|     | 1    | 2  | 3  | 4  | 5  | 6 | 7 | 8    | 9  | 10 | 11 | 12 | 13  | 14 | 15 | Average |
|-----|------|----|----|----|----|---|---|------|----|----|----|----|-----|----|----|---------|
| AP  | 0    | 0  | 0  | 0  | 0  | 0 | 0 | 0    | 50 | 0  | 0  | 50 | 0   | 0  | 0  | 6.7%    |
| AVP | 33.3 | 0  | 20 | 50 | 0  | 0 | 0 | 16.7 | 0  | 0  | 0  | 0  | 0   | 0  | 0  | 8%      |
| OIP | 0    | 50 | 0  | 50 | 50 | 0 | 0 | 50   | 0  | 0  | 0  | 0  | 100 | 0  | 0  | 20%     |

besides database domains can be achieved more easily by dealing with phrase structures in sentences avoiding grammatical nuances.

Next, it is also evident that we can avoid extensive token matching by isolating the significant phrases first. Extensive token matching becomes intractable in wider range. Soft computing and other nontraditional techniques like partial matching, heuristics in the form of studying prefixes and suffixes, etc. come to the rescue to certain extent in this regard.

Lastly, we find that a kind of generality may be achieved by accommodating techniques that find phrase structures from the types of sentences other than those we investigated. We think, it would be a good addition to NL understanding.

And we would like to present our beliefs as our reasons in favor of our proposed methodology. Besides efficiently constructing intelligent interfaces for massive databases, we think, it can be used as a tool to shed an insight into understanding sentences in general. It would be more appropriate if the representation of the world is assumed to be a collection of semantic networks or ontology of various things. The paper is presented here as a report of an ongoing research, and we hope to go on adding efforts in this line. Our future plan also includes extensive use of soft computing techniques for matching phrases to DB components as well as enhancing NL understanding study using proposed structures.

ankuj.gupta@nsitonline.in

**Abstract**— With the demand of accurate and domain specific bilingual dictionaries, research in the field of automatic dictionary extraction has become popular. Due to lack of domain specific terminology in parallel corpora, extraction of bilingual terminology from Wikipedia (a corpus for knowledge extraction having a huge amount of articles, links within different languages, a dense link structure and a number of redirect pages) has taken up a new research in the field of bilingual dictionary creation. Our method not only analyzes interlanguage links along with redirect page titles and linktext titles but also filters out inaccurate translation candidates using pattern matching. Score of each translation candidate is calculated using page parameters and then setting an appropriate threshold as compared to previous approach, which was solely, based on backward links. In our experiment, we proved the advantages of our approach compared to the traditional approach.

**Index Terms**— Wikipedia, Bilingual Dictionary, Wikipedia Mining, Automated translation.

## I. INTRODUCTION

Dictionary extraction from large amounts of bilingual text corpora is an emerging research area. A bilingual dictionary is a dictionary that is usually used to translate words or phrases from one language to another. There can be two approaches for extracting bilingual terminology—manual or automatic creation. But as stated in [1], the manual creation of bilingual dictionaries is not efficient, as they are time consuming and new or highly specialized domain specific words are difficult to cover. Moreover, linguistic knowledge is expensive. The problem proliferates when we consider two entirely different languages like English and Japanese as sufficiently large parallel corpora is not available for both languages.

Therefore, in order to provide a higher degree of accuracy and coverage, [1] propose the extraction of bilingual terminology from multilingual encyclopedias like Wikipedia, as it is continuously expanding encyclopedia containing millions of pages in hundreds of languages with a broad variety of topics. For extracting bilingual terminology from Wikipedia structure an approach is given in [1]. The previous research work was based only on backward links of each translation candidate neglecting page parameters. As a result, the dictionary [4] proposed

by [1] lags behind in many aspects, namely - fewer results, lesser coverage of words/ phrases, case sensitivity.

Thus, in order to cover all the aspects that were missing in the previous approach, we performed pattern matching which eliminated most of the wrong translations. For all the translation candidates, we calculated a score based on page parameters like page length and page random (which are present in the Wikipedia database), so that we can eliminate the translations with low scores and to make a better relativity with the searched string. In order to evaluate our method, we extracted Japanese translations for 200 English words and compared them for the accuracy and coverage with that of the previous dictionary [4].

The remainder of this paper is organized in the following way, related work in the field of bilingual terminology extraction, followed by shortcomings which we discovered in earlier approaches and the process exercised by us to amend them. Subsequent sections explains the Basic terminology, System design, Algorithm implemented by us. Further, the results obtained from both approaches are compared. In the last section, we have concluded the paper by mentioning certain features that can be worked upon.

## II. RELATED WORK

In 2008, Maïke Erdmann et al.[1] collected bilingual terminology based on the dense linked structure of the Wikipedia. They used number of backward links as the criteria for generating score of a translation candidate. But a score calculated without considering the page parameters defined by Wikipedia is inappropriate.

For translations from English to Japanese, one of the most commonly used dictionaries is, freely available online dictionary **EDICT** [2]. It comprises of more than 99,300 terms as on 2004. However, even with the aid of a large community, the manual creation of such a dictionary is a time-consuming process as mentioned in [1].

Besides this, the coverage of domain specific words and their related terminology was less. Moreover, while for high frequency terms usually good results can be achieved, the accuracy decreases drastically when the terms to be translated are domain specific.

### III. MOTIVATION AND CONTRIBUTION

The research described in this paper is motivated by the larger goal of improving the previous work [1]. The dictionary [4] based on [1] had some grave problems which are stated as under :-

- 1) Wrong translations for some words came into picture while trying. For instance, take "India" whose one of the translation candidate came out to be "heaven".
- 2) The translation candidate's score was solely calculated based on the number of backward links not taking into consideration the page parameters.
- 3) Another problem was case sensitivity. There were words like "eu" (abbreviation for European Union) which did not have any results but "Eu" had results.
- 4) The dictionary didn't have common words used in the day to day life like evening, etc. even though they were present in Wikipedia.
- 5) The number of translation candidates or related topics was pretty less and the score given for these related topics was not appreciable.

In the view of above mentioned points we analyze the dense link structure of Wikipedia and found a scope of improvement in them.

We briefly describe our approach to amend these points. For incorporating the first point, we performed pattern matching of the translations using the interlanguage link title and redirect page title which eliminated most of the incorrect results.

We explored some new parameters present in Wikipedia i.e. page length and page random instead of 'backward links' which was used by the previous research [1]. This concept helped the score to become more flexible and authentic. The coding was structured in such a way so as to make dictionary case insensitive. The search string was searched in the page table of the Wikipedia database which has all the titles of Wikipedia articles, so that each and every word of Wikipedia can be covered (including common words used in the daily life).

We improved the quality of the score by assigning proper weights to the parameters based on experimental results. This gave scores varying from 0-1 which made the dictionary more versatile and effective.

In continuation with the above mentioned points we enlarged our scope to other languages also. We downloaded the SQL tables from the Wikipedia dump [3] for three languages: English, Japanese and French and use them to make the following language conversions:-

- English to Japanese
- English to French
- Japanese to French
- Japanese to English
- French to English and
- French to Japanese

### IV. WIKIPEDIA LINK STRUCTURE

Our idea is to use a multilingual Web-based encyclopedia such as Wikipedia for extracting bilingual terminology. Wikipedia currently contains more than 10 million articles. It covers general topics, domain specific topics as well as proper nouns, containing even latest terminology since Wikipedia is being updated all the time. Moreover, Wikipedia contains a lot of links among its articles, not only within the articles of one language but also between articles of different languages. Before describing our method we would like to explain the different types of links and pages that are present in Wikipedia.

**Interlanguage Link:-** An interlanguage link in Wikipedia is a link between two articles in different languages. We assume that in most cases, the titles of two articles connected by an interlanguage link are translations of each other.

**Redirect Pages:-** Redirect pages in Wikipedia are pages containing no content but a link to another article (target page) in order to facilitate the access to Wikipedia content. When a user accesses a redirect page, he will automatically be redirected to the target page. Redirect pages are usually strongly related to the concept of the target page. They often indicate synonym terms, but can also be abbreviations, more scientific or more common terms, frequent misspellings or alternative spellings etc.

**Link Texts:-** A link text, is the text part of a link, i.e. the text that is presented to the user in the browser where he clicks to reach the target page. In Wikipedia, the title of the target article is displayed as the link text by default. The link texts are usually strongly related to the target page title. In many cases, they differ only in capitalization, but sometimes they are changed in other ways to fit in the sentence structure of the linking article.

**Page Parameters:-** Wikipedia provides a number of parameters for each page that exists within Wikipedia. Each page has an entry within its databases which identifies it by title and contains some essential metadata.

- `page_is_redirect`: Indicates whether a page is redirect or not.
- `page_random`: Random value between 0 and 1.
- `page_len`: Uncompressed length of page in bytes.

Before moving further we have defined few terms and notations.

### V. TERMS AND NOTATION

- 1) **Source Page(*sp*)**: It is the page corresponding to search string in input language.
- 2) **Target Page (*tp*)**: It denotes the target page in the desired language.
- 3) **Target Page's Title (*ill*)**: It represents the target page's title.
- 4) **Redirect Page Titles (*RP{tp}*)**: It denotes the titles extracted from the redirect pages of *tp*.

- 5) **LinkTexts Titles ( $LT\{tp\}$ )**: It signifies the titles of the linktexts of  $tp$ .
- 6) **Translation Candidates ( $TCs$ )**: This parameter gives the value of the total number of translation candidates after extraction and pattern matching.

$$TCs = \sum \{ill\}URP\{tp\}ULT\{tp\}$$

- 7) **Type**: It signifies two ways to get the result set. One is basic which covers only  $ill$  and other enhanced which extends to  $RP\{tp\}$  and  $LT\{tp\}$ .
- 8) **Filtered  $TCs$ ( $FTCs$ ) and Removed  $TCs$ ( $RTCs$ )**: The undesired translation candidates are filtered out using pattern matching. Let the filtered out translation candidates be denoted by  $FTCs$  and the removed translation candidates be denoted by  $RTCs$ . Thus  $FTCs$  is equal to

$$FTCs = TCs - RTCs$$

- 9) **Result Set( $RS$ )**: These are  $FTCs$  after applying threshold.
- 10) **False Positive Ratio( $FPR$ )**: It is the count of false positives appeared in the results per total number of results obtained

$$FPR = \frac{Count(false\ positives)}{Count(RS)}$$

- 11) **Zerom**: It is the count of the total number of results whose translations could not be found in the dictionary.
- 12) **Sensitivity**: This term checks for the case sensitivity in searching of translations.

In the remainder of the paper we will be using the above mentioned abbreviations and terminology.

## VI. SYSTEM DESIGN

The blocks in Figure 1 are explained in the following text.

- **User Interface**: It provides a basic interface for user to enter the string that the user wants to search,  $type$  and the choice of languages. It also includes Form Validator, which checks for the correctness of the data entered. If the entries are correct the values are passed to server for further processing.
- **Language Code Generator**: It generates code for input and output languages based on the Wikipedia codes.
- **Dname and Tablename Generator**: It takes the source language code and desired language code and decided which databases need to be used.
- **Query Generator**: The function of the query generator is to generate SQL queries to be used by four processes namely: *Source Page finder*, *Target Page Finder*, *Redirect Page Finder* and *LinkText Finder*. It

Fig. 1. System Design: Meliorated Approach for Extracting Bilingual Terminology from Wikipedia

generates four type of queries namely  $Q_1$ ,  $Q_2$ ,  $Q_3$  and  $Q_4$  which are passed into process in earlier mentioned order.

- **Temporary Storage**: Temporary storage is partitioned in two segments one each to store the incoming query from the processes and one to store the incoming resultsets from the DBengine.
- **DBengine**: A database engine is the underlying software component that a Database Management System (DBMS) uses to create, retrieve, update and delete data from a database.
- **Source Page Finder**: It searches for the source page in the source language. It takes query  $Q_1$  from Query Generator passes it to Temporary Storage which passes the query to DBengine which finally fires the query to the stored Wikipedia databases. The tables generated are stored again in the temporary storage from where they are returned back to the calling process i.e. Source Page Finder.
- **Target Page Finder**: After the source page is found its interlanguage link's page is found in the desired language. It is known as target page. The title  $ill$  of  $tp$  becomes the translation candidate. It takes query

$Q_2$  from Query generator and performs the same operation as mentioned for *Source Page Finder*.

- **Enhancement by Redirect Pages:** Once the target page is found, its redirect pages are searched. The title of these redirect pages becomes the Translation candidate (TCs). The process is called *Redirect Page Finder*. It takes query  $Q_3$  and performs the earlier mentioned process.
- **Enhancement by LinkTexts:** The TCs is further improved by including the titles of all the linktexts within the target page. The title set of linktexts is denoted by  $LT\{tp\}$ . The process is known as *LinkText Finder* and it takes query  $Q_4$  and performs the above mentioned process.
- **Summation:** Now all the outputs from three processes form the part of Translation Candidates. Thus, all the three outputs are summed to give the final set of Translation Candidates. Now TCs becomes

$$TCs = \sum \{ill\}URP\{tp\}ULT\{tp\}$$

- **Pattern Matcher:** Since all the translation candidate are not suitable pattern matching is performed based on the target page  $tp$  title  $ill$  and the redirect page titles  $RP\{tp\}$ . The undesired translation candidates are removed. It gives FTCs as output
- **Score Calculator:** Even after pattern matching some of the TCs are still not suitable translations of the source page title. Experimental results confirmed that the page parameters of the target page can be used to estimate the accuracy of a TC. We calculated the score of every TC by assigning weightages based on observation to these parameters. Moreover within the translation candidates that were filtered out, if it is a redirect page title then it has more priority as compared to linktext page titles, but less than that of the target page's title  $ill$ . This is due to the fact that the linked texts are just titles related to the target page title and not the exact translations. After score calculation a threshold was set to filter out the undesired results.
- **Displayer:** It returns the resultset back to User Interface.

## VII. SYSTEM WORKING

First, user inputs the search string, *type*(basic or enhanced), and the input & output languages. The languages are passed to the *Language Code Generator* which generates the code of the languages as used in the Wikipedia. These codes are processed by the *Dname and Tablename Generator*. Output of this along with search string,  $tp$  and  $sp$  is fed into the *Query Generator* which generates SQL queries based on the set templates which are  $Q_1$ ,  $Q_2$ ,  $Q_3$  and  $Q_4$ . The output queries are compared to the set templates and are then sent to the

respective processes namely *Source Page Finder*, *Target Page Finder*, *Redirect Page Finder* and *LinkText Finder*. From these processes queries are passed to Temporary Storage which calls the DBEngine. The returned results are stored in Temporary storage, from where they are transferred to the calling process. Now, these results from above mentioned processes is passed to *Summation*. It generates TCs which act as input to *Patternmatcher*. The output of *Patternmatcher*, which is FTCs is then passed to score calculator which eliminates undesired FTCs using a threshold. Finally, the RS thus obtained is sent to user interface to be displayed based on the choice of type. With the aim to implement the above mentioned system design we have proposed the following methodology.

---

**Algorithm 1** *Fundamental variables to be used in our algorithms*

---

- Require:** query: search string entered by user  
**Require:** queries: An array storing SQL queries  
**Require:** string: Search string entered by user  
**Require:** type : basic or enhanced  
**Require:** input language: Language for input  
**Require:** output language: Language for RS  
**Require:** srclang : input language code  
**Require:** deslang : output language code  
**Require:**  $Q_1$ ,  $Q_2$ ,  $Q_3$  and  $Q_4$ : Predefined SQL queries template  
**Require:** dbname : Name of database on which query is to executed  
**Require:** tablename : Name of table on which query is to executed
- 

---

**Algorithm 2** *PatternMatcher( $ill, RP\{tp\}, LT\{tp\})(n)$*

---

- Require:** An integer  $i = 0$   
**Require:** An integer  $count\_ill = count(ill)$   
**Require:** An integer  $count\_rp = count(RP\{tp\})$   
**Require:** An integer  $count\_lt = count(LT\{tp\})$   
**while**  $i \neq count\_ill$  **do**  
     $j \leftarrow 0$   
     $k \leftarrow 0$   
    **while**  $j \neq count\_rp$  **do**  
        **while**  $k \neq count\_lt$  **do**  
            **if**  $eregi(ill[i], LT\{tp\}[k])$  or  $eregi(RP\{tp\}[j], LT\{tp\}[k])$  **then**  
                 $results[] = LT\{tp\}[k]$   
            **end if**  
            **end while**  
             $k++$   
        **end while**  
         $j++$   
    **end while**  
     $i++$   
**end while**
- 

## VIII. EXPERIMENTS AND RESULTS

We implemented the Bilingual Dictionary extraction algorithm, proposed by us, using PHP (version 5.2.4) and

---

**Algorithm 3** *Language Code Generator*(input language, output language, srclanguage, deslanguage)

---

```

if input language == NULL or output language
==NULL then
 exit
else
 for $i = 0$ to $\text{length}(\text{languages})$ do
 if inputlanguage == languages[i] then
 srclanguage = languages[i][code]
 break
 end if
 end for
 for $i = 0$ to $\text{length}(\text{languages})$ do
 if outputlanguage == languages[i] then
 deslanguage = languages[i][code]
 break
 end if
 end for
end if

```

---

---

**Algorithm 4** *Bilingual Dictionary*(input language, output language, srclanguage, deslanguage)

---

```

LanguageCodeGenerator(inputlanguage, output
language, srclang, deslang)
queries = QueryGenerator(srclang, deslang,
sp, tp, string, dbname, tablename)
for $i = 0$ to $\text{length}(\text{queries})$ do
 if queries[i] LIKE Q_1 then
 $sp \leftarrow \text{SearchpageSearcher}(\text{query})$
 end if
 if queries[i] LIKE Q_2 then
 $tp \leftarrow \text{TargetpageSearcher}(\text{query})$
 end if
 if queries[i] LIKE Q_3 then
 $RP\{tp\} \leftarrow \text{RedirectSearcher}(\text{query})$
 end if
 if queries[i] LIKE Q_4 then
 $LT\{tp\} \leftarrow \text{LinkTextSearcher}(\text{query})$
 end if
end for
 $TCs \leftarrow \text{Summation}(\text{ill}, RP\{tp\}, LT\{tp\})$
 $FTCs \leftarrow \text{Patternmatcher}(\text{ill}, RP\{tp\}, LT\{tp\})$
 $RS \leftarrow \text{Scorecalculator}(FTCs)$
Displayer(RS, type)

```

---

MySQL (5.0.45 community-NT server) on an Intel Celeron 1.7 GHz personal computer with 1GB DDR RAM and MS Windows Xp operating system.

First, we implemented the Wikipedia MySQL databases available at [3]. After that we designed a list L, which consisted of a sample set of 200 words covering domain

specific (egs. methane, fauna, usb, etc.) and frequently used (egs. shirt, industry, etc.) terms from various fields like history, biology, accounts, etc. In order to prove effectiveness of our approach, we compared the resultsets for list L, returned by both methods(ours and [4]). To calculate the number of false positives RS were converted back to English and were checked for the relatedness or closeness to the searched term. Results which were synonyms or were related to searched string have been considered desired cases. The resultsets were compared on the parameters namely: Number of RS and FPR for each word in list L and graphs were plotted. Besides this a graph pertaining to words which were only present in our dictionary was also drawn for the above mentioned parameters. Experimental proof of our observations is given by the accompanying screenshots.

Search String is:India

| Page Title  | Page score     |

Fig. 4. Zerom - Example of new word extracted

There were a lot of commonly used words which were not present in the dictionary available at [4]. But whose RS existed in ours. These terms are referred to as **Zerom**. As cited in our screenshot in Figure 4 we have results for the word "evening" but the previous work did not incorporate it. Further graphs for the RS of such words and their FPR were plotted in Figure 5.

Graph 4 in Figure 6 shows the number of RS for each word in List L. It is clearly evident from the graph that number of RS is much more in our approach as compared to previous approach.

## IX. CONCLUSION AND FUTURE WORK

In this paper we have presented an approach for extracting bilingual terminology from Wikipedia. We have proposed the use of page parameters to provide a relativity between the searched string and the translation candidates. Our method is useful for specialized domain-specific terms because accuracy and coverage are better than that of the bilingual text corpus approach. We believe that Wikipedia will become more comprehensive in near future which will result in a better coverage.

We are planning to include Indian languages which are not present in the online dictionaries. It is also promising

(a) Graph2

(b) Graph3

Fig. 5. Zerom

Fig. 6. Graph 4

to analyze and find some more parameters to enhance the dictionary. Moreover, a Web Bot may be implemented to automatically update the databases from the website of Wikipedia.

# Comparing FLV and MPEG4 (H.264/AVC) Multimedia File Format with Wireless Network Parameters

<sup>1</sup>Mehedi Mahmud, <sup>1</sup>Sadia Monir, <sup>1</sup>Tanjila Khan, <sup>2</sup>Mohammad Abdur Rahim Mustafa and <sup>3</sup>Hasan Sarwar

<sup>1</sup>Department of CSE, MIST, Dhaka, Bangladesh, <sup>2</sup>Department of CSE, BUET, Dhaka, Bangladesh, <sup>3</sup>Department of CSE, UIU, Dhaka, Bangladesh.

**Abstract** — Accommodating multimedia resources in the wireless media is a long cherished service. In this paper, we compared the FLV and MPEG4 (H.264/AVC) format of multimedia content using frame rates, sizes and byte rates. Thus we showed that MPEG4 performs better than FLV.

**Index Terms** — FLV, MPEG4, CoQV, MBMS, pixel, macroblock, screenshare.

## I. INTRODUCTION

As wireless communication has lower bandwidth support, many researchers have been trying to transmit multimedia resources using different file format such as MPEG4 part2, MPEG4 part10 (H.264/AVC), 3GP, FLV (V6) etc. So we compared MPEG4 and FLV video file format as to ensure this purpose.

The intention of using H.264/AVC for the sake of its capability to provide good video quality at substantially lower bit rates than previous standards (e.g. half or less the bit rate of MPEG2, MPEG4 part2) without increasing the complexity of design so much that it would be impractical or excessively expensive to implement.

Flash Video is used because it is a file format used to deliver video over the low bandwidth as it is one of the upcoming features in short times.

In order to fulfill our purpose we used different tools to parse video format and measured the variations.

## II. RELATED WORKS

The frame rate of MPEG4 has been examined in [1]; video standard, video sequences and the comparison have been measured to generate measure the coefficient of quality variance (CoQV). The lower the variance, the quality is better.

Prevailing studies of MPEG4 part 2, H.264/AVC (MPEG4 part 10), MPEG4/SVC codec [1], [2] generally illustrates the rate distortion performance, video quality function (PSNR) and CoQV. The study of the bit rate variability or frame rate variability as a function of video quality demonstrates bit-rate-variability-distortion (VD) curve.

Comparison based studies like [3] expresses the comparison of actual average numbers of texture bits per frame with corresponding models, comparison of actual variances of numbers of texture bits per frame with corresponding models, comparison of actual average numbers of motion bits per frame with corresponding models etc.

It is quite obvious that the gradual migration of transcoding from MPEG2 to H.264 is at the expense of higher computational complexity due to its improved inter-and intra-prediction modes. So a novel macroblock (MB) mode decision algorithm for P-frame prediction based on machine learning techniques [4] and based on data mining techniques [10] to be used as part of a very low complexity MPEG-2 to H.264 video transcoder.

Implementing MPEG2 to H.264 transcoding schemes in the pixel domain introduces a high degree of computational complexity. In order to solve this algorithms and equations are proposed that compensate for the luminance half-pixel and chrominance quarter/three-quarter pixel interpolation errors are derived. Thus, the compensation scheme includes a closed-loop H.264 motion compensation process, which is implemented in the pixel domain and our scheme is compared with two different cascaded pixel-domain transcoding structures [5]. The experimental results show that the proposed compensation algorithms achieve 5-dB quality improvement over the open-loop transform-domain-based transcoding. Again in order to motion re-estimation in video transcoding and to improve the searching speed a new transcoding scheme that uses the MPEG2 DCT coefficients [8] to predict the block size partitioning for H.264 is introduced.

H.264 has expand its arena in Medical video compression also and in this process it improves the H.264 rate control algorithm [6] with better perceptual quality. H.264 can achieve a significant average peak signal-to-noise ratio (PSNR) gain of up to 4.35 dB for the test medical video sequences, and thus is much more effective when applied in medical video compression.

The Achilles' heel of video over wireless services continues to be the limited bandwidth of wireless

connections and short battery life of end-user handheld devices such as cell-phones and PDAs. In [7], strategies are proposed to reduce the complexity of various H.264 operations. Using the knowledge of the context of the scenes in the video sequences, unimportant regions in the frames are isolated and unnecessary processing is avoided.

On the basis of architectural features of architectural features of TMS320DM642 and the computational complexity analysis of H.264 encoder [11], for the video sequences with CIF format, the optimized H.264 encoder can achieve the encoding speed of more than 24 frames per second, which can meet the real-time requirements of the applications. Now rate control algorithm is developed [12] for the H.264 baseline-profile encoder under the constant bit rate constraint, to improve performance.

Recently, three Rate Distortion (RD) optimization algorithms (a graph-based algorithm) are put forward [13] for near optimal Soft Decision Quantization (SDQ) in H.264 baseline encoding given motion estimation and quantization step sizes, an algorithm for near optimal residual coding in H.264 baseline encoding given motion estimation, and an iterative overall algorithm to optimize H.264 baseline encoding for each individual frame given previously coded reference frames-with them embedded in the indicated order.

Research on the statistical analysis of video traffic and video traffic models has also received significant interest [1]. The existing works generally focuses on the statistical report of traffic and bit rate variability as a function of quality level or quantization scale.

In contrast, in this paper we comprehensively study and compare the frame size [byte] per 0.8 second and the byte rate of MPEG 4 with FLV (Flash Video) and in addition we find out the variations plotting those points to decide which on is of better quality between these two.

### III. BASIC DEFINITIONS

#### A. H.264/AVC

H.264 (MPEG 4 part 10) is a latest video coding standard of the ITU-T Video Coding Expert Group (VCEG) and the ISO/IEC Moving Picture Expert Group (MPEG). H.264/MPEG4-AVC has recently become the most widely accepted video coding standard and it covers all common video conferencing to IPTV, HDTV and HD video storage.

H.264 has fringe benefits [9] and H.264/AVC's intra-frame coder is so efficient that we can make it operate as a still image coder that outperforms the existing state-of-the-art still image compression standard (JPEG-2000). MB coding mode decisions in H.264 video have a correlation with the distribution of the motion compensated residual in the decoded video. Data mining

tools can be used to exploit the correlation and derive decision trees [10] to classify the incoming decoded MBs into one of the several coding modes in H.264.

Keeping full compatibility with the H.264 standard syntax and decoding behavior in case of single description reception based on the concept of redundant slices [14], An analytical setup is employed in order to optimally select the amount of redundancy to be inserted in each frame, taking into account both the transmission condition and the video decoder error propagation.

#### B. Flash Video (FLV V6)

Flash Video files contain video bit streams which are a variant of the H.263 video standard, under the name of Sorenson Spark. The Flash Video file format supports two versions of a so called 'screenshare' codec which is an encoding format designed for screencasts. These formats are bitmap tile based can be lossy by reducing color depths and are compressed using zlib.

#### C. MBMS

Multimedia Broadcast/Multicast Service (MBMS), as specified in Release 6 of 3GPP For such mobile TV services, improved video compression [17] performance, in conjunction with appropriate mechanisms for error robustness, is key — a fact that is well reflected by the use of H.264/MPEG4-AVC together with forward error correction schemes in all of those mobile-broadcasting systems.

#### D. Coefficient of Quality Variance (CoQV)

The coefficient of variation of frame sizes [unit free] is defined as

$$\text{CoQV} = \frac{S_x}{\bar{X}}$$

Where  $S_x$  is the root of variance and  $\bar{X}$  is the mean frame size. CoQV is widely employed as a measure of the variability of the frame sizes, i.e., the bit rate variability of the encoded video. Plotting the CoQV as a function of the quantization scale (equivalently, the PSNR video quality) gives the rate variability-distortion (VD) curve [1].

#### E. Mode Decision Algorithm

The algorithm of mode decision for inter-frame coding is introduced and the complexity of the H.264 encoder is analyzed from the side of transform and quantization. In order to speed up the H.264 encoder without causing a

great decrease in encoding efficiency, a fast intra-mode decision method for inter-frame coding is also introduced. The experimental results show that the inter-frame coding with fast intra mode decision can reduce the computational complexity of the H.264 encoder remarkably while incurring little, if any, loss in quality [18].

#### IV. DATA EXTRACTION AND ANALYSIS

##### A. Parsing MPEG4 (H.264)

The comparative study mainly focuses on the frame size per second between MPEG4 and FLV. In order to do so, we use several tools such as MPEG4 Parser, FLV Converter, Xilisoft video converter, flvmdigui (XML generator for FLV). The metadata of MPEG4 is generated using the tool “MPEG4 PARSER” developed by the video trace research group at Arizona State University. This material is based upon work supported by the National Science Foundation, USA. As we have compared on the basis of frame size per second we generated frame size and frame type using MPEG4 Parser. We used several video files of MPEG format and we parsed these MPEG format video files into CSV file.

A lot of values of Frame size [byte] and frame type [P type or I type] have been generated. Then those are parsed to calculate the linearity and byte rate. Total 266 points of byte rate have been used to calculate the average.

##### B. Parsing FLV

We converted the video into FLV format using FLV converter and by the help of FLV parser (flvmdigui) we generated the same data set for FLV using FLV parser and FLV parser generates the accumulated value for frame size in every 0.8 second in XML. Then we parsed to calculate the byte rate. Total 302 points of byte rate have been used to calculate the average.

##### C. Environment

For this comparison we worked on HP laptop, core2duo processor (centrio), 2GB RAM, Windows Vista. For plotting points we used MatLab7.1.

#### V. EXPERIMENTAL RESULT

Using MPEG4 Parser we generated the following frame type and frame size:

Fig. 1. Parsing MPEG4.

Using parser we generated the following frame size per 0.8 second:

Fig. 2. Snapshot of the output data of frame size [byte] per 0.8 second

Using flvmdigui following XML data has been generated:

```

Fig. 4. Snapshot of frame size of XML data for FLV

Fig 1 shows the MPEG4 parser and generated CSV file. Fig 2 depicts the incremental output data for frame size [byte] at every 0.8 second. Fig 3 shows the XML root data that demonstrates different data-type for FLV file format. Fig 4 is the continuation of Fig 3 and represents the frame size per 0.8 second.

Graphical representation of the experimental result of average byte rate for both MPEG4 and FLV format is depicted below:

Fig. 5. Comparison of FLV and MPEG4 data file with respect to byte rate and variations showing mean, median and standard deviation of MPEG4.

Fig. 6. Comparison of FLV and MPEG4 data file with respect to byte rate and variations showing mean, median and standard deviation of FLV.

Fig 5 & 6 shows the experimental result of FLV and MPEG4 format. In Fig 5 the X axis represents the time and the Y axis represents the frame rate. It is quite evident that FLV has better byte rate.

From Figure 5 we found, the MPEG4 has mean 86900 byte, median 86310 byte and standard deviation 10190 byte. We also found the variation and fluctuation of MPEG4 is high and MPEG4 has lack of constantability.

From Figure 6 we found, the FLV has mean 44540 byte, median 44320 byte and standard deviation 9067 byte. We also found the variation and fluctuation of FLV is lower than MPEG4 and FLV is more stable than MPEG4.

## VI. CONCLUSION

In this paper we examined in detail the variations that occur due to variable frame size per second. From the study, the characteristics that we can convey are: Firstly, FLV generates lower variations than MPEG4 format. Secondly, FLV has better linearity. Thirdly, from the comparison the spikes and fluctuation of frame rate of MPEG4 is more than FLV. Finally, FLV is more competent introducing it in wireless multimedia features.

## ACKNOWLEDGEMENT

I would like to take this opportunity to thank all people who have been instrumental in the preparation of the work. First of all, appreciation goes to Mohammad Abdur Rahim Mustafa for his in depth guidance and support during the course of this thesis. I am extremely grateful to him for providing assistance in literature survey and

suggesting improvements to bring the thesis to its final form. I would also like to thank Dr. Hasan Sarwar for helping me in many helpful technical discussions. Finally I would thank MIST CSE department for giving me facilities to carry on this work.

# Direction of Arrival Algorithms for Adaptive Beamforming in Next Generation Wireless Systems

Mohammad Ismat Kadir<sup>1</sup>, Md. Shadiul Hoque<sup>2</sup>, Saiful Islam<sup>3</sup>

Electronics and Communication Engineering Discipline

Khulna University, Khulna – 920800, Bangladesh

E-mail: ismat\_kadir@yahoo.com<sup>1</sup>, sadiul\_ece04@yahoo.com<sup>2</sup>, sunny\_khulna@yahoo.com<sup>3</sup>

**Abstract** - Different beamforming algorithms like Side-lobe Cancellers, Linearly Constrained Minimum Variance (LCMV), Least Mean Squares (LMS), Recursive LMS, and Direction of Arrival (DOA) exist in literature. Among the Direction of Arrival (DOA) algorithms, MUSIC and ESPRIT play the most important role. These two algorithms were implemented and their performances were compared. The algorithms were simulated for different signal levels and the DOAs were computed for use in next generation wireless. ESPRIT was found to be a better DOA technique for uncorrelated source used in beamforming.

**Keywords** - Antenna array, Beamforming, DOA estimation, Eigenvalues, ESPRIT algorithm, MUSIC algorithm.

## 1. INTRODUCTION

The performance of next generation wireless can be greatly improved by using adaptive beamforming algorithms [3], [6].

Beamforming can meet the challenge of increasing spectral efficiency and improving wireless communication system performance by significantly increasing the reception and transmission ranges and reducing the probability of interception of secure transmission.

Adaptive Beamforming is a technique in which an array of antennas is exploited to achieve maximum reception in a specified direction by estimating the signal arrival from a desired direction (in the presence of noise) while signals of the same frequency from other directions are rejected. This is achieved by varying the weights of each of the sensors (antennas) used in the array.

## 2. BEAMFORMING BACKGROUND

Beamforming is a form of spatial filtering used to distinguish the spatial properties between a SOI and the noise and the interfering signals. Beamforming principles apply to both the transmission and reception of signals.

Beamforming is accomplished through the use of an array of sensors such as antenna, hydrophones and so on. In order to proceed with the discussion of beamforming, it is important to note some basic assumptions. First, a signal originating far away from the sensor array can be modeled as a plane wave. Next the signal received by each sensor element is a time-delayed (phase shift) version of the signal

received by other sensor elements. Finally, an N-element beamforming system is capable of forming up to N beams.

For the beamformer to steer the radiation in a particular direction and to place the nulls in the interfering directions the direction of arrival has to be known beforehand. The Direction of arrival algorithms does exactly the same; they work on the signal received at the output of the array and compute the direction of arrivals of all the incoming signals. Once the angle information is known it is fed into the beamforming network to compute the complex weight vectors required for beam steering.

Fig. 1: Beamforming setup with DOA Estimation

## 3. DIRECTION OF ARRIVAL

### A. Signal Model

Let a uniform linear array be composed of  $N$  sensors, and let it receive  $M$  narrow band source signals  $S_m(t)$  from , as shown desired users arriving at directions  $\theta_1, \theta_2, \dots, \theta_M$  as shown in Figure-2. The array also receives  $I$  narrow band source signals  $s_i(t)$  from undesired (or interference) users arriving at directions  $\theta_1, \theta_2, \dots, \theta_I$ . At a particular instant of time  $t = 1, 2, \dots, K$ , where  $K$  is the total number of snapshots taken. The desired users signal vector  $x_s(t)$  can be defined as

$$x_M(t) = \sum_{m=1}^M a(\theta_m) s_m(t) \quad (1)$$

Fig. 2: Geometry of a uniform linear array.

where  $a(\theta_m)$  is the  $N \times 1$  array steering vector which represents the array response at direction  $\theta_m$  and is given by

$$a(\theta_m) = [\exp\{j(n-1)\psi_m\}]^T : 1 \leq n \leq N \quad (2)$$

where  $[\cdot]^T$  is the transposition operator, and  $\Psi_m$  represents the electrical phase shift from element to element along the array. This can be defined by

$$\Psi_m = 2\pi \left( \frac{d}{\lambda} \right) \sin(\theta_m) \quad (3)$$

where  $d$  is the inter-element spacing and  $\lambda$  is the wavelength of the received signal. The desired users signal vector  $x_M(t)$  of (1) can be written as

$$x_M(t) = A_M s(t) \quad (4)$$

where  $A_M$  is the  $N \times M$  matrix of the desired users signal direction vectors and is given by

$$A_M = [a(\theta_1), a(\theta_2), \dots, a(\theta_M)] \quad (5)$$

and  $s(t)$  is the  $M \times 1$  desired users source waveform vector defined as

$$s(t) = [s_1(t), s_2(t), \dots, s_M(t)]^T \quad (6)$$

We also define the undesired (or interference) users signal vector  $x_I(t)$  as

$$x_I(t) = A_I i(t) \quad (7)$$

where  $A_I$  is the  $N \times I$  matrix of the undesired users signal direction vectors and is given by

$$A_I = [a(\theta_1), a(\theta_2), \dots, a(\theta_I)] \quad (8)$$

and  $i(t)$  is the  $I \times 1$  undesired (or interference) users source wave form vector defined as

$$i(t) = [i_1(t), i_2(t), \dots, i_I(t)]^T \quad (9)$$

The overall received signal vector  $x_M(t)$  is given by the superposition of the desired users signal vector  $x_M(t)$ , undesired (or interference) users signal vector  $x_I(t)$ , and an  $N \times 1$  vector  $n(t)$  which represents white sensor noise. Hence,  $x(t)$  can be written as

$$x(t) = x_M(t) + n(t) + x_I(t) \quad (10)$$

where  $n(t)$  represents white Gaussian noise. The conventional (forward-only) estimate of the covariance matrix defined as

$$R = E\{x(t)x^H(t)\} \quad (11)$$

Where  $E\{\cdot\}$  represents the ensemble average; and  $(\cdot)^H$  is the Hermitian transposition operator. Equation (11) can be approximated by applying temporal averaging over  $K$  snapshots (or samples) taken from the signals incident on the sensor array. This averaging process leads to forming a spatial correlation (or covariance) matrix  $R$  given by [8]:

$$R = \frac{1}{K} \sum_{k=1}^K x(k)x^H(k) \quad (12)$$

Substituting for  $x(t)$  from (10) in (12) yields

$$R = A_M R_{ss} A_M^H + n(k)n(k)^H + A_I R_{ii} A_I^H \quad (13)$$

where  $R_{ss} = E\{s(t)s^H(t)\}$  is an  $M \times M$  desired users source waveform covariance matrix;  $R_{ii} = E\{i(t)i^H(t)\}$  is an  $I \times I$  undesired users source waveform covariance matrix.

### B. Algorithm for MUSIC estimation

Consider an  $N$ -element linear array that detects  $M$  signals impinging on it whose directions of arrival need to be known. From the previous discussion we know that the received signals at the output of the array have the following form.

$$x(t) = A(\theta)s(t) + n(t)$$

Or in matrix notation it can be represented as,

$$X = AS + n \quad (14)$$

Where  $S$  is the signal vector,  $A$  is the array propagation vector and  $n$  is the noise vector with zero mean and variance.

The covariance matrix is given by,

$$\begin{aligned} R_x &= E\{XX^*\} = AE\{SS^*\}A^* + E\{nn^*\} \\ &= AP^*A + \sigma^2 I \end{aligned} \quad (15)$$

Where  $P = E\{SS^*\}$

$$AP^*A = R_x - \sigma^2 I$$

When the number of signals  $M$  is less than  $N$  then  $AP^*A$  is singular and has a rank less than  $N$ . The eigenvalues of can be found by,

$$|AP^*A| = |R_x - \sigma^2 I| = 0$$

The eigenvectors of  $R_x$  must satisfy

$$R_x e_i = \sigma^2 I e_i \quad (16)$$

$$(R_x - \sigma^2 I) e_i = 0 \quad (17)$$

where  $e$  is the eigenvector and  $i$  varies from 1 to  $N-M$ .

Let the noise eigenvector be defined as  $E_N$  such that,

$$(R_x - \sigma^2 I) E_N = 0 \quad (18)$$

Or,

$$AP^*A E_N = 0 \quad (19)$$

Based upon this approach, the pseudospectrum  $P(\theta)$  is given by

$$P(\theta) = \frac{1}{A(\theta)^* E_N E_N^* A(\theta)} \quad (20)$$

When the pseudospectrum  $P(\theta)$  is plotted, peaks appear at the angles of arrival of the incident signals.

### C. Algorithm for ESPRIT estimation

ESPRIT (Estimation of Signal Parameters via Rotational Invariance Technique) is one of the most efficient and robust methods for DOA estimation. It uses two arrays in the sense that the second element of each pair is displaced by the same distance in the same direction relative to the first element. It is not required to have two separate arrays but can be realized using a single array by being able to select a subset of elements.

Let the array signals received by the two arrays be denoted by  $x(t)$  and  $y(t)$  such that

$$x(t) = As(t) + n_x(t) \quad (21)$$

$$y(t) = A\theta s(t) + n_y(t) \quad (22)$$

$A$  is a  $K \times M$  matrix; where  $M$  is the number of steering vectors produced by  $N$  elements of the array.  $n_x(t)$  and  $n_y(t)$  denotes the noise induced at the elements of the two arrays. Now, by using the available methods, the numbers of directional sources  $M$ , are estimated based on principles such as Akaike's information criterion (AIC) and Minimum description length (MDL). Two matrices  $U_x$  and  $U_y$  are formed which denote the  $M$  eigenvectors corresponding to the largest eigenvalues of the two array correlation matrices  $R_{xx}$  &  $R_{yy}$  (Array correlation matrices). The eigenvectors of the following  $2M$  by  $2M$  matrix are obtained and are denoted by

$$V = \begin{bmatrix} H & H \\ U_x & U_y \end{bmatrix} \begin{bmatrix} U_x & U_y \end{bmatrix} \quad (23)$$

Once the eigenvector  $V$  is obtained its eigenvalues  $\lambda_m, m = 1, \dots, M$  can be computed.

Now the DOA is given by

$$\theta_m = \cos^{-1} \left\{ \frac{\text{Arg}(\lambda_m)}{2\pi \Delta_0} \right\}, m = 1, \dots, M \quad (24)$$

$\Delta_0$  is the element separation in terms of wavelength. Other variations of ESPRIT include beam-space ESPRIT, resolution-enhanced ESPRIT multiple invariance ESPRIT and higher order ESPRIT.

#### 4. IMPLEMENTING MUSIC AND ESPRIT

The above algorithms were implemented and the directions of arrival were computed. It is obvious from the analysis that MUSIC gives the pseudospectrum from which we can compute the direction of arrival as the pseudospectrum peaks. But in case of ESPRIT, we can get the direct polar plot.

Two sets of amplitudes have been used to be the signals at the elements of a linear array. Using the algorithms, the DOAs are calculated. The arrays are simulated to have three elements. There can be the provision for variable number of elements too. The distance between the elements is  $\lambda/2$ . The amplitudes of three element signals for first case are considered to be [1 2 3] and for second case [1.5 2.5 3.5] in voltage units.

Fig. 3: ESPRIT for first signal

Fig. 4: ESPRIT for second signal

The directions of arrival for different element signals are shown for the first amplitude set in Fig. 5 and those for the second set in Fig. 6. The pseudospectrum  $P(\theta)$  s for the two cases are plotted in Fig.3 and Fig.4 respectively, from where the spectrum peaks can be taken to be the DOAs.

Fig. 5: MUSIC for first signal

Fig. 6: MUSIC for second signal

Table 1 summarizes the results found in the corresponding experimentations. We can have a comparative view of the two algorithms for beamforming from this result.

Amplitude	MUSIC			ESPRIT		
[1 2 3]	17 <sup>0</sup>	38 <sup>0</sup>	57 <sup>0</sup>	20 <sup>0</sup>	10 <sup>0</sup>	13 <sup>0</sup>
[1.5 2.5 3.5]	15 <sup>0</sup>	38 <sup>0</sup>	55 <sup>0</sup>	15 <sup>0</sup>	19 <sup>0</sup>	10 <sup>0</sup>

Table 1: Comparative DOA

## 5. CONCLUSION

For first signal in MUSIC Estimation we get the peak of power spectrum at 17, 38, 57 degrees and for second signal at 15, 38, 55 degrees respectively. This gives an idea about the process of DOA estimation. The element angles exhibit greater variation, although in case of signal amplitude variation, the angles of peak power spectrum does not differ that much. In case of ESPRIT estimation we get 20, 10, 13 degrees and 15, 19, 10 degrees for the first and the second signals for the three elements respectively. No doubt, the variations are not that much pronounced and the estimated angles for different elements remains to be almost same.

So, the ESPRIT DOA algorithm can be treated as a more robust and faster estimation technique as compared to MUSIC. The computation is also less complex comparatively. However, ESPRIT has the disadvantage of not being capable of handling correlated sources. Finally, this accurate direction will help to obtain better beamforming which is very essential for next generation wireless systems.

**Abstract** — In this paper a complete step by step method is described to increase the capacity of Global System for Mobile Communication (GSM) using the Intelligent Underlay Overlay(IUO) with frequency hopping and Discontinuous Transmission (DTX). The IUO splits the available frequencies into two layers, super and regular. Super layer frequencies have tighter reuse factor and can be accessed by only mobile stations (MS) having good C/I ratio while the regular frequencies can be used by MS's throughout the cell. The most promising work of this paper is that C/I ratio (hence reuse factor) is obtained by considering the first tier co-channel cells are also using IUO network structure. Analysis is performed by taking some default parameters into account shows that capacity enhancement up to 31 percent can be obtained with respect to a normal frequency hopping network.

**Index Terms** — Carrier to Interference Ratio (C/I), Discontinuous Transmission (DTX), Global System for Mobile Communication (GSM), Grade of Service (GOS) and Intelligent Underlay Overlay (IUO).

## I. INTRODUCTION

At present, increasing the capacity of the cellular network with limited resources (like available spectrum or number of base stations) is one the most crucial problem for the network operators. The general approach towards increasing the capacity with limited spectrum is cell splitting, sectoring, hierarchical cell structure like micro and pico cells [1, 2], or multiple reuse patterns with frequency hopping [3]. But most of these involve additional network elements like base stations or transmission network-which costs a lot. The most desired solution is to increase the capacity with minimal investment while maintaining the quality of service (QoS). There are two possible solutions may be mentioned here such as Frequency hopping (FH), and Intelligent underlay overlay (IUO) which was first proposed by Nokia Telecommunications [4]. The idea behind IUO is to partition the channels into two groups with different frequency reuse factors. The MS's having good C/I ratio

(better than a predefined threshold) will be assigned to the frequencies with tighter reuse factor which eventually enhances the capacity. The other frequency group with normal reuse factor provides the coverage. Several design methods have been proposed for the IUO. Some are well suited for networks without frequency hopping [4, 5, 7, 8]. In some papers, analysis was done by taking predefined value of reuse partitioning and channel assignment strategy [7, 9, 10]. Though the C/I ratio was considered in [5, 8, 10, 11] it was not a function of co-channel cells super area coverage factor. In this paper, an analytical approach has been taken considering that the C/I ratio is a function of super area coverage factor and carried traffic in co-channel cells. Hence, dynamic channel assignment strategy for a given Grade of Service (GOS) can be obtained. In analysis, it is also assumed that the network is large, homogeneous with symmetric traffic and using frequency hopping. At last the IUO model is compared with a normal cell considering some default parameters for performance evolution.

## II. PRINCIPLE OF INTELLIGENT UNDERLAY OVERLAY (IUO) SCHEME

The principle of IUO is that, the available radio frequencies are split in two groups, a super layer and a regular layer frequency group. The super frequencies are meant for the mobile stations with a good C/I, while the regular frequencies can be used by all MS's. A mobile station always starts on a regular frequency, because the C/I ratio of the call is not yet known. If this calculated C/I ratio is higher than a predefined C/I good threshold, the mobile is allowed to enter one of the super frequencies. If there is no available super frequency, the MS stays in the regular group but continue trying to enter the super layer. In the same way while the mobile station is already using a super frequency, it is continuously evaluated whether the C/I ratio is less than so called good C/I ratio, in that case

the MS is handover to the regular frequencies. The IUO algorithm doesn't distinguish moving or non moving vehicles. It considers that a non moving vehicle will not try for handover while the moving vehicles will. And there will not be any direct handover from super to a neighbor cell. The handover rate from super to regular or regular to super are calculated in [7] considering the speed of MS, the coverage factor of the super layer, the radius of the cell, the probability that the MS will move in a direction to increase or decrease the C/I ratio.

### III. MODELING ASSUMPTIONS

A model is considered for the analysis. The assumptions taken for modeling is described here,

- A single cell is taken into considerations for the sake of simplicity. It is also considered that the amount of incoming handover is equal the amount of outgoing traffic from the cell. However the model kept the opportunities to consider this. It is advised that in the practical case it should be considered.
- The source of traffic is uniformly distributed throughout the cell.
- For a particular coverage factor same reuse factor is considered for all the super layer frequencies.
- Number of super channel is SC and regular channel is RC. Any time the amount of occupied channel in regular layer is  $R_{reg}$  and occupied channel of regular but residing in the super is  $R_{sup}$ . The number of super channel occupied is  $Sup$ .
- The ratio of moving MS is  $Rmv$ .
- The moving MS are assumed to move uniformly in a random direction with a velocity  $Vms$
- New call arrival rate is assumed to be a Poisson process with arrival rate .
- The total incoming handover rate is  $\lambda_h$  and outgoing is  $R_{reg} \cdot \mu_{hout}$
- The time needed to calculate the C/I ratio is exponentially distributed with mean  $\frac{1}{\mu_{cal}}$ .
- The call holding time is assumed exponentially distributed with mean  $\frac{1}{\mu_t}$ .
- The channel dwell time is exponentially distributed with mean  $\frac{1}{\mu_{hout}}$ .

- The time needed for a moving vehicle to move from a super to regular area or regular to super is exponentially distributed random variable with mean value  $\frac{1}{\mu_{sup-reg}}$  and  $\frac{1}{\mu_{reg-sup}}$  which is given in [7]

### IV. EQUILIBRIUM MODEL

The model described here utilizes the fact that for certain amount of traffic in the super and regular layer, the sum of call termination rate and call blocking rate (GOS given by the operator) will be equal to call arrival rate. Hence at maximum traffic carrying condition there will be an equilibrium state. Channel allocation and suitable coverage factor will be calculated from there. From fig 1, we find the maximum carried traffic for blocked call rate B,

$$\begin{aligned} & \lambda \cdot cov + R_{reg} \cdot \mu_{reg-sup} - R_{sup} \cdot \mu_t - R_{sup} \cdot \mu_{cal} \\ & - B \cdot \lambda \cdot cov - R_{sup} \cdot \mu_{sup-reg} \\ & = 0 \end{aligned} \quad (1)$$

$$\begin{aligned} & \lambda \cdot (1 - cov) + \lambda_h + sup \cdot \mu_{sup-reg} + R_{sup} \cdot \mu_{sup-reg} \\ & - R_{reg} \cdot \mu_{reg-sup} - R_{reg} \mu_t \\ & - R_{reg} \mu_{hout} - B \lambda (1 - cov) \\ & = 0 \end{aligned} \quad (2)$$

$$R_{sup} \cdot \mu_{cal} - sup \cdot \mu_{sup-reg} - sup \cdot \mu_t = 0 \quad (3)$$

Solving equation 1, 2, and 3  $R_{reg}$ ,  $R_{sup}$  and  $sup$  can be found.

Fig 1. Equilibrium model of IUO cell

TABLE I  
TRANSITION RATE [7]

Event	Rate
New Call in regular layer	$(1 - cov). \lambda$
New call in super layer	$cov. \lambda$
Incoming handoff	$\lambda_h$
Good SIR calls	$R_{sup} \mu_{cal}$
Super to regular	$sup. \mu_{sup-reg}$ $R_{sup} \cdot \mu_{sup-reg}$
Soft blocking	$sup. \mu_{sup-reg}$
Regular to super	$R_{reg} \cdot \mu_{reg-sup}$
Call terminating	$R_{reg} \cdot \mu_t$ $R_{sup} \cdot \mu_t$ $sup. \mu_t$
Outgoing handoff	$R_{reg} \cdot \mu_{hout}$

#### V. DESIGN PROCEDURE

The design procedure is described with the flow chart in fig 2.

Fig. 2. Design procedure with flow chart

#### A. Calculation of traffic

The maximum traffic can be calculated from section IV. Here it is noticeable that  $sup = SC$ . All the other values are different for different cells and can be estimated by field measurement.

#### B. Cluster size

It is assumed that the users are uniformly distributed, hence the probability that a user using a slot in a carrier in a frequency hopping network is uniformly distributed [12]. In a simple cell this distribution of user is extended over the area with radius 0 to R. In a model like IUO and coverage factor  $cov$  distribution will take place in two different areas. For super the users are distributed from 0 to  $cov.R$ . In case of regular layer a fraction of regular layer user  $R_{sup}$  resides in super layer area. And the other are distributed in regular layer area  $R_{reg}$ . So the average interference power present in BTS due to super frequency user  $sup$  in j th cell will be [11].

$$E[Y_j] = \frac{S}{\pi(cov.R)^2} \int_0^{cov.R} \int_0^{2\pi} \left(\frac{r}{d_j}\right)^\alpha E\left[10^{\frac{\zeta}{10}}\right] r dr d\phi$$

And for regular frequency user ( $R_{sup} + R_{reg}$ ) this will be a conditional case as the frequency hopping takes place. So the average interference power will be

$$E[Y_j] = \left(\frac{R_{sup}}{R_{reg} + R_{sup}}\right) \cdot \frac{S}{\pi(cov.R)^2} \cdot \int_0^{cov.R} \int_0^{2\pi} \left(\frac{r}{d_j}\right)^\alpha \cdot E\left[10^{\frac{\zeta}{10}}\right] \cdot r dr d\phi + \left(\frac{R_{reg}}{R_{reg} + R_{sup}}\right) \cdot \frac{S}{\pi(R - cov.R)^2} \int_{cov.R}^R \int_0^{2\pi} \left(\frac{r}{d_j}\right)^\alpha \cdot E\left[10^{\frac{\zeta}{10}}\right] r dr d\phi$$

Here  $d_j$  is the distance between MS in j th cell and BTS. It

Fig. 3. IUO cell

is a function of cell radius, coverage factor  $cov$  and cluster size. Now, the C/I ratio at the BTS for uplink transmission (assuming reciprocity) will be,

$$C/I = \frac{S}{\mu \sum_{j=1}^6 E[\gamma_j]}$$

Where  $\mu$  is the voice activity factor (VAF), which allows discontinuous transmission (DTX) to include in the model. To model the IUO for the worst case we considered here VAF=1. For various coverage factors  $cov$  and to maintain a minimum level of C/I ratio which is predefined by operator, we will get different cluster size. However, in the case of co-located overlay and underlay cell, Broadcast Control Channel (BCCH) is carried by a regular frequency [4], hence, this BCCH should be kept clean as much as possible. It is the next problem to allocate frequency to super and regular layer so that none them is allocated more or less with respect to expected carried traffic.

### C. Optimization

First the required number of frequency is estimated considering for a given GOS. The frequencies are allocated considering that regular layer frequencies consist of 7 TCH, and super layer consist of 8 [7]. Then a graph is plotted for required total frequency vs. offered traffic. From the curve a minimum point can be achieved which best fulfills the offered traffic and power management.

## VI. ANALYTICAL RESULT

To observe the practical outcome of the proposed model, we analyzed a cell with some default configurations. The objective is to provide adequate frequency for super and regular layer. If there is not enough frequency, to the GOS has to be increased or the available frequency should be increased which is not desired or cost effective. The default parameters are presented in Table 2 and the results are analyzed in subsequent graphs.

TABLE 2  
ANALYSIS ASSUMPTION PARAMETERS

Parameters	Values
Call holding time	80sec.
Cell radius	3km
Ratio of moving MS	50%
Speed of moving MS	50km/hr
The path loss exponent,	4
The standard deviation of shadow fading,	8
Voice activity factor, $\mu$	1
Blocked call rate, $b$	5%
Threshold level	12db

The resultant graphs show that for different values of  $cov$  the C/I ratio for MS in super frequencies decreases as the  $cov$  increases.

Fig. 7. Total channel versus offered traffic for different super area coverage factor

The same result for regular is obtained. Hence the cluster size increases as *cov* increases. This was expected because as the *cov* increases more and more MS spread throughout the cell. Hence the MS comes into more vicinity to neighbor co-channel BTS, hence the interference power increases thus the C/I decreases. Another thing is that different number of frequencies is required to meet the GOS for different *cov*. A careful observation is necessary before allocating frequencies. A handoff between the amounts of simultaneous subscriber served in a cell and the number of frequencies available to operator is to be considered. Performance improvement will depend completely upon the efficient partitioning of available frequency and maintaining the minimal threshold of C/I at the same time. By assuming lost call cleared system, it is seen that the capacity is increased up to 31% with respect to the FH GSM network. If the cluster size is not taken some discrete values like 3,7,12 ( $i^2 + ij + j^2$ ) etc, more enhancement can be found.

## VII. CONCLUSION

This paper focused on designing Intelligent Underlay Overlay (IUO) scheme and optimization of capacity without compromising the Quality of Service of a cellular network. The analysis results characterize the effect of IUO on the performance of a cell as a function of the coverage factor, offered traffic, the mobility of MSs, QoS and GOS. The proposed model indicates that significant capacity enhancement can be achieved with increased complexities of frequency partitioning and network optimization.

# Cell Database Based Time Specific Resource Reservation Scheme

## ABSTRACT

**Abstract** — Increasing cellular network offers services with diverse quality-of-service supports users to access telephony, paging, instant messaging, and trivial web-browsing on the same device. The mobility of communication devices and channel imperfection makes the service offerings much more challenging with limited resources. Resource reservation plays a very important role in cellular communication in terms of availability of services. There are various schemes present to manage the resources in an efficient way. In this paper, we have tried to analysis several resource management schemes and their drawbacks. We have proposed a time dependent resource reservation scheme which has significant advantages over other schemes.

**Index Terms** — Mobility Management, handoff, Call Admission Control (CAC), Call dropping probability (CDP), Call Blocking Probability (CBP), Cell Visiting Probability (CVP).

## I. INTRODUCTION

In a cellular network MU is connected with base station (BS), which uses a dedicated frequency spectrum. The BS is connected with the BSC by microwave antennas that are again connected with MSCs for controlling purpose. MSCs are interconnected using the optical fiber backbone in most of the cases except some conditions where wireless connectivity is needed that acts as a gateway to the external links.

Bandwidth [8] reuse principle is used on the limited available radio frequency spectrum that divides it into smaller spectrums for maximum uses. Smaller sized cells required by the next generation cellular networks to support higher transmission rates of multimedia applications that create increasing handoff problems in the cellular network. That's why resource management becomes a major concern in the perspective field. There are three major aspects to deal with. These are Call Admission Control (CAC), Resource Reservation, and Resource Allocation.

The paper is organized as follows. Introduction, Different past policies and difficulties with them, Our contribution, Our proposed scheme, Mathematical Relations, Conceptual backend database design, Comparison with old schemes, Conclusion and Future works.

## II. DIFFERENT POLICIES FOR RESOURCE RESERVATION

### A. Elementary guard channel (GC)

This GC policy [3] reserves fixed portions of the cell capacity causing huge wastage of resources & higher call blocking probability. Instead of resource reservation, controlling new service admission random walk model decreases CDP below a threshold [1, 3, 5] level. Shadow cluster is formed with neighbouring cells likely to be visited by an MU. Resources are reserved estimating the CVP for an MU relying on historic information rather than current mobility information. Initiating a new service is done on basis of resource limitation by giving priority to the existing call. Most of the CAC [1,5] & resource reservation schemes are designed by reserving a certain bandwidth in each cell or by keeping CDP less than threshold value.

### B. Non-Mobility Based Resource Reservation Schemes

A fixed portion of bandwidth is reserved in each cell for handoff services in conventional resource management schemes (Ex: Guard channel scheme). Unused channels are shared by handoff and new services. If we say  $CH_i^T$  is the number of total channels,  $CH_i^u$  number of unused channels,  $CH_i^a$  allocated channels,  $CH_i^r$  reserved channels,  $CH_i^f$  and number of free channels, then according to this scheme

Fig. 1. Cell Capacity Distribution

a new service is admitted if and only if  $CH_i^f = CH_i^u - CH_i^r$ , the free channels can support it. Distribution is shown in Fig.1. Handoff is functional when it is supported by unused channels. Handoff service queuing (HQ) model on top of the GC scheme was introduced by Hong and Rappaport.

In this model they assume that a MU can simultaneously communicate with more than one cell;

Received Signal Strength Indicator (RSSI) level is used for handoff decision. For a MU the handoff procedure is implemented if RSSI level is less than the handoff threshold signal strength level and also less than the RSSI of any neighbouring cell's BS. For unavailable channels of the next cell service are queued until the RSSI of the current BS drops below an acceptable received threshold. Tekinay and Jabbari introduced in HQ model measured based priority-queue scheme (MBPS) to maintain priority in the queue, higher priority is given to the services with lower RSSI level. Performance of this HQ model has been studied both experimentally and analytically using the birth-death queuing model [4]. This scheme though can detect handoff situation perfectly but resource reservation part has not been given much concern. Fixed amount of resource is reserved in all the neighbouring cells costing a huge amount of resource wastage.

### C. Symmetric Random Walk Model Based Schemes

SRWM [7] estimates CDP and/or CBP using different statistical measures & keep them below some threshold values for new/handoff services admission decision.

#### C.1. Threshold Bounded New Service Admission Control Models

In threshold bounded new service admission control schemes [1, 2, 5] new services are accepted if the number of new services or CDP in a cell is below a given threshold. Handoff service is admitted by the remaining unused channels in the cell.

#### C.2. Diffusion Equation Based Models

The properties of the diffusion equation are used to predict the mobility of MU. The influences of MU from the neighbouring cells are taken into consideration. Diffusion equation based models takes the CAC decision that expected CDP is kept below  $P_i^D$  (a certain limit). No resource is reserved for this purpose. Principles of the diffusion process cannot explain free-will motion of MUs in a cellular environment guided by geographical features.

### D. Handoff Profiling Based Schemes

This schema predicts future mobility of an individual MU based on the mobility history stored in profiled databases. Path segment or mobility, route & timing information of the visiting MU is recorded in the database.

#### D.1. Path Segment Based Schemes

For dynamic location tracking Tabbane used user specific handoff mobility profiling database based on the quasi-deterministic mobility behavior. Liu and Maguire further pursued the model by tracking repetitions of movement patterns. Location of the MU estimated based on these movement patterns, using pattern matching/recognition-based mobile motion prediction (MMP). Random movements cannot be

classified by the simple mobility patterns. MMP algorithm is high sensitive to this is its main drawback. To solve the problem Liu et al. proposed inter-cell mobility predictor. Here routine routes of the user are identified from mobility profile database by using an approximate pattern matching technique. For each user's mobility patterns (UMPs) are recorded and indexed by the occurrence time. It is much less sensitive to small deviation from the user's actual path (UAP). In UMP it is assumed that the direction of MU is not changed within a path segment like within a cell. For a cellular network with micro-cells or Pico-cells using UMP is meaningless. It has high computational complexity and huge storage requirements that is not suitable for real-world situations.

#### D.2. Mobility Route Based Schemes

Levine et al. proposed the scheme where route based user mobility information is profiled at regular intervals. That estimates handoff, cell residence time for each cell and cell-independent call duration. It gives us the time-dependent CVP for the MU considering all possible routes to visit neighbouring cells.

This technique is very expensive as it requires constant updating for each MU in profiled databases. Again the number of possible routes could be infinite. Recording individual or aggregated mobility history is time and space consuming task. Reducing complexity by distributing database demands extra memory and processing power. As aggregated mobility history must be kept centrally, distributed database cannot resolve the problem too.

#### D.3. Route Independent Traffic Flow Based Schemes

This scheme profiles up handoff histories in the form of quadruplets. It has the departing time from the current cell, the index of the previous cell the MU resided in before entering the current cell, the index of the cell the MU entered after departing the current cell, and the current cell dwelling time. CVP is then estimated. Profiling each handoff for a large period of time (at least 24 hours) is space consuming. Here from all the handoff profiling based schemes we found that a major common problem is cost. These models cost huge time and money. Different models records different topics like Movement patterns, Route based mobility information, Handoff histories etc for taking resource reservation decision. But among this Route Independent Traffic Flow Based Schemes are better as they records handoff, though it is very much costly.

### E. Cell Topography Based Schemes

Sleem et al. extended cell topography knowledge to predict CVP directly from the location road-map. From its current position an MU takes the next path with equal probability from the paths ahead. At location A, MU can turn left or turn right or take a U-turn. CVP for cells 1, 3, and 5 are 1/3 from cell 4. It is shown in Fig 2. Information of road networks is taken into account

ignoring mobility information. It is highly complicated in a city with complex road-networks.

Fig. 2. Cell Topography based on CVP estimation

In this model road networks and environment are taken under consideration. Surely this knowledge helps to handle handoff situation perfectly.

#### F. Parametric Mobility Support Schemes

In this scheme key mobility parameters are used. They are position, direction, and speed. This information is used for CVP estimation, shadow cluster formation technique, solitary resource reservation policy, complete resource reservation and CAC policies.

##### F.1. Shadow Cluster Formation without Explicit CVP Estimation

Using the direction and speed information of the MU this scheme proposed an elliptical shaped (Fig 3) shadow cluster formation technique [6, 10]. It does not estimate any CVP. MU is the focus of the ellipse and direction is the axis.

Fig. 3. An elliptical shaded shadow cluster is formed.

In the shaded region which is the backside of the MU's current position, visiting probability is extremely low. Elliptical cluster reserves resources unnecessarily for the area. From the position of the MU the radial span of the cluster should be equal. This should be irrespective of the direction. Next, CVP has no bearing. So the shape and size of the cluster remains same irrespective of the MU current cell. As there is no CVP estimation [11, 12], so resource reservation policy is not effective one. Direction of MU has no influence on the amount of reservation.

### III. OUR CONTRIBUTION

As far as we know the database based schemes are mostly not applicable because of their high cost and maintenance problems. Again these database based schemes can not give an optimally efficient performance for the whole network at a time. They actually focus on giving optimal performance for most of the cells.

We have proposed a new database based scheme that is able to reserve resources much more effectively. We tried to find out the causes behind performance problems and proposed the new idea with some specific improvements. In this paper we also tried to show how we can overcome the problems with the help of this theory. This scheme would take decision for each and every cell separately. This would be effective for having a constant efficient performance for whole the network. Details for these topics are given below.

### IV. PROPOSED SCHEME

#### A. Time Specific Cell Database Scheme:

In the proposed time specific cell database scheme a database is maintained for each and every cell. Now the cell database is created by watching the MUs' movement for a period of time. It then takes the decision depending on the database. It updates its database after a defined period of time to notice the change in the cell area.

Fig.4. Time specific cell database scheme

In the Fig. 4 we can see how the cells are using the database to take the reservation decision. Suppose, a city is divided into two parts which are Residential area and office area. Now the cell observer finds out that during the 7am-10am period of time the handoff is happening very frequently in these cells because of the movement of people from home to office. So, for this period the handoff probability is very high in these cells. So the larger portion is reserved for handoff managing to control the handoff rush properly.

Then from 10am-5pm cell observer finds a static situation within the cell and that's why use larger portion of its resources for call initiating.

Again from 5pm-9pm again rush on road causing same situation during 7-10am because of rush on the road. On the highway, as all the vehicles are moving fast and handoff probability is much higher so always handoff portion should be more for highway cells.

Again for weekends we should have different strategies as there is no rush for office area in that period. For amusement & market areas the rush would be higher & handoff should be managed just as before.

### B. Mathematical relationship

Here we are actually trying to give a basic idea how different parameters are related with the handoff probability and how they change its value. To give the relations mathematically we assume-

$H_p$  = Handoff Probability for the cell

$R_h$  = Resource reserved for handoff

$R_i$  = Resource reserved for call initiating

Then the relation would be:

$$H_p \propto R_h \quad (1)$$

$$H_p \propto 1/R_i \quad (2)$$

As considering only equation 1 we can take our threshold value decision we are only focusing on this-

$$H_p \propto R_h \Rightarrow H_p = k \cdot R_h \quad (3)$$

Here K depends on the factors like,

U= Number of user resident at the moment.

C= Number of call initiated

N= Number of users in neighboring cells

P= Probability of users to move in this cell

T= Average time period for the initiated calls.

And K is dependent on this factor in the following way-

$$\frac{NP}{UCT}$$

So equation 1 can be written as-

$$H_p \propto \frac{NP}{UCT} R_h \quad (4)$$

### C. Conceptual database design for Cell Database Scheme

Suppose we store data in the database for a 2 hour time gap for all 7 days in a week. Observer observes the cell for a specific period of time and stores the handoff percentage for the cell happened in each slot of time. From database if we find handoff probability for a cell more than 40 % then we reserve larger portion of the resource so that we can minimize the CDP. Again if handoff probability is less than 40 % then resource portion is smaller to minimize the CBP.

	6-8 am	8-10 am	10-12 am	12-2 pm	2-4 pm	4-6 pm	6-8 pm	8-10 pm	10-12 pm	12-2 am	2-6 am

Thu	20	70	55	30	40	55	60	30	20	10	10

Fig. 5 Database model view for the proposed scheme

So, for the database schema design we have to have one database in the MSC and one in the BSC because it is difficult to maintain bulky data at BSC. This costs much. To reduce the cost and to gain speed in retrieving we use a distributed database. A sample view of database for a Time Specific Cell Database Scheme is shown in Fig 5. The schema design for the backend database is shown.

Fig. 6. Schema design of backend database for Cell Database Scheme

### D. Assumptions & Specifications

#### D.1 High data retrieving rate

Data retrieving rate is high in this scheme as we are storing data in the BSC database. So the data can be retrieved in a much shorter time than other schemes where others are retrieving data from the OMC.

From the graph (Fig. 7) we can see that data size with respect to time is growing up. Though the rate of it low in other schemes in spite of that the time limit is higher. On the other hand the growing scale takes a high jump after 2GB as we consider more than 2GB of data should

Fig.7. Data retrieving rate graph

be retrieved from the MSC. But the graph clearly shows us that high growing rate does not make it ineffective but still it is effective in time savings and high rate data retrieving.

#### D.2 Constant & Efficient CBP & CDP Management

As in other schemes frequency is managed for whole network at a time depending on historic movement of MU. Though this is applicable for most of the cells but for some cells it may cause hazardous situation.

From the graph (Fig. 8) given we can see the effect of this situation. From 7am-10am MUs' much movement causing heavy handoff rushes. For this reason, larger portion of frequency is reserved for managing this handoff situation in the whole network. But it is not efficient for all of the cells. Cells like residential area may need higher portion of frequency for call initiating while much frequency is reserved for managing handoff situation. This causes high CBP. Again from 10am-5pm frequency is reduced for handling handoff situation now which is given for call initiating. But this also causes problems for highway as handoff is occurred frequently in highway. Some other situations are also given in the graph.

In our schema as we maintain cell database, it helps us to take decision on a specific cell that what level of resource it should have for managing the handoff. So here we can ensure that while we are giving high reservation in most of the areas that may not cause high CBP in the residential area. As we are serving it with a low resource reserved, this gives us a constant efficiency Fig. 8) all the time in all the cells. From the graph we get some more situations where CDP & CBP is managed efficiently.

Fig. 8. Efficient management of CBP & CDP

#### D.3 Cost Effective data storage

In Mobility Based schema path movement for each MU is taken into consideration & movement of each MU is stored in the database. So here database is huge which causes high cost for managing as well as for storing & retrieving.

Fig. 9. Cost effective data storage

But in Cell database schema number of handoff per cell is calculated with respect of time. As here we don't calculate each MU's movement other then handoff condition. So, database is small. It is also easy to manage the database as it is distributed. So, our scheme has less costly data storage than Mobility route based scheme (Fig. 9).

#### E. Working procedure for the Cell Database Scheme:

This flow chart (Fig. 10) is given for showing the working procedure of Cell Database Scheme. From the flow chart it is visible that each time it is taking the decision that it is now going to get new data to store or it is going to take decision on stored data. If it needs to take decision it then checks for the data size. If it is

smaller than a fixed amount it looks for the data in the BSC database else it looks in the MSC database which is more time consuming.

After gathering of data it takes the decision of the amount of resources to be reserved. According to the decision it reserves the resources. Or it finds out that it is going to gather new data to store. Then it starts by checking out when last database was updated. If it is more than four months ago then the observer gathers new data and stores it. If it was updated within four months then it takes the decision that data is valid for use.

Fig. 10. Cell Database Scheme Flow chart

### III. CONCLUSION & FURTHER WORK

Above we have discussed some related schemes that contributed a lot in the telecommunication evaluation. But none of them are the optimal one. We have proposed a new concept of resource reservation, where we have taken under consideration the problems of the previous schemes. But we have some further improvements to do in it like:

1. Call duration should be taken into account. That means a database should be maintained for ongoing calls for each cell to limit its excessive holding of a channel. If a call duration limit exceeds then its CDP would be higher and new initiating calls will be given much priority.

2. Mobility and Non mobility based issues should be merged. Previous schemes discussed only with one of those aspects completely ignoring the other one in most of the cases. Schemes those considers both of the aspects actually focuses only one aspect in practical use. Schemes concerned about both the aspects practically will be much more effective.

3. As cell database is used, the database would be a distributed one, which makes it hard to manage. So database management should be taken under consideration.

# Developing a Model of E-governance for Urban and Rural Areas of Bangladesh

Gazi Zahirul Islam<sup>1</sup>, Md. Ibrahim Khan<sup>2</sup>, Md. Anas Boksh Mazady<sup>3</sup>

<sup>1</sup>CSE Department, Primeasia University, Banani, Dhaka, Bangladesh.

<sup>2</sup>CSE Department, Chittagong University of Engineering & Technology, Chittagong, Bangladesh.

<sup>3</sup>Core Network Development, Aktel, Gulshan-1, Dhaka, Bangladesh.

**Abstract** — Several developing countries including Bangladesh are realizing the role ICT (Information & Communication Technology) can play in the governance sector, and are putting into practice innovative e-governance models that may be technologically simple but are drastically changing the way information is distributed in the society. This paper depicts and implements a model of e-governance for urban and rural areas in Bangladesh. The project deeply considered existing ICT infrastructure in Bangladesh and put effort to implement the model in a cost effective and flexible manner. A clear, comprehensive layout and network architecture for rural and city areas is given separately. We also described complementary tasks such as database implementation, system development, web related task etc. for e-governance. The main objective of the project is to implement e-governance in an easy and cost effective way to suit with existing ICT infrastructure in Bangladesh to provide better information and service delivery of government to the people.

**Index Terms** — ICT, VPN, Public network, Private network, Baud rate, Dial-up network

## I. INTRODUCTION

E-governance is the public sector's use of information and communication technologies with the aim of improving information and service delivery, encouraging citizen participation in the decision-making process and making government more accountable, transparent and effective. Bangladesh and many other developing countries are apprehending the importance of information and communication technology (ICT) in the governance arena, and are putting into practice innovative e-governance models that might be technologically simple but are abruptly changing the way information is distributed to the public [15], [11]. In this paper we delineate a model of e-governance through rural and city areas in Bangladesh.

The project deeply considered current ICT infrastructure in Bangladesh and tried to implement the project in a cost effective manner. A clear, comprehensive layout for urban and rural areas is drawn separately and is shown in section III of this paper. Since, in Bangladesh government telephone line is the most widely spread data

communication line; we have chosen a VPN (virtual private network) model for implementing e-governance and is explained in section IV. In section VI we described complementary tasks such as database implementation, system development, web related task etc. to establish a full-fledged model of e-governance. We have developed sample database, forms and web pages which views are included in this paper. The goal of this paper is to implement e-governance in a flexible and cost effective manner to suit with current infrastructure in Bangladesh to provide better information and service delivery of the government to the public; and hence promote democratic practices through public participation and consultation.

## II. OBJECTIVE OF E-GOVERNANCE

E-government refers to the delivery of government services and information to the public, using electronic means to transform the way it serves its constituents [3], [9]. In this case, in general, citizens are seen as passive recipients of the digital information and services. But the trend has been changing drastically and citizens are now demanding more user-friendly programs.

However, most importantly, e-government must be on governance and not just IT; on citizens and their needs and not just on computers; on transforming the process not on translating the process; and on software not on just hardware and focus on people but not on systems. Thus, e-government is not just 'e' but about facilitating the system by 'e' and getting it to work for citizens to benefit them in their daily activities of practical life [10].

### Goals of e-governance

- Improve the internal organizational processes of governments
- Provide better information and service delivery
- Increase government transparency in order to reduce corruption
- Reinforce political credibility and accountability

- Promote democratic practices through public participation and consultation
- Focus on disadvantaged communities, who otherwise will be excluded
- Provide that information or service which otherwise will not be provided
- Create an outcome which in absence of ICT will not be produced efficiently or timely

### III. LAYOUT DESIGN

Like other developing countries, the infrastructure of ICT between rural and urban areas in Bangladesh is different [1]. So, separate layout should be considered for cities and villages. Design of an e-governance scheme for a rural area involves many constraints such as connectivity, bandwidth and available infrastructure [12], [5]. In city areas the structure is stronger and easier to implement e-governance. By various scheme initiated by Government of Bangladesh, rural telephony penetrates into most of the remote villages of the country. This paper describes the design issues of a practical e-governance system for rural and urban areas. Emphasis was on giving a cost effective solution with minimal changes to the existing communication infrastructure and user-friendly interface to the system using English and Bengali Language. Also the issues like getting active network connection through dial-up modem have been taken into consideration.

#### A. Layout for rural areas

In rural areas District Commission Office (DCO) is the centre of control, where database server, web and application server, network hub etc. will be kept. Other areas are connected to District Commission Office. Kiosk or booth should be set up in different places for public to communicate with DCO office. We may choose Upazela Offices and Union Offices as the place to set up the kiosks. Without Upazela Office and Union Office a remote populated or important place may be choose to set up kiosk for ease of public. All kiosks should be equipped with at least a computer, a modem, telephone line and other equipments to communicate with DCO office. Figure 1 shows the layout of the model for rural areas. Upazela Office, Union Office and distant kiosk are directly connected to District Commission Office (DCO).

#### B. Layout for city areas

The infrastructure of ICT in cities are substantial than rural areas. It is easier to implement e-governance in city areas than rural areas. We can easily divide a city area by wards. In every Ward Commission Office a kiosk has to be setup. Here, City Corporation Office (CCO) will take the control of governance [2]. Every kiosk is connected to the CCO. The equipments in the kiosk are more equipped and

sophisticated in cities than rural villages. Figure 2 depicts the model.

Fig. 1. Layout for rural areas

Fig. 2. Layout for city areas

### IV. NETWORK ARCHITECTURE

There is a big gap between infrastructure needed for a pervasive e-governance and what is in-fact present in rural and city areas [14]. So, information and communication network designer needs to measure the success rate in terms of technological breakthrough of the system under design [13]. The concept of e-governance can be translated into practice by creating required ICT infrastructure and introduction of appropriate operational strategies. Following are the few ICT network scheme:

- Public Network
- Private Network
- Virtual Private Network (VPN)

A public network is owned and operated by a service provider similar to a telephone service. The chief advantages of a public network are flexibility and the ability to use state-of-art networking without maintaining technical expertise. A public network is flexible because an arbitrary subscriber at an arbitrary location can connect to the network at any time. But the system can not provide sufficient security and it is not suitable for particular decisions or policies. A network is said to be private if use of the network is restricted to the corporate or individual owner. The chief advantage of a private network is that the owner has complete control over both the technical decisions and policies. But a private network can be expensive to install and maintain. A Virtual Private Network (VPN) combines the advantages of private and public networks by allowing a company with multiple sites to have the illusion of a completely private network and to use a public network to carry traffic between sites [6].

We will choose a VPN model for implementing e-governance. The model will use government telephone line for data transmission. In our country government telephone line is the most widely spread data communication line. Actually, telephone network is the most suitable means for rural areas that can be used for implementing e-governance. So, we need to establish a dial-up communication line through government telephone line. Figure 3 shows the network structure for rural areas, where Upazela Office, Union Office and Distant Kiosk are connected to District Commission Office through the telephone line. It is not hard or complex to implement a Virtual Private Network (VPN) that could provide sufficient security for such a project. VPN can be implemented with a combination of easily acquirable hardware and software [4], [7].

Fig. 3. Dial-up networks of rural areas

Table 1. Data rate and dial-up speed

Forms	Characters	Required data rate	Worst case dial-up connection
Minimum field content	300	2700 bps	26100 bps
Maximum field content	2800	25200 bps	26100 bps

In city areas every ward offices are connected to City Corporation Office. Figure 4 shows the network structure for city areas. The communication medium of rural areas and city areas is same that is telephone line. Actually, more sophisticated medium and equipment may be implied in city area as the demand of city people is more than rural people. Since telephone line is available in every place in city and we consider a minimized cost, we designed the model with dial up telephone line as villages. Figure 4 shows the structure of city areas.

Fig. 4. Dial-up networks of city areas

## V. DATA RATE SPECIFICATION

The bandwidth of the telephone line should be considered to implement the model. To reduce the bandwidth, only data fields are transmitted to store it in the main database. Data rate is the number of bits per second and Baud rate (B) is the number of characters per second. A character frame consists of 8 data bits and 1 stop bit. So, character frame length is 9 bits. If modem speed is set at 33600 bps, then Baud rate,

$$B = 33600 / 9 = 3733 \text{ characters per second}$$

Therefore, 3733 characters per second can be transmitted through the telephone line. We consider that the worst case dial-up speed at distant places is at 26100 bps. Data will be transmitted successfully at this rate as described in table 1.

## VI. DATABASE AND SOFTWARE

To implement e-governance a huge class of software is needed in various developing stages. Many commercial softwares are available which should be purchased to implement the system. Of course, some software should be developed to provide desired services to the citizen. An important task is to create database. A large class of database is a significant criterion for such a project. One thing should be kept in mind during software development is that software should be flexible to use and be simple to suit with the existing communication infrastructure.

We have created sample databases, web pages and forms for our e-governance model [8], [16]. For convenience, we developed a virtual web site for Dhaka City Corporation. The real implementation would need rigorous analysis and planning to meet the people needs and corporation needs. We developed database, web site, and some forms for online job application. Figure 5 shows the view of the web site. The web pages are developed by html code and with the help of Microsoft Front Page.

Fig. 5. Web site of Dhaka City Corporation

There are several links of the main page of DCC website. The button “Apply for Job” is the link to the job application form. Clicking the button job form will appear. Users who are interested of the job they fill the form and submit online, then the data of the form is stored in the main database of the city corporation. We created a database named ‘JOB\_APPLICATION’ with php and mysql software. Figure 6 shows first portion of the job application form. This portion required personal information and career & application information about the intended candidate.

After submitting first portion successfully then second portion of the form will come. Figure 7 shows second portion which required information about academic and training information of the candidate. After filling the fields of second portion of the form, candidate has to submit it. If it is successfully submitted then last portion experience information will come.

At last, final and third portion of the form which required information about work experience will appear, if previous portion submitted accurately. Figure 8 shows the experience information portion. If this portion is completed and submitted successfully then all required information of the job application form would be gathered and stored into the main database of DCC.

## VII. SYSTEM IMPLEMENTATION

We focus to develop a flexible system as possible for developing our e-governance model. A cost effective and efficient system should be implemented to suit existing infrastructure. Special concentration should be given for rural areas due to weaker communication infrastructure in villages. Client and user software should be developed as simple as possible. Software interfaces and forms should provide information also in Bengali, so that rural people can easily understand the information and communicate with the government. Data can be submitted either in online or offline. Offline data submission reduces operational cost and also very flexible for a noisy and low bandwidth network. Data can be uploaded to central database 2 or 3 times in a day or more than that as required and availability of good connection. People can fill up the application forms

Submit

Fig. 8. Last portion of the of the job\_applicant form

at their nearest kiosk. After submission of the form he would be given a unique token number from DCO or CCO for identification of the submitted application. Local kiosks are also capable of delivering status information for online queries from central databases. Kiosks should also provide all of the facilities as people required specially for cities such as scanner, printer, web camera etc.

## VIII. CONSTRAINTS AND RECOMMENDATIONS

There are some infrastructural constraints in rural areas which should be carefully considered before implementing e-governance. So, project designer needs to measure the success rate in terms of technological breakthrough of the system under design [13].

In rural areas often the telephone lines are idle due to some technical failure or too noisy for computer data transmission. Network bandwidth, data speed and a noise free network connection are desired for on-line data transmission. To reduce the cost of operation of dial-up ICT network and getting this dial-up connectivity active the form submission process should made offline also. To reduce the bandwidth, only data fields could be transmitted to store it

in the central database. These types of communication problems may not arise in city areas.

To establish e-governance following principles should be obeyed:

- Consider rural and urban infrastructure separately to implement the project
- Focus on disadvantaged communities, who otherwise will be excluded
- Provide that information or service which otherwise will not be provided
- Focus on utilizing and where possible building upon what is existing rather than thrusting a new intervention
- Create an outcome which in absence of ICT will not be produced efficiently or timely

## IX. CONCLUSION

The term e-governance is of recent origin and has become the buzzword in all developing countries. In fact, it is the use of Information and Communication Technology (ICT) for redesigning the traditional mode of governance, through better coordination and sharing of power among different components of government; thus taking care of the traditional problems of governance. The lack of information and communication infrastructure results in people having to waste time and money [5], [12]. Lack of clarity in processes, and corruption and mismanagement in systems and operations, is rampant. In this context, Information and Communication Technologies (ICTs) can play a significant role in making information available at a reasonable cost. ICTs promise to provide innovative solutions to the problems of poverty and inequality by accelerating development and introducing transparency into systems and operations.

At last, establishing e-governance is utmost important for our country. In this paper, we proposed a comprehensive and cost effective model of e-governance considering existing ICT infrastructure of Bangladesh. We hope that this paper could provide important guidelines and information to government and others who deal with e-governance.

## Abstract

**Security and privacy have become crucial factors in auction design. Various schemes to ensure the safe conduction of sealed bid auctions have been proposed recently. We propose a secure sealed bid auction protocol. We introduce a new standard of privacy for auctions, that prevents extraction of bid information despite any collusion of participants. Present cryptographic protocol which is the realization of an electronic auction being the component of the e-government or e-commerce system. Our protocol provide non-reputation and correctness.**

**Keywords:** Sealed bid auction, Auction security, auction corruption, auction protocols.

## 1 Introduction

The Internet has been providing a commercial environment, where secure auctions are in demand. A usual type of them is a sealed bid auction. In the sealed bid auction, bidders submit their own bid prices to the auctioneer secretly, until the deadline. After the deadline, the auctioneer announces the winner and the clearing price. In the highest-price auction, the bidder who submitted the highest bid is the winner, and clearing price is the highest bid.

In the sealed-bid auction, two important properties are required. One is the bid privacy. The minimum is

the privacy until the deadline. Additionally, it is desired that the privacy continues even after the deadline, as pointed out in [6], since the information on the bids (i.e., prices) indicates bidders' preferences or powers. Furthermore, the statistics of bids in an auction help the auctioneer to learn the strategy of the bidders, which is useful for managing other auctions. The important property of privacy is Anonymity.

This paper is organised as follows: Section-2: discusses types of auction, Section-3: describe related works, Section-4: describes auction notation and terminology, Section-5: provides basic electronic auction protocol, section-6: discusses Security goals for sealed bid auction and section-8: provides conclusions.

## 2 Types of Auction

Auctions are means to transfer from one entity to another where the price of the goods is not easily determined and depends on the perception of the customer [23].

Auction can be classified according to the number of sellers and the manner by which bidders submit bids. An auction that has only one seller and many buyers is referred to a single auction. An auction with many sellers and many buyer's (i.e a securities market) is referred to as a double auction. The classification of Auctions are shown in bellow.

Bidding in an auction can typically be two types: sealed and open. In a sealed bid auction, secret bid (not known to other bidders ) are submitted to the

Figure 1: Taxonomy of Electronic Auction Schemes.

Auctioneer. Once the period closes, the bids are opened and the winner is determined according to some publicly known rule (e. g. ,the highest bidder wins) [6].

We look at different auction mechanisms for a sealed bid auction . We take the case of single - item auctions and study First Price and Second Price mechanisms, in this context. We note that both these mechanisms lead to an efficient allocation and under some simplifying assumptions, fetch the same revenue to the auctioneer.

First Price Auction mechanism, sealed bids are invited from all the bidders. The item is then allocated to the bidder with the highest bid, at his/her bid price

An English auction is a highest price, open bid auction. The bid amounts are known to all parties and bidders attempts to outbid each other. The highest bidder wins and must pay an amount equal to the wining bid. An English auction is the most well known type of auction and is widely used for real estate. An English auction is known as physical Auction. In physical auctions the responses must be received within seconds, while in cyber auctions it is conceivable that several minutes or hours will be allowed for the responses. English and vickrey auctions are considered as ascending due to the bidders bidding up the settlement price.

Alternatively an auction can be decreasing. This decreasing price (Dutch auction) of auction is similar to the English auction in that the bidding price varies over time; however, in this case, the price decreases

and at a time  $i$  is  $k \cdot i^* \nabla$ .

In a continuous Double Auction (CDA) there are many buyers and sellers who continuously trade a single commodity. CDAs are typically open bid. The best known example of CDA is a securities market

### 3 RELATED WORKS

Many papers consider secure sealed bid auction protocols. We shall now review selected proposals from the literature. The first cryptographic auction scheme was proposed by Franklin and Reiter [7]. The protocol uses a set of distributed auctioneers to evaluate bids and is based on secret sharing. The protocol prevents any single auctioneer from cheating during the auction, but reveals every bid to all the auctioneers once the winner is determined. so this scheme is not fully private, in the sense, that it only ensures that confidentiality of bids until the end of the protocol. Kikuchi, Harkavy and Tygar presented an anonymous sealed bid auction that uses encrypted vectors to represent bidding prices [8]. Harkavy, Tygar and Kikuchi proposed a Vickrey auction, where the bidding price is represented by polynomials that are shared by the auctioneers [15]. Kudo used a time server to realize sealed bid auctions [14]. Cachin proposed a sealed bid auction using homomorphic encryption and an oblivious third [4]. Sakurai and Miyazaki proposed a sealed bid auction in which a bid is represented by the bidders undeniable signature of his bidding price [13]. Naor, Pinkas and Sumner realized a sealed bid auction by combining Yao,s secure computation with oblivious transfer [16]. Juels and Szydlo improved this scheme [2]. Sako proposed a sealed bid auction in which a bid is represented by an encryption message with a public key that corresponds to his bidding price [21]. Kobayashi, Morita and Suzuki proposed a sealed bid auction that uses only hash chains [12][9] . Omote and Miyaji proposed a sealed bid auction that is efficient [18]. Kikuchi proposed an  $M+1$ -st price auction, where the bidding price is represented by the degree of a polynomial shared by auctioneers [11]. Baudron and Stern proposed a sealed bid auction based on circuit evaluation using homomorphic encryption [3]. Chida, Kokayashi

and Morita proposed a sealed bid auction with low round complexity [10]. Abe and Suzuki proposed a M+1-st price auction using homomorphic encryption [1]. Lipmaa, Asokan and Niemi proposed a M+1-st price with out threshold trust [17]. Omote and Miyaji proposed a M+1-st price auction using p-th residue problem [19]. For instant the electronic auction protocols have to guarantee confidentiality, privacy, integrity, non reputation anonymity of bidders. These security requirements are solved by the conception of the protocols using some cryptographic primitives. Achieved these properties correctly is not obvious and an automatic verification is useful to avoid some flows. There are many tools to check formally and automatically the cryptographic protocols [20].

Felix Brandt introduce a new standard of privacy for auctions ( full privacy) that prevents extraction of bid information despite any collusion of participants. His protocol is a verifiable bidder-resolved auction protocol. Shuo Zheng, Luke McAven and Yi Mu proposed another form of bidder resolved auction protocol [22]. Both protocol distributes their trust onto bidders divide their bids into n shares, keep one and send one share to each other bidder [20][5]. Felix Brandt states that the bidders are less likely to share their secrets since they are less likely to share their secrets since they are competing with other. Our protocol is based on the basic idea of n parts of a auction house resolved auction.

## 4 NOTATION AND TERMINOLOGY

- i) Auctioneer -:  $A_M$
- ii) Bidders -:  $B_i$  (  $i = 1, 2, 3, \dots, n$ )
- iii) Sub auctioneer -:  $A_i$  (  $i = 1, 2, 3, \dots, m$ )
- iv) Registration number -:  $ID_i$
- v) Public key -:  $PK$
- vi) Private key -:  $SK$ .
- vii) Digital signature -:  $DSig_i()$
- **Bid close time:** A time after which no new bids are allowed. In an English auction the bid

close time may be fixed or may be defined by a period of inactivity.

## 5 THE FIRST PRICE SEALED BID CRYPTOGRAPHIC AUCTION PROTOCOL

Our proposed sealed bid auction protocol contains four phases: Notification, Bidding, Opening and Winner selection. There are n bidders, one auctioneer and m sub-auctioneer. The role of auctioneer is to organize each auction run and announces the bid result at the end of the protocol run. He receives bids from bidders in a predetermined form and distributes the bids to m sub- auctioneers for the selection of the winning price and winner, then publishes the result. The channels between auctioneer and sub-auctioneers are supposed to be secure and reliable which means all messages transferred between two entities finally reach to the communicating party without compromising. We describe the protocol in details as follows.

### 5.1 Notification

The auctioneer publishes the details of the item for auction. A price vector,  $V = (v_1, v_2, v_3, \dots, v_n)$  is also published. The n prices satisfy  $v_i < v_j$ . The security parameter m,  $2 \leq m \leq n$  is also published. Each party interested in the item downloads the public certificate for the  $A_M$ , which includes the public key  $PK_A$  ( auctioneer public key) and the price vector V.

Every participant is supposed to have a particular identification say registration number to attend auction. Now here we describe a sub-protocol for registration. Each bidder generates a pair of keys ( $SK_{B_i}, PK_{B_i}$ ). To register they submit a note of interest with their own public key certificates, including their encryption and verification public keys. For each bidder  $B_i$ , the seller publishes the certificates and a unique identity  $ID_i$ , simply a non negative integer representing the order in which participants registered. Let N be the number of sub-auctioneers.

## 5.2 Bidding

Each registered  $B_i$  performs following operations:

- Selects a bidding price  $v_j$  from the vector  $V$  and determines  $R_i = H(v_j + Seq)$ .
- $A_M \leftarrow C_i = \{DSig_i(ID_i || R_i)\}_{PK_{A_M}}$  as a commitment of bid.
- Uses the rules below to generate a vector  $V_i = (H(v_j + Seq), H(v_j + Seq), \dots, R_i, v_{j+1}, \dots, v_{n-1}, v_n)$ . If  $B_i$  selects price  $v_j$  then the  $j^{th}$  value in  $V_i$  equals  $R_i$ . Higher indexed positions have the same value as the corresponding position in  $v$ , while lower indexed positions have values  $H(v_j + Seq)$ .
- Divides  $V_i$  into  $m$  shares  $V_{ik}$ ,  $1 \leq k \leq m$  such that  $V_i = V_{i1} + V_{i2} + V_{i3} + \dots + V_{im}$ .
- Each bidder  $V_i$  is send to the auctioneer with identity  $(ID_i + k)(mod N)$ . Then auctioneer each  $V_{ik}$ ,  $1 \leq k \leq m$  is send to the sub-auctioneer with  $(ID_i + k)(mod N)$ .
- Each participant sums all  $m$  parts and submits the result to the auctioneer as  $V'_i$ .

## 5.3 Opening

The auctioneer perform the following-:

- Adds all incoming shares together to recover 
$$V' = \sum_{i=1}^N V'_i.$$
- Evaluates the vector  $W = V' - NV$  and finds the index  $w$  of the first non zero value in  $W$ , reading from right. The highest bidding price is the value  $(V_w)$  from  $V$ .
- Calculates  $B_{id} = W_w - (N - 1)v_w$ .
- Opens all the commitments  $C_i$  and locates the winner who has the same commitment as  $B_{id}$ .

## 5.4 Winner selection

Let  $w$  is the index of the winner. In the full privacy model the  $A_M$  publishes the winners signed commitment  $Dsigs(R_w)$ , so every one can verify whether the revealed  $R$  is the same as that committed to the seller.

In the partial privacy model the seller publishes the winner's price  $V_w$  and also  $Dsigs(ID_w || R_w)$ . The winner is asked to publish the random  $r_w$  chosen to create  $R_w$ , so that each participant can verify the correctness of the result by comparing  $R_w$  with  $H(V_w || r_w)$ .

## 6 SECURITY GOALS FOR SEALED BID AUCTIONS

Sealed bid auctions possess unique security goals due to the fact that bids must be sealed during the bid submission. The following outlines the additional security goals for sealed bid auctions:

- Confidentiality**- Once a submitted bid has been sealed, it must remain secret until the winner determination phase of the auction.
- Unforgeability**- Nobody can impersonate a certain bidder.
- Anonymity**- Nobody including an authority can identify the loser bidders even after the opening phase.
- Non-Reputation**- A winner cannot deny that she/he submitted the highest bid after the winner decision procedure. A winner is exactly identified.
- Fairness**- All bids should be fairly dealt with.
- Efficiency of bidding**- The computational and communicational amount in both bidding and verifying a bid is practical.
- Privacy of Losing Bids**- The winner determination phase, the values of the losing bids must be kept secret. Further questions also arise over how much information is disclosed regarding the winner and winning bid. For example, should only the seller and winner know the

amount of the winning bid? What information should subprotocol the Auctioneer learn about winning/losing bids?

- (i) **Unlink ability**-The Auctioneer should not be able to learn information about individual bidders based on previous auctions conducted. This information could be used in future auctions in a manner that disadvantages the bidder.

Our protocol satisfy all the above conditions.

## 7 Conclusion

Electronic auctions are continuing to grow in popularity, but fraud seems to be a major problem. We presented a secure first price sealed auction protocol, where information is shared among part of the auction house (Servers). Our protocol achieving correctness, privacy, non reputation and efficiency.

# Short Messaging Service (SMS) Based m-Banking System in Context of Bangladesh

Md. Subrun Jamil, Fouzia Ashraf Mousumi<sup>1</sup>

Chittagong Online Limited, Chittagong-4100, Bangladesh.

<sup>1</sup>Computer Science & Engineering, University of Chittagong-4331, Bangladesh.

**Abstract** — m-banking has become one of the most familiar banking service providing technologies in different western countries. Now-a-days billions of inhabitants of Bangladesh are within a network through mobile network coverage. But in the commercial sectors like banking, m-commerce technology has not been adopted broadly yet. Considering m-commerce perspective in Bangladesh a SMS based m-banking system has been proposed which is able to provide several essential banking services only sending SMS to bank server from any remote location. This proposed system is divided into five major phases: Interfacing Module, SMS Technology Adoption Module, SMS Banking Registration Module, Service Generation Module, and Data Failover Module. This system facilitates bank customers by providing four major services like balance enquiry, balance transfer between authenticated customers, DPS payment and bill payment without going to bank physically and save their precious time. At least, after evaluating each module of this developed system a satisfactory accuracy rate 93.18 % is obtained.

**Keywords** — Balance Enquiry, DPS, Data failover, m-banking, SMS

## I. Introduction

The physical world gradually becomes more and more integrated due to the vast development of information and communication technologies. The ICT departments of different modern organizations e.g. Banks, Commercial or non-commercial firms etc are struggling to keep up with the demand for computing, rapid technology changes and the fundamental transformation of work [1]. As a result, the enhancement of Electronic Commerce technologies (E-Commerce) has increased day by day which impacts have been on our economic, social infrastructure E-Commerce brings the universal access of the Internet to the core business process of buying and selling goods and services [2]. Electronic Banking – the execution of financial services of a Bank via the Internet – is one of most appreciable example of E-Commerce. Because it has changed the business of retail banks significantly, at the same time reducing costs and increasing convenience of customer

[3]. Since cellular networks has become an essential component of the economic and social infrastructure of developed and developing countries, a new subset of electronic banking has created, mobile banking (m-banking). M-banking refers that technology which covers account management via mobile devices [3].

Communication purpose email and messaging have become part & parcel of our daily life. But it is true that most of the people of Bangladesh, basically in the rural areas have lack in Internet skills, access to a personal computer and on top of all these, we lack in sufficient Internet infrastructure. But these people of rural areas have a remarkable contribution for earning foreign exchange. Due to the huge advancement of our telecommunication sector, mobile devices have become prominent to every level of people [4]. There are about 1.5 billion people across more than 210 countries and territories, 15 million mobile users in Bangladesh and it is only 10% of our total population. In our country, not only the price of mobile sets gradually reduced but also the cellular operators are providing an acceptable call rate to the subscribers. Even in rural and Chittagong Hill Tract areas, the mobile network coverage has been made available. Day by day's people accepts mobile not only their communication device but also an information transfer media which is highly necessary for their livelihood [5]. Short Messaging Service (SMS) has become the most popular and cheapest service on our mobile phones. It permits us sending message of alphanumeric characters between mobile phones. In Bangladesh the numbers of GSM mobile subscribers are 42.0 million at the end of June, 2008 while the number was 25.39 million at the end of May, 2007. Considering these issues, SMS technique can be integrated in our banking sector. It is the nature of human being to get services within short time. In our country, several private banks have introduced the facilities of online banking, phone banking and at last SMS banking with too limited services. But our nationalized banks i.e. Sonali Bank, Janata Bank, Agrani Banks and other specialized financial institutions like Krishi Bank do not provide such

facilities. A huge amount of people are the customers of these banks.

In this paper, an approach is proposed to develop a system with the integration of SMS technology to automate our banking system which is convenient and hassle free to use. Through this proposed SMS based banking system, a bank customer can be able to get different services only sending text SMS to SMS server while that person is in remote or not been able to attend the bank physically. It saves not only customers time and energy but also gives a mental satisfaction, by giving all updated information about all of his/her banking transactions. The key challenges of m-banking are security, usability and data failover [3]. In our proposed system these key issues are handled significantly.

## II. Related Works and Motivation

The filed of m-banking is not very old. According to the sweeping enthusiasm that characterized much of the news reporting in the years 1999 and 2000 mobile banking should by now have been firmly established as the most important distribution and communication channel for Retail Banking [3]. Dukic and Katic developed such a m-order payment model via SMS for the Republic of Croatia, which give emphasis for increasing security of the user requested information by Steganography method [6]. In developing countries like Iran has been welcomed M-banking. Shinali et al. has developed a system which is capable to be connected through Bluetooth which is installed in the bank and offered banking services. But their developed system, only works within the bank are not from the remote location [7]. Like other countries, in Bangladesh several research works have been done. Mahfuz et al. described in their paper the prospect of using SMS technology as an effective tool in B2E (Business to Customer Commerce) [5]. A. Azi et al. analyzed existing systems for the aspect of developing

Fig.1. The schematic view of our proposed SMS based m-Banking system

countries, focused on limitations and presented alternative frameworks for e-commerce and electronic payments[2].

From the survey on different research work it is found that in western and developing countries - e- banking, M-banking systems are developed according their country perspective. In Bangladesh, researchers found out SMS as m-banking tool, but yet no remarkable standard SMS banking service model has been determined. In this paper we took an attempt to develop a real time banking service specified SMS based mobile banking system in context of Bangladesh.

## III. The Proposed SMS Based m-Banking System

The basic objective of this paper is to develop a SMS based mobile banking system for Bangladesh which is able to provide several current services that are manually provided by our Nationalized and Private Banks. In our proposed system, when a customer sends a SMS of enquiry or service request to bank, the bank server acquires the SMS through modem. Then the SMS server truncates necessary information from SMS and provides corresponding services to customer by retrieving and updating customer accounts related database. In this system, proper tracks have been kept to face any type of data type of data failure problem due to server failure or unusual behavior of system control software. The proposed system is divided into five major modules are as follows: A) Interfacing Module B) SMS Technology Adoption Module C) SMS Banking Registration Module D) Service Generation Module and E) Data Failover Module. Some well defined sequential methods are applied in these modules. The schematic view of the architecture of our proposed system is depicted Fig.1.

### A. Interfacing Module

In this module, we presented an interfacing technique between bank server PC and server mobile for our proposed system. At first GSM modem has been interfaced with Bank server PC by Bluetooth or RS-232C cable using COM or serial port. The NokiaN70, SimensC-35 and Wavecom mobile devices has been used as server modem of our proposed system.

### B. SMS Technology Adoption Module

Short Messaging Service (SMS) is a communication protocol allowing the interchange of short text messages between mobile telephone devices. Most SMS messages are mobile-to-mobile text messages, though the standard supports other types of broadcast messaging as well [8]. The SMS is a store and forward service. In other

words, short messages are not sent directly from sender to recipient, but via an SMS center. Each mobile telephone network that supports SMS has one or more messaging centers to handle and manage the short message [9]. This module describes the process of communicating with the GSM modem which is the most important provider of our SMS service. This process of communication has been done through a number of attention commands (AT). This AT commands makes our bank server modem to be able to send and receive SMS from customers mobile and vice-versa. AT commands are used to control a modem which stands for Attention. GSM /GPRS modems and mobile phones support an AT commands set that is specific to the GSM technology, which include SMS. Table I indicates several common AT commands which are used in this proposed system.

Table I  
List of Several AT Commands

Commands	Description
AT+CMGS	Send SMS Message
AT+CMSS	Send SMS Message from storage
AT+CMGL	List SMS Messages
AT+CMRR	Read SMS Messages

To check the connection between Bank server desktop/laptop computer and GSM mobile/modem, hyper terminals is opened and AT commands are sent. If the modem replies with OK then it can be stated that communication between modem and PC/Laptop are correct. GSM modems can have different AT commands specific of their type but all most all modems supports minimum common commands. The SMS specification has defined two modes in which a GSM/GPRS modem or mobile phone can operate. They are called SMS text mode and SMS PDU (Protocol Data Unit) .Usually string values are defined for text mode while numeric values are defined for PDU mode. We used PDU mode as it supports more features than text mode like it includes detailed Meta information with the raw SMS like actual SMSC number, time stamp, and length of the actual message in hexadecimal. With the help of J2EE and XML for sending and receiving SMS from bank server software to customer mobile an SMS server has been designed. In Fig.2. the interface of the bank server software for the activation of SMS server which is adopted throughout this SMS technology adoption module is represented.

(a)

(b)

Fig.2. The interface of bank server software (a) SMS server activation and (b) tracing window during modem connection establishment

### C. SMS Banking Registration Module

To activate the SMS based m-banking system and getting its facilities, the customers have to be registered according to our proposed model. For this, at first the bank server modem broadcasts SMS giving a notification of their SMS based M-banking service. When a customer wants to register for this service he/she has to send SMS to bank with account number and password. Through the server modem the required information is truncated automatically from the customer SMS and stored in bank's central database. If the account number of the customer is valid, then that customer has been registered for all time and server sends a positive acknowledgement. In Fig.3. a customer registration request process is shown.

Fig. 3. The SMS request for registration from remote customer mobile

### D. Service Generation Module

Service generation is the most important module of our SMS based banking module. This module composed of four services: Balance Enquiry, Balance transfer between authenticated account holders, DPS utility and Bill Payment. For getting these services a customer of bank must be registered and have to send SMS in pre-specified format. In case of Balance Enquiry service, when a customer sends a SMS for checking current account balance, the bank server modem replies through SMS with balance information. But before replying to customers, the authentication procedure is

performed by matching his/her registered mobile number and password.

The next service of our system is balance transfer only between pre-authenticated account numbers of the same bank that are specified by the account holder. This authentication has been done automatically by extracting related information from customer SMS and matching with bank's central database. In our system, after the transaction, concurrent balance update of both account holder have been done automatically and the bank server sends updated account status to both account holders.

Another effective service of this system is deposit payment. This service gives alert to the deposit account holder before one week of his/her deposit amount payment deadline.

In Bill Payment Service different payment types such as mobile bill payment, electricity bill payment etc are implemented. Before paying bills, the status of current balance of the customer have been checked in parallel with registered mobile number. The whole system working procedure is represented by a flowchart in Fig. 4.

### E. Data Failover Module

The data failover module is the most essential and a new inclusion of our SMS based M-banking system. We have developed an algorithm for overcoming the data failure which can be occurred due to bank server failure during the customer SMS information processing. According to this algorithm if server fails on the halfway of a SMS request processing, at first server stores that message with a not processed flag like NO. Then another flag counts the number of total unprocessed SMS. When server again restores, the first unprocessed SMS request is processed and reply is sent to the customer. Then check for other unprocessed SMS and process one by another. Thus this system overcomes the difficulties in case of SMS data failure due to server unusual failure.

#### IV. Experimental Results and Analysis

For our proposed system, application software has been implemented using J2EE and XML. This application software will be installed in the Bank Server PC which contains the banking database of customers. This central Banking database contains all related information of customers for SMS banking facilities. The accuracy of the system is measured by testing major modules with a set of real time SMS data. The accuracy of the interfacing module is tested in case of both wireless and guided media. The success this module is 90.78% and failure rate is 9.22%. And from analyzing the output it has been found that, the SMS

delivery and receive will not hamper while interfacing media has been changed. We have also tested our interfacing unit using different types of modems as shown in Table II. Similarly SMS Technology Adoption Module, SMS Banking Registration Module, Service Generation Module, and Data Failover Module are evaluated by 300 short text SMS using the following equations:

Success Rate = (Total no of Success/ Total no of sample input)\*100) %. Failure Rate = (100 – Success Rate) %

Accuracy Rate = (100 – Failure Rate) %

Table II  
Experimental results of interfacing module

Server Modem Name	Interfacing Media (Between Server PC & Modem)	No of SMS Delivery & Reception	Successfully Delivered & Received	Success Rate	Failure Rate
Nokia N70	RS232C Bluetooth	50 50	47 47	94%	6%
Siemens C35	RS232C	30	28	93.33%	6.67%
Wavecom	RS232C Bluetooth	40 40	34 34	85%	15%
Average				90.78%	9.22%

Table III  
Result of overall SMS based m-Banking system success and failure rate

Modules	Success Rate	Failure Rate
Interfacing Module	90.78%	9.22%
SMS Technology Adoption	91.58%	8.42%
SMS Banking Registration Module	95.89%	4.11%
Service Generation Module	94.66%	5.34%
Data Failover Module	93%	7%
Average	93.18%	6.82%

## V. Conclusion

In today's busy environment, with so many deadlines to fulfill, appointments to keep and meetings, customers of a bank have little time to visit a branch or to wait for customer services operator to come on phone line. Though SMS Banking in Bangladesh has just been started but this telecom integration with Banking is not yet in full motion. So in this paper, an attempt is taken to develop a SMS based mobile banking system for 24 hours banking convenience which helps customers stay on top of any recent changes made in their current or deposit account through Short Messaging Service (SMS). One of most attractive feature of our proposed banking system is that balance transfer from one account to another of different branches of same bank without attending the bank physically. This system not only warns the customer deposit holders to pay their premiums in due date but also provides the track to pay this deposit premium by sending SMS in a pre-defined format from remote. Through our proposed system, customers would not face problems due to server failure while the server was in processing with customers SMS. Because if bank server become out of order due to some accidental causes, a track of data failure has been kept to handle this situation. In future we have a plan to add more services in our proposed system to enrich flexibility, usability and security of the proposed SMS based system accordance to Bangladesh perspective.

The whole system performance rate is measured by evaluating each module success or failure rate which is depicted in Table III. The overall system accuracy rate is obtained 93.18%.

# A study of major Mobile payment systems' functionality In Europe

Shahriyar Mohammadi, Hediye Jahanshahi

IT GROUP-Faculty of Industrial Engineering-K.N toosi University of Technology

**Abstract** — Mobile payment is an exciting domain, which will rapidly evolve in the years to come. The key to mobile payment acceptance is in the hands of customers. In this paper first some of the major European mobile payment systems are introduced and evaluated base on security, cost, convenes and functionality requirement criteria, then the results of past researches about the customer and merchant adoption of mobile payment systems (mp) are reviewed and barriers and drivers from both customer and merchant view are compared. Here by, this paper tries to find shortcomings in major mp systems and presents the major barriers and drivers to wide spread adoption of mobile payment from both customer and merchant point of view.

**Index Terms** — mobile Payment system ; Customer adoption ; Mobile commerce.

## I. INTRODUCTION

With the flourishing of electronic commerce and widespread use of mobile devices, a new type of service is emerging that extends e-business using wireless technology by enabling e-commerce services on mobile devices [1]. Mobile payments are payments for goods, services, and bills with a mobile device (such as a mobile phone, smart-phone, or personal digital assistant (PDA)) by taking advantage of wireless and other communication technologies [2]. The key to mobile payment acceptance is in the hands of customers [3]. The most important problem to broad acceptance and usage of an mobile payment (MP) procedure is the obtainment of a critical mass. This tends to be an hen-egg-problem: On the one hand customers will not use the procedure unless a significant number of merchants accepts it, on the other hand merchants will not be willing to accept the procedure unless a significant number of customers uses it [4].

## II. MP PROCIDURES

We A MP transaction can take place in four different general settings, distinguished with regard to the point of sale or service [5]:

- The mobile commerce scenario (MC): New applications and services, e.g. context-sensitive information or video/audio streaming on mobiles

- The electronic commerce scenario (EC): All kinds of B2C and C2C excluding MC, e.g. purchase of goods or content via the Internet

- The stationary merchant scenario: "Bricks and mortar" commerce with transactions between a person (customer) and a person (e.g. cashier, taxi driver) respectively or a machine (e.g. vending of tickets, cigarettes)

- The customer-to-customer scenario (C2C) : Money transfers between individuals, e.g. for settling an E-Bay transaction, as pocket-money for children, for settling debts for small amounts

### A. Customer requirements to MP procedures

MP procedure will be widely accepted by customers if it [6]:

- covers all payment scenarios,
- ensures confidential treatment of data,
- issues payment confirmations via SMS or e-mail,
- incurs none or little costs for customers,
- does not oblige customers to buy a new mobile device,
- easy to handle and responds quickly,
- accepted by a high number of merchants suitable for the execution of bank transfers,
- Suitable for Pico payments (amounts below 20 cents).[6]

At present, there are many examples of successful mobile payment applications such as the mobile content market which has developed into a billion dollar business, PayPal. Wider adoption of mobile payments, however, has not been as rapid or widespread as expected and there is a long list of discontinued mobile payment services such as the Simpay initiative and the Paybox launched in several European countries[7]. There is some debate about types of m-payments. Some parties see m-payments as a new product, whilst others see m-payments as a new service [5]. The European Central Bank categorizes m-payments as m-payments, a new payment initiative that is accessible via mobile phones. The funds, defined as electronic money (or e-money), "an electronic store of monetary value on a technical device that may be widely used for

making payments to undertakings other than the issuer without necessarily involving bank accounts in the transaction, but acting as a prepaid bearer instrument,” are used to pay for products and services [5].

### III MOBILE PAYMENT SYSTEMS IN EUROPE

In this section, we briefly describe some of the MP systems in Europe, Pousttchi and zenker[6] uses a frame work and evaluate 3 main mp procedures in Germany. Factors in their frame work are: “Applicability in all scenarios”, “security”, “cost”, “convenience” and “special functionality requirements”. “security “ includes not only integrity, authorization, authentication, confidentiality and non-repudiation of transactions, but also the issue of subjective security from the customer’s perspective, “costs” includes direct transaction costs and fixed costs of usage plus the cost of the technical infrastructure for the customer (e.g., a new mobile phone), “convenience” includes any issues related to ease and comfort of use[8] . in this paper their frame work was used to analyze mp system in Finland, Germany ,Serbia and compare their functionality, then try to analyze the current deadlock on the mobile payment market in order to develop a set of requirements to an integrative solution for a Mobile Payment System .

#### A. FINEID in Finland

The Finnish electronic identity (FINEID) card along with the supporting infrastructure [1] is a system maintained by the Population Register Centre (PRC) of Finland. The card is a usual microprocessor smart card accepted as a valid ID in all EU countries and several others. The card contains two Citizen Certificates: the authentication certificate of the card holder and the signature certificate of the card holder. Private keys of both certificates are generated by the card and stored exclusively in its protected memory.

**Security:** The Finnish National PKI infrastructure, which is used in FINLAND mobile payment system for authenticating users and for ensuring the non-repudiation of payments. Signatures produced by the FINEID card are legally equivalent to the card holder’s handwritten signature .Additionally, the card contains the PRC’s own Certification Authority (CA) certificate. **Cost:** A mobile subscription customer can request a FINEID compatible PKI-SIM card from their mobile network operator and register it at a police station. Authentication cannot be done without the participation of the mobile network operator, and naturally, operators charge both customers and service providers for authentication. Apparently, this is a major threshold for joining the system

**Convenience:** The current implementation of FINEID on SIM cards is based on a platform developed by SmartTrust The advantages of the SmartTrust platform include its compatibility with almost any GSM mobile phone, and the availability of all the infrastructure needed. Each registered individual gets a unique Finnish Electronic User ID (FINUID). The public keys of each user can be downloaded via a search with the appropriate criteria. Moreover, a revocation list of invalid certificates is available from the FINEID directory [1].

**Functionality Requirements:** FINEID certificates are only available to Finnish citizens and those permanently living in Finland. At the moment, a legal entity such as a merchant or a bank cannot obtain a FINEID certificate[1].

#### B. DINA Card in Serbia

The National credit card, DinaCard, is being issued by almost all banks in `Serbia. That gave a possibility for connecting existing mobile payment system to one point, National center for payment cards (further NCPC), instead of connecting it to each bank separately, which is on the other side connected to all the banks that are issuers of DinaCard. This will give opportunity to many users who didn’t have a chance to use SMS top up, because their banks didn’t have an agreement with mobile operator, to register and start using the service. the system covers Ec ,MC and POS scenario.

**Security:** All the files that are exchanged between NCPC and core of the system are encrypted by file secure program and smart card reader. Encryption and decryption is done by authorized personnel. Personal data about registered users are firstly checked by the bank and NCPC, and then imported automatically into the core database, in order to minimize the possibility of error during manual import. When new user is imported for the first time, mPIN is generated and sent to his registered mobile phone number via SMS. In the database, mPIN is stored in encrypted form, and there is no possibility to view it.

**Cost:** Mobile payment services can be enabled to all

Subscribers of mobile network operator who are owners of DinaCard ,Registration process starts in the bank that issued DinaCard.

**Convenience:** Interface to applications is unified for all types of services. It is based on http and has several methods that can be used in order to realize payment , Single mPIN is used for all defined services and accounts. Mobile payment services are enabled to the user from the moment mPIN is received.

### *C. Mobile Payment systems in Germany*

#### *a. Pay Box*

The most well-known MP procedure in Germany is Paybox. The operator of the procedure was a technology driven payment startup which falls in the category of specialized intermediaries. Having started in May 2000 the service was the first mover in its field. Pay box acted not only as a payment intermediary, but also actively acquired merchants and offered them the technical solution to integrate Pay box in their systems. Within 3 years Paybox enrolled more than 500,000 customers and 6,500 merchants. Payments were authorized using IVR (Interactive Voice Response)[9].

The particular way of authenticating payments imposed restrictions on the use of Paybox within the MC scenario. For example, Paybox could not be used for WAP services since the customer during a WAP session could not be called to conduct the authorization. Paybox was especially targeted to the stationary merchant and EC scenario.

**Security.** The confidential treatment of data was vouched for by Paybox. For the confirmation of payments a number of options were supported depending on the kind of transaction and on the payment scenario, including SMS and e-mail.

**Cost:** The annual basic fee was 10 €, transaction fees did not exist. As it can be assumed that an important part of customers enrolled with a 50-100% discount on the basic fee, the high number of customers does not allow any inference on the acceptance of high basic fees. Paybox could be used with any mobile phone. Thus preliminary costs were low and facilitated customers' participation.

**Convenience:** The procedure was easy to use and understand as the customer only had to know his MS ISDN and could rely on the IVR system to guide him through the transaction or authorization process. Customer experience in the handling of voice-based transactions afforded Paybox the reputation of an easy-to-use and subjectively safe system. Fast processing of transactions was possible, costs were low and facilitated customers' participation[6].

**Functionality Requirements.** Bank transfers through Paybox were possible. Pico payments were technically possible yet not efficient since costs for the used debit procedure and the system's call-back function tended to outweigh transaction amount.

#### *b. I-mode*

The inherent payment procedure of i-mode is an MP procedure that can only be used within the i-mode MC platform. The MP procedure is limited to the MC scenario, e.g. to pay for news or the purchase of tickets.[8]

**Security.** Responsibility for both the confidential treatment of data during payment procedures and the safe handling of customers' data lies with E-Plus. Customers have confidence in the well-known MNO EPlus. Thus, its reputation enhances a feeling of security in customers and the criterion of subjective security is satisfied. Confirmation of payment is handled via a special confirmation page displayed on the mobile device.

**Cost:** The payment does not generate additional transaction fees for customers. I-mode itself can only be used if an E-Plus customer both subscribes to i-mode (monthly basic fee, minimum 5 €) and purchases a special i-mode mobile phone. Subscribers from competing MNO are excluded from the service[6].

**Convenience:** The i-mode MP procedure is easy to use and understand. Payment-related data as a rule do not have to be entered. Thus, the extent of customer experience necessary to handle the system tends to be very low.

**Functionality Requirements.** The requirement of a capacity for the execution of a bank transfer is only partially met. Pico payments can be easily performed since these can be aggregated.

#### *c. Vodafone m-pay*

The latest MP procedure of the three is Vodafone m-pay Which is Devised for the MC scenario but also usable in EC, it can up to now handle payments up to a maximum of 10€ (although this is a deliberate restriction in order to gain experience with the procedure).

**Costs.** The use of m-pay does not entail extra costs for customers, i.e. there are neither basic nor transactions fees. This includes even the SMS being sent by the payment server within the EC scenario. Purchase of a special device other than a WAP-enabled phone is not required.

**Security.** Security requirements like the confidential treatment of data are met. No payment-related data are transmitted from customers to content providers or merchants during the transaction, since these data have been stored by the payment server and used only internally.

**Convenience.** M-pay is basically easy to use and understand. Duration of payment procedures is similar to that of i-mode within the MC scenario and thus comparatively low. In the EC scenario the procedures take slightly more time since the forwarding and entering of a TAN is required. As far as merchant participation is concerned, m-pay is – up to now - at a great disadvantage.

**Functionality Requirements.** As with i-mode the regular MNO billing system is used to process payments. The requirement of a direct bank transfer is met only partially. Picopayments pose no problem since the procedure has been specially designed to enable those[8].

#### d. Rating of current Germany MP procedures

Pousttchi and zenker evaluate mp systems In Germany by a questionnaire based research and base on customer perspective. Base on Pousttchi and zenker research [6] None of the mp procedures in germany reaches the top score since various shortcomings detracted from the procedures' effectiveness. It is apparent, however, that each carries a burden that might deter customers from usage: Paybox' lack of payment in the MC scenario, i-mode's inability to cover scenarios others than MC and the insufficient number of merchants and content providers for m-pay[8] . Because of not accessing to user of mobile payment in Serbia and Finland we couldn't held a questionnaire based survey like the one in [6] and find real evaluation base on customer perspective. but base on our library research We did not find an "ideal type" and do not believe that we will see one in the future.

#### IV. THE PROPOSED CRITERIES OF MP THAT CAN MEASURE CUSTOMER OR MERCHANT SATISFACATION

Roger's Diffusion of innovations [10] is multidisciplinary theory frequently applied in IS adoption research. Empirical research has supported the applicability of the diffusion theory in predicting the adoption of various information systems such as spreadsheets, WWW and operating systems .The diffusion of innovations theory has also been widely used to explain the adoption of a variety of financial and mobile technologies including smart cards, mobile commerce and mobile banking[7] . This paper explores customer and merchant adoption of mobile payment base on a frame work which is based on diffusion of innovation theory:

##### A. Compatibility

Compatibility captures the consistency between an innovation and the values, experiences, and needs of potential adopters . In IS adoption research, the compatibility of the technology has commonly been assessed in relation to the potential adopter's work and tasks .Regarding payment systems, the consumers' ability to integrate them into their daily life is an important aspect of compatibility . Compatibility has been found as a significant determinant of mobile technology and service adoption.

TABLE I  
EVALUATION OFS MP PROCEDURES ON THE GERMAN MARKE  
BASE ON CUSTOMER VIEW [3]

	Pay-box	i-mode	m-pay
<b>Scenarios (0-6)</b>			
MC scenario	1	2	2
Stationary merchant scenario	2	0	2
EC scenario	2	0	2
<b>Security (0-4)</b>			
Confidentiality of data	2	2	2
Confirmation via SMS or e-mail	2	2	2
<b>Costs (0-4)</b>			
None or low costs	1	2	2
No Purchase of a new device	2	0	2
<b>Convenience (0-3)</b>			
Easy handling	1	1	1
Fast processing	1	1	1
Accepting merchants	1	0.5	0
<b>Functionality requirements (0-1)</b>			
Bank transfer possible	0.5	0.25	0.25
Payment < 20ct possible	0	0.5	0.5
<b>Sum (max. 18 points)</b>	<b>15.50</b>	<b>11.25</b>	<b>16.75</b>

##### B. Complexity

In the diffusion of innovations theory, complexity is determined as the "degree to which an innovation is perceived as difficult to understand and use" [10].Complexity and problems with usability have contributed to the low adoption of a variety of payment systems, including smart cards and mobile banking [7]. Mobile payments are commonly expected to increase consumer convenience by reducing the need for coins and cash in small transactions and increasing the availability of payment possibilities [8].Limitations in mobile device features, however, diminish the usability of mobile technologies. Typical limitations include small keypads, limited transmission speeds and memory, and short battery life.

##### C. Cost s

In traditional adoption research, the cost is incorporated in the relative advantage construct .but In recent studies , cost is treated as a separate factor to clearly differentiate it from the relative advantage of time and place independence. Kim[6] found that the perceived fee has a significant effect on the perceived value of mobile Internet. Perceived service cost has also been found as a significant determinant for the intention to use wireless

financial services ,mobile banking ,and mobile commerce transactions .

*D. Network externalities and critical mass* Network externalities are considered as a relevant factor in mobile payment adoption Because payment technologies exhibit indirect network externalities. Failure to create critical mass has impacted the continuance of several previous payment systems .Mobile payments represent a new payment network in the market. A consumer's decision to adopt the network is significantly affected by the amount of merchants using it, since that amount determines the opportunities for consumers to use the new payment service. New consumers adopting the network indirectly increase the value of the network for all consumers because they attract new merchants to join the network[7]

#### *E. Security and trust in mobile payment systems*

The importance of trust is highlighted in electronic and mobile commerce because of the spatial and temporal separation between buyer and seller when buyers are required to give delicate personal information such as telephone number or credit card number to the seller[7] .Consumers' concerns about the privacy and security of mobile payments are commonly related to authentication and confidentiality issues as well as to concerns about secondary use and unauthorized access to payments and user data.

### V. CRITERIA'S IN CONJUNCTUION WITH CUSTOMER AND MERCHANT VIEW

#### *A.. Criteria's in conjunction with customer view*

The findings suggest that the relative advantage of mobile payments is related to the specific benefits provided by the new mobile technology; time and place-independent payments, remote and ubiquitous access to payment services, and the possibility to avoid queuing and to complement cash payments. Furthermore, the findings indicate that the relative advantage becomes more important in certain use situations including the presence of queues, an unexpected need to make the payment, time pressure, and lack of cash or loose change. The most compatible application areas for mobile payments include electronic ticketing, purchases on vending machines, mobile content and services, and payments at POS. Factors found to prevent mobile payment adoption include complex solutions, premium pricing, low adoption rates, perceived risks and perceived incompatibility with large value purchases. These findings suggest that in order to

create volume, mobile payments need to be better integrated with existing financial and telecommunication infrastructures. Proprietary systems with exclusive service providers and infrastructures are not likely to be successful in the long term. Instead, compatibility with consumers' existing services and common standards between different

TABLE II  
DRIVERS FROM CUSTOMER VIEW POINT

Adoption factor	Drivers
Relative advantage	• Time and place independent payments     • Queue avoidance     • Enhanced payment instrument availability     • Complement to cash
Compatibility	• High with digital content and services     • High with small value purchases at POS
Complexity	----
Cost	----
Network externalities	----
Trust and security	• Trust In merchants     • Trust In telecom operators     • Trust In financial institutions

service providers could facilitate adoption[9] . barriers and drivers from customer view point are shown in table 2,3.

#### *B. Criteria's in conjunction with Merchant view*

several barriers are defined to merchant adoption, most clearly in four categories: relative advantage, compatibility, complexity and costs[11].form merchants point of view , Existing mobile payment systems are perceived to be compatible with small value purchases of digital content and services, but lack of technical standards as well as incompatibility with current business practices are considered as significant barriers to more wide-scale adoption of mobile payments. Furthermore, existing solutions are still perceived by most as too complex and difficult to use[9] . premium pricing has prevented the adoption of mobile payments in both merchant and consumer side[9]. ]Payment service providers should price the upcoming solutions competitively so that their provisions would be similar to credit card provisions. The cost of a transaction for\consumers should be independent from the payment method. Costs of the payment solutions

TABLE III  
BARRIERS FROM CUSTOMER VIEW POINT

Adoption factor	Barriers
Relative advantage	----
Compatibility	• Low with large value purchases
Complexity	• Complex data input formats, codes, service Numbers     • Management of separate accounts burdensome     • Complex registration procedures
cost	• Premium pricing &amp; high transaction costs
Network Externalities	• Lack of wide merchant adoption     • Proprietary devices/services
Trust security	• Unauthorized use     • Transaction errors     • Lack of transaction record and documentation     • Vague transactions     • Concerns on device and network reliability     • Concerns on privacy

are still a significant barrier to adoption for the merchants. Security and service provider trustworthiness are essential Requirements in all service relationships and their importance is highlighted when the service involves monetary transactions. The interviewees stated that the reliability of the technical solution and trustworthiness of the payment service provider are essential factors affecting

the payment solution adoption. Merchants and service providers were of the opinion that the role of mobile payment provider would be most suitable to banks and large telephone operators. The security issues were not, however, as important barriers as the issues related to network externalities and costs [9].

#### *C . Comparison of drivers and barriers for mp adoptin from merchant and customer view point*

In this paper barriers and derivers found in [7],[8] and [11] are compared. The main barriers form but customer and merchant view exist in cost, compatibility and complexity criteria's .Also derivers are in Trust and relative advantage domain. both groups trust on payment service providers and mobile network operators and

believe they are trustworthy .it seems that security is yet a barrier for customers . Also both group think that mobile devices are secure and suitable for payment.

#### VII. CONCLUSION

The contribution f this paper can be divided n t three sections: At first This paper analyzed some of the major mobile payment systems in Europe based on five criterion: Scenarios, Security, Cost, Convenience and Functionality Requirements. Seond After survieing the mobile payment systems in finland,serbia and germany (3 cases) the paper contributes to a frame work consists of 6 cirteries. The criteries can be used for evaluating mp system adoption by customers and merchants. Third ,the paper introduces some of the major drivers and barriers that can be effecting on customer and merchant adoption Combination of more detailed survey and using simulations, importance of the mentioned criteria's individually as well as their importance in related to each other can be evaluate

## The opportunities and challenges of using ICT by State Owned Enterprises in Bangladesh: Case of SOEs under Privatization Commission

Ahsanullah M Dewan<sup>1</sup>, Saifullah M Dewan<sup>2</sup>, Shams Ara Nazmin<sup>1</sup>

<sup>1</sup> East West University, <sup>2</sup> University of New South Wales, Email: amd@ewubd.edu

**Abstract** — The potential contribution of information and communication technology (ICT) to increase the productivity of State Owned Enterprises (SOEs) in developing countries has long been recognized. However, the realization of this potential has been problematic and over recent years there have been a number of initiatives supported by government, non government and foreign agencies which have endeavored to aid and encourage the up take of ICT to enable access to such promised benefits. Despite strong theoretical arguments suggesting that ICT has much to offer to SOEs, the study would seem to suggest that use of ICT by SOEs listed under Privatization Commission is still in its infancy. It also identifies some significant barriers which are impacting upon the level of ICT adoption amongst SOEs, and confidence on ICT of the SOEs in Bangladesh. This paper is based on the study conducted as part of the IDA funded Enterprise Growth and Bank Modernization Project and explores the opportunities and barriers of using ICT to provide a necessary lever to enhance competitiveness and productivity of SOEs in Bangladesh.

**Index Terms** — ICT, e-business, SOE

### I. INTRODUCTION

The prospect of using information and communications technology (ICT) to improve the competitiveness and productivity of state owned enterprises (SOEs) has long been recognized world wide. Despite the recent initiatives by the government, non government and foreign agencies to aid and encourage the up take of ICT to enable access to such promised benefits, the study suggests that the use of ICT by SOEs listed under Privatization Commission is still in its infancy. One of the factors that have been identified as impacting upon the level of ICT adoption amongst SOEs is access to, and confidence of the management on ICT. Climbing the technological ladder does require skills upgrading through explicit learning in the new technologies.

Privatization in Bangladesh has gone through various phases since its Independence. Just after the war of Independence in 16 December 1971, the Government had to step in to fill the vacuum in economy as the then-owners, abandoned their properties and left the country. In addition, the nationalization policy of March, 1972 of major industries like Jute, Textile, Chemical and other basic industries, DFIs, Banks and Insurance etc. brought

into fold nearly 90% of such enterprises under Government control. However these public sector enterprises right from inception could not run profitably and efficiently and many of them ran into severe financial difficulties and serious management problems. By end of 1975, the Government began to reverse its policy of nationalization due to the heavy burdens created by the public sector enterprises on the national exchequer. During the period 1976-1992 about 500 SOEs had been sold or returned to their former owners.

The Privatization Commission which came into being in March, 1993 is entrusted with the overall responsibility of privatizing State-Owned Enterprises identified for privatization, whether small, large, profitable or non-profitable. The Commission is now headed by a Chairman with the rank and status of a State Minister to the Government. The Commission has been placed under the administrative jurisdiction of the Cabinet Division which is headed by the Hon'ble Chief Advisor. Ministries having SOEs under their control have either set up or in the process of setting up Privatization Cells for assisting the Privatization Commission in identifying, preparing, processing, implementing and monitoring SOEs for privatization. Since the creation of Privatization Commission as the special agency in March, 1993 by the Government to implement the program of divestiture of SOEs, till to-date 74 SOEs have been privatized so far. It is worth mentioning that 25 more SOEs have been handed over to Privatization Commission for privatization as well. Moreover, decisions to off-load the shares of some public limited companies have also been taken [1].

Due to the ICT's capability to transfer, collect, manage a great amount of information and to reduce the distance and time barriers new opportunities could well take in place both to create new ventures and to modify the existing businesses. Therefore, SOEs may reduce the transaction costs of information-intensive activities by resorting to ICT. These opportunities may especially favor SOEs that in most cases operate in a dense inter-firm relationship and need to manage a great amount of information.

SOEs performance is highly associated with learning capabilities, level of technology, firm-level knowledge, skills and experience. The successful adoption of ICT tools is likely to enhance individual SOE's productivity

in sectors such as electronics and general machinery. In the more traditional sectors such as jute and textile, there is a propensity for significant rise in product quality and more precise processing. To achieve the goal of better quality products, SOEs should undertake greater training and investment in skills and knowledge upgrading [2].

This paper explores the potential of ICT to provide a necessary lever to enhance competitiveness and productivity of SOEs in Privatization Commission's consideration. The paper in particular addresses issues related to: the opportunities of using ICT applications in the value-creating processes for SOEs, and challenges in adopting these ICT tools by the SOEs in Bangladesh.

## II. CLASSIFICATIONS OF ICT TOOLS

The widespread adoption of ICT worldwide has given rise to an increasing number of studies on this field recently. These studies have dealt with different and complementary aspects, such as: potential effects of ICT on the organizations, the inter-organizational relationships, the market, and the social-economic systems; ICT classification; analysis of the organizational and managerial actions required to support the ICT adoption; and interpretation of the enabled opportunities [3] [4] [5] [6].

ICT tools have been classified and distinguished into several ways where each one is based on different and complementary aspects of ICT. Independent of their classification, thanks to the capabilities of reducing the time and costs of processing and communicating information; storing and elaborating great amount of data and information; organizing and structuring data and information on the basis of the user needs, ICT tools can allow data, information, experiences, and the knowledge owned by individuals and organizations instantaneously available and enable easier sharing. ICT tools in this paper have been classified as follows:

- Integration tools: to help in the integration and coordination of the processes supporting the information transfer (LAN, WAN, database, shared elaboration systems, data modeling support systems, information flows modeling support systems, CASE, group working support systems, EDI, groupware, Internet, ERP, DSS, CAD etc.);
- Knowledge management tools: to support the processes of problem solving and organizational learning, as well as the relationships and integration among individuals and among different organizations (Lotus Notes, software agents, groupware, Internet).
- Process tools: to concur in the transformation of the inputs in output (Dedicated software).

The main capabilities of ICT tools and the related advantages of these tools on the organizational processes are as follows [3] [7].

TABLE 1 - ICT CAPABILITIES AND ADVANTAGES

Capability	Examples of ICT Tools	Advantages
Analytical	Dedicated software, workstations	To bring complex analytical methods to bear on a process
Automational	Artificial intelligence, CAD, EDI, search engine	To replace or reduce human labor in a process
Geographical	EDI, Internet, Intranet, videoconferencing, tele network	To allow an easy and fast information transfer between large distance, making processes independent of geography
Interactivity	CAD/CAM, EDI, Internet, Intranet	To connect parties that would otherwise communicate through an intermediary
Knowledge management	Artificial intelligence, groupware, shared databases, data mining, videoconferencing	To capture and dissemination of knowledge and expertise
Multimedia	Videoconferencing, audio-conferencing, search engine	To deal with and deliver a great amount of information expressed in several ways: graphics, sound, video
Sequential	Groupware technology, shared databases, Internet, Intranet	To enable changes in the sequence of tasks in a process, often allowing multiple tasks to be worked on simultaneously
Tracking	Artificial intelligence, CAM, sensors, Internet-based applications	To allow the detailed tracking of task status, inputs, and outputs
Transactional	Artificial intelligence, dedicated software, groupware technology	To transform unstructured processes into routinized transactions

### III. ICT AND VALUE CREATING PROCESS FOR SOEs

The adoption of ICT by the SOEs can improve the performance of the organizational and inter-organizational processes and, as a consequence, of the value-creating processes. ICT can follow the existing system of inter firm relationships to implement and automate a number of activities involved in the value creating processes carried out across the supply chains, such as vendor seeking, ordering, inventorying, delivering, co-design, etc [8]. The effects of the ICT on three main value-creating processes, namely marketing and customer relations; logistic and networking; and innovation and knowledge management are analyzed in the following.

#### A. *Marketing and customer relations*

The global spread of the Internet and the 24 hour availability of web server have created time and geographical independence and enable customer service to be decoupled from supplier availability [7]. Overcoming the geographical constraints and creating time independence, ICT enable the SOEs to get access, promote and sell goods and services (e-commerce) in a global market. Dealing with and delivering great amount of information in different ways (text, graphics, sound, video), ICT enrich the opportunities for the promotion of goods and services and for the provision of in-depth information.

The new intelligent agent software helps to identify the customer profile (taste and characteristics) and the pattern of purchases. All the information can be easily organized and stored in a database that supports customer service, marketing, and new product development processes. Web technology and the related online trading models (business-to-business and business-to-consumer) provide supplier assets and customer benefits, namely lower transaction costs, better prices, reduction of time to market, affirmation of brand image, market share and access to markets, customer orientation, customer choice increasing, and customer-driven design. Supporting application-to-application as well as person-to-person and person-to-application interactions, ICT allow the direct interaction and continuous links with customer. This in turn provides opportunities for better targeting goods and services. [7] [9]

#### B. *Networking and Logistic*

The impact of ICT on networking processes is due to three main effects: (1) the electronic integration effect, (2) the electronic communication effect and (3) the electronic brokerage effect [9]. The electronic integration effect allows suppliers and procurers to create joint, inter-penetrating processes at the interface between value-adding stages. This effect is due to the combination of different ICT capabilities, such as tracking, sequential, and automational, which enable to

link one activity with the others and make real time data created in one activity available both within the company and with outside suppliers, channels, and customers [11]. ICT allow the supplier and the procuring SOE's inventory management processes to be linked, reducing total inventory costs; the connection between sales activities and order processing as well as manufacturing processes and inventory levels of multiple suppliers, optimizing the supply chain; the integration of the new product development phases carried out in different teams or organizations; and check the status of a payment or a shipping process.

Due to the possibility of communicating more information in the same amount of time decreases the costs of communication, making communication independent of the geographical proximity. This means that ICT enable the SOEs to enrich the content of the information transferred within a client-supplier relationship in the global market. As an example, ICT (CAD/CAM with Web) can support the exchange of complex product models among parties located far away [11].

The electronic brokerage effect is due to the possibility of creating an "electronic broker" that electronically connects a large number of potential buyers and suppliers through a central database, filters the different alternatives, and helps to match one party to the other, thereby reducing the need for buyers and suppliers to contact a large numbers of alternative partners individually. Thus, ICT (Internet, software agents, databases, search engines, etc.) increase the number of alternatives that can be considered, increase the quality of the alternative eventually selected, and decrease the cost of the whole selection process [10]. Low cost and fast expansion of the number of relationships enable the development of new business models based on networking processes, for example, online auction of the machineries of SOEs.

#### C. *Innovation and knowledge management*

The ICT tools supporting knowledge management (i.e. groupware, videoconferencing, Internet, Intranet etc.) are basically aimed at facilitating the inter-connection and integration among individuals through the fast and effective exchange of information and knowledge. SOEs can use the digitization to transmit information, avoiding the contents' modification. The knowledge management technologies allow interactive communication. Besides, thanks to the virtual abolition of the distance, the communication of such kind of knowledge, which has been always limited within a bounded territorial system or a business unit, can now spread in meaningful way. ICT tools can also be used in the new product design and development. It may shorten the development cycle, increase number of alternative designs considered, reduce development costs and produce higher quality products [10].

It is argued that the customers contribute greatly to the development of new products. Listening to the customers and, beyond that, engaging them in a dialogue and listening to their comments on the products are important means of obtaining input for sustained innovation. To that end, SOEs may regularly use, besides traditional means, e-mail response addresses, FAQ lists, discussion forums and online questionnaires. Information for innovation can also be obtained by monitoring online the customer behavior (by tracking visits & downloads) [11] [12].

#### IV. E-BUSINESS MODELS FOR SOES

The adoption and implementation of ICT tools allow businesses to implement new forms of business models. The most relevant e-business models for SOEs along with their implications are listed in Table 2.

TABLE 2: E-BUSINESS MODELS FOR SOES

E-business models	Implications
Collaboration platforms	Electronic business process cooperation, e.g. collaborative design
Electronic customer community	Direct access to a wide community of customers that express their needs and give feedback; targeting and customization
E-mall	Promoting on a global scale a company's products and services
E-procurement	Tendering and procurement on a global scale; automation of the tendering and procurement processes; electronic forms of collaboration and negotiation (electronic implementation of bidding mechanisms) on a global scale
E-shops	Promoting the products and services on a global scale
Professional virtual community	Direct access to a wide community of professional expertise; extended network of complementary competencies

#### V. ROLE OF ICT FOR SOES

The opportunities offered by the adoption and implementation of ICT lie not only in the improvement of the processes carried out at a local level, but also in the possibility of carrying out the same processes on a global scale independent of the firm size. In particular, referring to the three value-creating processes, the implementation and adoption of ICT within SOEs can allow the following positive effects:

- Reinforcing the existing relationships within SOEs, helping the integration of the economic actors

operating along global supply chains (business-to-business, electronic data interchange, Intranet, etc.);

- Providing SOEs with new opportunities of networking with firms located outside the country (business-to-business);
- Expanding the business boundaries of SOEs (web sites, electronic portals, etc.);
- Managing the relationships with the end-markets, offering new services and new ways to create value (electronic commerce, on-line marketing, etc.);
- Supporting both the joint innovation processes developed by SOEs and private industries and by the adoption of exogenous innovations.

#### VI. CHALLENGES TO ADOPT ICT TOOLS BY SOES

There is a wide range of reasons why SOEs are not adopting or using ICT tools in Bangladesh. Reasons do vary widely among sectors but most commonly faced challenged by SOEs in Bangladesh include:

- Unsuitability for business
- Lack of availability of ICT skilled personnel
- Cost of developing and maintaining ICT Tools
- Lack of Network infrastructure issues
- Building security and trust

These barriers are explained below [3, 13]:

##### A. *Unsuitability for business*

The leading reason given by SOEs for not engaging in ICT use is that it is not suited to the nature of their business. Findings of the survey on SOEs showed that among the operational SOEs, around 60% do not use the Internet for their business because they consider that Internet does not suit their type of business and/or products. Other reasons for not e-business models include lack of personnel with appropriate ICT skills, concerns over unbalanced costs and benefits, insufficient customer access to Internet and technology concerns, such as on-line security. During the survey several SOEs recalled that they did receive few inquiries regarding possible e-mailing of orders. Very few of its regular customers had used the Internet, and some preferred receiving confirmation of their order via fax or telephone. These concerns come from the practical judgment of SOEs on the benefits of using ICT.

##### B. *Lack of availability of ICT skilled personnel*

SOEs listed under Privatization Commission generally lack the human resources needed for ICT and e-business, because they focus on day-to-day operations and lack the time to understand the benefits of new technologies. Even when they are aware of the potential benefits of adopting ICT tools, they require know-how or qualified personnel. The SOEs that adopted ICT tools

are likely to have within the SOE someone who has a reasonable amount of knowledge of the specific technology and/or technology in general. Interestingly, the study found that they were not necessarily ICT professionals, but simply people interested in technology. It was also found that ICT are largely adopted by the SOEs which are working in the field of banking and engineering.

#### C. Cost of developing and maintaining ICT Tools

Most SOEs will not adopt ICT tools if the benefits do not outweigh the costs of developing and maintaining the system. The issue is costs relative to benefits expected, not cost itself. Nevertheless, SOEs are generally concerned about the costs of establishing and maintaining ICT tools since they generally suffer from budget constraints and are less sure of the expected returns on the investment. The study found that many SOEs cannot afford to adopt sophisticated ICT tools due to severe fund crisis.

#### D. Lack of Network infrastructure issue

The availability of a wide range of Internet connections and other communication services, preferably at competitive prices, is very important in that it allows SOEs to choose different and appropriate services according to their specific needs and (initial) expectations from ICT tools. Telecommunication networks are likely to continue to serve as the primary means of Internet access for many SOEs because of their relatively lower cost. Availability of broadband connections may affect SOEs' decisions to adopt ICT tools specially Internet usage. Faster Internet connections improve the overall on-line experience for both individuals and businesses, encouraging them to explore more applications and spend more time on line. Slow Internet connections and data transfer have in fact discouraged some SOEs from adopting Internet: over 75 percent of the SOEs indicated excessively slow or unstable data communication as a major hindrance to Internet use.

#### E. Building security and trust

Survey showed that security issues (viruses, hackers) are among the most important perceived barriers to Internet use by SOEs. Barriers to e-business models included payment uncertainties, contract and delivery guarantee uncertainties.

### VII. ICT SPREAD WITHIN SOES: THE CASE OF PRIVATIZATION COMMISSION LISTED SOES

The survey has been carried out by the team on twenty five state owned enterprises listed under Privatization Commission as part of the IDA funded Enterprise Growth and Bank Modernization Project in the financial year 2007-08. It highlights that the process

of adoption of ICT within SOE is still in the very early stage. A large gap exists between Internet connectivity and e-business models adoption and, more in general, between the possession of ICT and the actual use of it.

It could well be pointed out by the survey that the connection to the Internet does not support the unstructured and informal communication processes within SOEs. For example, the utilization of e-mails for the inter-firm relationships or for intra-firm informal communications is very limited. In 59% of SOEs surveyed, there are no significant experiences of informal exchanges of e-mail, 30% of SOEs' management have never used Internet for communicating with buyers. These percentages are almost unthinkable in the case of other forms of ICT-based interactions with customers, such as mailing list and discussion forum.

Further information on the current spread of ICT-based tools within SOEs are shown in Table 3 by using a scale rising from 1 (low) to 5 (high). It clearly shows that SOEs are seriously lagging in the use of Internet. Currently, Internet is used as a simple means of communication and, in particular, it is used more for communication outside Bangladesh rather than inside. However, SOEs that is being run by ICT literate individuals were found very enthusiastic about using ICT tools. However, it was expected, due to the above mentioned challenges that SOEs in Bangladesh would be seriously lagging when it comes to using ICT tools.

TABLE 3: SPREAD OF ICT BASED APPLICATIONS

ICT based applications	Current
Production (ERP) Software usage	1.2
B-to-C activities with on-line sales	0.0
Managerial Software usage	3.1
Promotional sites	1.5
Communications via e-mail, Internet	2.9
Use of Mobile and other traditional methods	5.0

The survey also shows that the degree of diffusion of advance software is still very low. These in fact require relevant investment by the management and, above all, the business processes re-engineering. This aspect, more than the economic one, represents a challenge to the adoption for the greater part of SOEs, which consider traditional way of operating as a distinctive competitive asset [14].

### VIII. CONCLUSION

Shared databases, integrated information systems, and ICT-based applications supporting the marketing and logistic activities can greatly improve the efficiency of the key supply chain business processes such as customer relationship management, customer service management, demand management, order fulfillment, manufacturing flow management, procurement, product

development and commercialization. It is possible to state that the adoption and implementation of ICT by the SOEs in Bangladesh can offer the following main opportunities [15]:

- favoring interactions & information exchanges among SOEs within same business;
- improving communication channels to allow correspondence with potential buyers of the global market;
- optimizing the production processes performance by redefining the relationships with customers and suppliers.

It can be argued that SOEs need institutional support for their survival in the era of globalization. The adoption of ICT by Indian SOEs is a proof of this point [2]. The burden and risk had been shared with the encouragement given by the Government of India (GOI) for private sector participation in providing technological infrastructure. Consequently SOEs have better access to web-enabled and portal based e-business technologies. However, the Government of Bangladesh still has to take initiative for providing uninterrupted utility services so that SOEs can become more competitive in international markets. Finally, the study suggests that SOEs in Bangladesh need much greater infrastructural support in order for them to reap the benefits of ICT and to develop the capabilities to contribute to economic development. Proper policies and programs aimed at providing required infrastructure need to be initiated by the Government of Bangladesh in order to make SOEs more competitive in the domestic and international markets.

#### ACKNOWLEDGEMENT

Ahsanullah M Dewan has served as the MIS Consultant for the year 2007-08 at the Privatization Commission, Chief Advisor's Office under the IDA funded Enterprise Growth and Bank Modernization Project. Authors would take this opportunity to show their gratitude to all his colleagues and management of SOEs for their support and cooperation. Without their support this study was not possible.

# Parallel Performance of Domain Decomposition Method on Distributed Computing Environment

\*A.M.M.Mukaddes and \*\*Atsushi Uragami

\*Department of Industrial and Production Engineering, Shahjalal University of Science and Technology, Sylhet, Bangladesh

\*\* Department of Intelligent Machinery and Systems, Kyushu University, Japan

**Abstract** - Distributed parallel computing, which uses general-purpose workstations connected by a network as a large parallel computing resource, is one of the most promising trends in parallel computing. Over the last two decades, the growth in the use of such parallel computing environment has ensured the interest on the parallel finite element method. In this work, parallel finite element method using domain decomposition technique has been adapted to the distributed parallel environment of networked workstations and the supercomputer. Using the developed code, several model problems are solved and the parallel performances are analyzed on the network of eight Pentium IV PC cluster and GP7000F workstations. Finally, very large size of problem over 11 million DOFs has been solved using 1024 SR8000 supercomputer.

**Index Terms** – Domain decomposition, finite element, parallel computing, workstation cluster.

## I. INTRODUCTION

Large scale problem, particularly those defined in three dimensional domain, often need substantial computation time and memory to run on ordinary sequential computers. Even if they can be solved, powerful computation capability is required to obtain the accurate and precise results within a reasonable time. Parallel computing can meet requirements of high performance computation [1]. Among the various parallel computing algorithms, domain decomposition method has become much popularity in the recent years [2]. In this method, the whole domain to be solved is first decomposed into a number of subdomains without overlapping. Finite Element Analysis (FEA) is defined and solved in each subdomain in parallel and then partial solutions are assembled together to get the global solution.

This method is exclusively implemented on structural analysis [3], heat conduction problem [4] and fluid analysis [5]. Most of the papers emphasizes only on the implementation of the method without analyzing the parallel performance as well as taking the necessary advantages of the parallel computing environment. In this research, the two parallel approaches (dynamic load distribution [6] and static load distribution) of domain decomposition method

with a suitable preconditioner have been adapted to the distributed parallel environment of networked workstations [7] and the supercomputer.

Using the developed code several models are solved and the performances are measured in different computing environments. The important factors affecting the performance of parallel computing using the domain decomposition method are found and analyzed. This analysis will be useful as a guideline for the user of the domain decomposition based software in the parallel computing environment.

## II. DOMAIN DECOMPOSITION METHOD

*Main method:*

Consider a linear system of algebraic equations,  

$$[K]\{u\} = \{f\} \quad (1)$$

arising from a finite element discretization of a linear elliptic boundary value problem in the domain  $\Omega$ , where  $K$  is the global stiffness matrix,  $u$  is an unknown vector and  $f$  is a known vector. The domain  $\Omega$  to be solved is first decomposed into  $N$  number of subdomains,  $\{\Omega^{(i)}\}_{i=1,\dots,N}$ , for which the union of all subdomains boundaries is

$$\Gamma = \bigcup_{i=1}^N \Gamma^{(i)}. \quad (2)$$

Let  $K^{(i)}$  be the local stiffness matrix corresponding to subdomain  $\Omega^{(i)}$ . Then as usual the global stiffness matrix  $K$  can be generated by subassembling:

$$K = \sum_{i=1}^N R^{(i)} K^{(i)} R^{(i)T} \quad (3)$$

where  $R^{(i)T}$  is the 0-1 matrix which translates the global indices of the nodes into local numbering. With superscript  $T$  we denote the transpose of a matrix (or vector). Let  $u^{(i)}$  be the vector corresponding to the variables in  $\Omega^{(i)}$  and it can be expressed as  $u^{(i)} = R^{(i)T} u$ . Each  $u^{(i)}$  is

split into degrees of freedom  $u_B^{(i)}$ , which correspond to  $\partial\Omega^{(i)} \setminus \Gamma_u$ , called interface degrees of freedom and the remaining interior degrees of freedom  $u_I^{(i)}$ . The subdomain stiffness matrices  $K^{(i)}$ , the vector  $u^{(i)}$  and the 0-1 matrices  $R^{(i)T}$  are then split accordingly:

$$K^{(i)} = \begin{pmatrix} K_{II}^{(i)} & K_{IB}^{(i)} \\ K_{IB}^{(i)T} & K_{BB}^{(i)} \end{pmatrix}, \quad (4)$$

$$u^{(i)} = \begin{pmatrix} u_I^{(i)} \\ u_B^{(i)} \end{pmatrix}, \quad (5)$$

$$\text{and } R^{(i)T} = \begin{pmatrix} R_I^{(i)T} & 0 \\ 0 & R_B^{(i)T} \end{pmatrix}. \quad (6)$$

$$u_B^{(i)} = R_B^{(i)T} u_B, \quad i = 1, \dots, N \quad (7)$$

Let  $V^{(i)}$  be the space of the interface degrees of freedom for the subdomain  $\Omega^{(i)}$  and  $V$  denotes the space of all degrees of freedom on  $\Gamma$ . The unknown in the interior of the subdomain  $\Omega^{(i)}$  is eliminated by Gaussian elimination according to the equation (8) using an initial value of  $u_B^{(i)}$ ,

$$u_I^{(i)} = K_{II}^{(i)-1} (f_I^{(i)} - K_{IB}^{(i)} u_B^{(i)}). \quad (8)$$

Then, after elimination of the interior degrees of freedom, the problem (1) reduces to a problem on the interface space  $V$ ,

$$S u_B = g \quad (9)$$

where  $S$  is the Schur complement matrix:

$$S = \sum_{i=1}^N R_B^{(i)} S^{(i)} R_B^{(i)T}, \quad (10)$$

$$S^{(i)} = K_{BB}^{(i)} - K_{IB}^{(i)T} (K_{II}^{(i)})^{-1} K_{IB}^{(i)}. \quad (11)$$

The problem (9) is solved using the preconditioned conjugate gradient method.

*Preconditioners [8]:*

The present domain decomposition method includes the following preconditioning techniques [8]

**Simplified diagonal scaling:**

$$Q_{DIAG} = \sum_{i=1}^N R_B^{(i)} \left( \text{diag}(K_{BB}^{(i)}) \right)^{-1} R_B^{(i)T} \quad (12)$$

**Balancing domain decomposition (BDD):**

This preconditioning matrix is defined as

$$M_{BDD}^{-1} = Q_c + (I - Q_c S) Q_l (I - S Q_c) \quad (13)$$

where  $Q_l$  is the local level part and  $Q_c$  is the coarse level part of the preconditioner.

**Balancing domain decomposition with diagonal scaling:**

$$M_{BDD-DIAG}^{-1} = (I - Q_c S) Q_{DIAG} \quad (14)$$

**Incomplete balancing domain decomposition (IBDD):**

$$M_{IBDD}^{-1} = \tilde{Q}_c + (I - \tilde{Q}_c S) \tilde{Q}_l (I - S \tilde{Q}_c) \quad (15)$$

where  $\tilde{Q}_c$  is constructed from the incomplete factorized coarse operator

**Incomplete balancing domain decomposition with simplified diagonal scaling (IBDD-DIAG):**

$$M_{IBDD-DIAG}^{-1} = \tilde{Q}_c + (I - \tilde{Q}_c S) \tilde{Q}_{DIAG} (I - S \tilde{Q}_c) \quad (16)$$

### III. PARALLELISM OF THE DOMAIN DECOMPOSITION METHOD

Constructing the DDM algorithms for parallel computers, a good principle is to divide the original domain into parts, which are further decomposed into smaller subdomains. In this research we adopt Hierarchical Domain Decomposition Method (HDDM) [6] which is a well known parallel DDM. This hierarchically structured DDM classifies processors in two different following ways.

*Dynamic load distribution (h-mode):*

The h-mode classifies processors into 3 groups, ‘Grand Parent’, ‘Parent’ and ‘Child’. Fig. 1 illustrates the practical implementation of hierarchical organized processors in the present method. One of the processors is assigned as Grand Parent, a few as Parent, and others as Child. The number of processors assigned as Parent is the same as that of parts. The number of Child processors can be varied; and it affects the parallel performance.

The role of Grand Parent is to organize all processor communications (i.e. message passing) which occur between all processors. Parents prepare mesh data, manage FEA (Finite Element Analysis) results, and coordinate the CG iteration, including convergence decision for the CG iteration. Parents send data to Child processors, where FEA is performed in parallel. After the FEA, Child processors send the results to Parents. This computation will be repeated until the CG iteration is convergent.

*Static load distribution (p-mode):*

However, because almost all computation is performed in Child processors and the most communication time is taken between Parent processors and Child processors, so the communication speed becomes important. In recent years although the communication performance has also been improving by improvement in network technology, the high-speed network is still expensive. On the other hand, for the PC cluster generally used, the network speed becomes a bottleneck to the processing performance of CPU. Moreover, when a parallel processing performance is considered, it is important to reduce the amount of communication time as much as possible. Therefore, the Parent-Only type (static load distribution: p-mode) is useful than the conventional Grand-Parent-Child type (h-mode).

Fig. 1 Hierarchical domain decomposition method (left), dynamic load distribution (right)

Fig. 2 Parallel processor scheme (p-mode)

Fig. 2 shows the parallel processor scheme of p-mode. In the p-mode, the Parent processors perform the FEA by themselves, which is computed by the Child processors in the h-mode. In the h-mode, although Parent processors store some of the subdomain analysis data and coordinate the CG iteration as the main work, the idling time of CPU increases because of less computation in Parent processors.

On the other hand, in the p-mode, since all processors perform the FEA and CPU can be used without futility, in uniform processor's environment, p-mode is considered to be predominance to h-mode. In the p-mode also, the number of Parent processors should be equal to the number of parts.

#### IV. PARALLEL PERFORMANCE

##### Speed up:

The key issue in the parallel processing in a single application is the speed up achieved, specially its dependence on the number of processors used. For

simplicity speed up with  $n$  processors,  $S_n$  is defined as follows:

$$S_n = \frac{t_1(A)}{t_n(A)} \quad (17)$$

where  $t_1(A)$  and  $t_n(A)$  are total time for solving the problem using one processor and  $n$  processors, respectively. Also scaled speed up  $S'_n$  is defined as follows:

$$S'_n = \frac{n \times t_1(A)}{t_n(nA)} \quad (18)$$

where  $t_n(nA)$  is the total time for solving the problem of size  $nA$ .

##### Sequential processing and parallel processing:

The program might be sequential, parallel or combination of sequential and parallel. The execution time to solve a problem of size  $n$  having the sequential processing is given by the equation (19)

$$T(n) = T_{calc}(n) + T_{i/o}(n) \quad (19)$$

where  $T(n)$ ,  $T_{calc}(n)$ ,  $T_{i/o}(n)$  are the total execution time, calculation time and input/output time. Again the execution time to solve a problem of size  $n$ , having the parallel processing also is given by the equation (20)

$$T(n, p) = T_{calc}(n, p) + T_{i/o}(n, p) + T_{comm}(n, p) \quad (20)$$

where  $T(n, p)$ ,  $T_{calc}(n, p)$ ,  $T_{i/o}(n, p)$  and  $T_{comm}(n, p)$  are the execution time, calculation time input/output time and time for communication respectively.

The ratio of the calculation time, input/output time and communication time over the total execution time is defined as follows

$$R_{calc} = \frac{T_{calc}(n, p)}{T(n, p)}, R_{i/o} = \frac{T_{i/o}(n, p)}{T(n, p)}, R_{comm} = \frac{T_{comm}(n, p)}{T(n, p)} \quad (21)$$

and

$$R_{calc} + R_{i/o} + R_{comm} = 1 \quad (22)$$

## V. NUMERICAL RESULTS AND DISCUSSIONS

### A. Physical model and computational environment:

Using the developed code, two heat transfer models [4] are analyzed here. Models are High Temperature Test Reactor (HTTR) and Advanced Boiling Water Reactor (ABWR) which are shown in fig. 3. The calculations are performed in three different computational environments shown in Table 1 and the model descriptions are shown in Table 2.

### B. Scalability and speed-up:

We evaluate the parallel scalability of the BDD and IBDD-DIAG preconditioner, varying the number of processors employed. Such evaluation is performed using the HITACHI SR8000. The results are shown in fig.4. Fig. 4 reports that BDD and IBDD-DIAG can compute faster solutions of a fixed mesh problem when the number of processors is increased. The speed-up is compared with the number of processors, referring the value for using 8 processors in Fig. 5 while the scaled speed-up with different number of processors refereeing the value of using 8 processors in Fig. 6. The results shown in figures confirm the parallel scalability properties of the BDD and IBDD-DIAG preconditioners. Since the program has both parallelable and nonparallelable portion, results are too far from the ideal one. For the parallelable portion, parallel computing with  $n$  processors can shorten computation time to  $1/n$  in ideal.

### C. Results concerning the number of subdomains:

Fig. 3 Part decomposition of HTTR and ABWR model

The number of subdomains is the major concern in the domain decomposition method. We compare the computation time (for IBDD-DIAG) in two different computational environments corresponding to the number of subdomains and results are shown in Fig. 7. CM shows better performance than GP7000F. The ratio of the calculation time, time for input/output data and communication time corresponding to the number of subdomains are shown in the Fig. 8 (p-mode) and Fig. 10 (h-mode). In p-mode with the increase of number of subdomains, ratio of calculation time decreases while ratio of input/output time and communication time increases. Since the network speed of GP7000F is faster than the CM, the communication takes less time compared to the CM clusters. The Fig. 9 shows the computation time for h-mode in two different computation environments, which shows that when the number of subdomain is 3000 the computation time increases in CM cluster compared to the GP7000F. This is because, in the h-mode the more communication takes place between the Parents and Childs as the number of subdomains increases thereby in CM it takes more time for the communication. So in the parallel computing environment having low performance it is better to use the static load distribution mode and having high performance it is better to use the dynamic load distribution mode.

ABWR model is analyzed in the vector type supercomputer SR8000 changing number of processors. Fig. 11 (p-mode) and Fig. 12 (h-mode) shows the variation of the computation time using the different number of processors in SR8000. As the number processor increases, the difference decreases. As a result, the difference between the time required using 512 processors and 1024 processors is too small. So it is not necessary to use more than 1024 processors for this model.

## VI. CONCLUSION

Two parallel approaches, static load distribution and dynamic load distribution of the domain decomposition method are adapted to the parallel computing environment and their parallel performances are analyzed.

Static load distribution seems to be more efficient in the parallel computer having low network speed while dynamic load distribution shows good performance in the high speed networked parallel computers. By the performance test, the effectiveness of the domain decomposition method in the parallel computer is verified. Important factors affecting the performance of the distributed parallel computing are found and analyzed. By using workstation cluster, a huge size of problem having over 11 million DOFs is solved successfully.

# Routing Algorithm for Vertically Stacked Optical Banyan Networks with the Time Complexity $O(N)$ using Pipelined Processors

Md. Mamun-ur-Rashid Khandker

Department of Applied Physics and Electronic Engineering, University of Rajshahi, Bangladesh.

**Abstract** — Centralized control routing algorithm for optical banyan networks on vertical stacking scheme has time complexity  $O(N \log_2 N)$  for rearrangeably nonblocking structure. A distributed algorithm with  $O(\log_2 N)$  has been recently proposed in which authors have considered an  $N$  completely connected processors to take routing decision which practically would be very difficult to implement for large  $N$ . In this paper we have proposed a distributed routing algorithm with processors work in pipelined fashion and take the routing decision in linear time. Also they do not need to be completely connected which makes it more practical for implementation.

**Index Terms** — Vertically Stacked optical Switch networks, Nonblocking Switch Networks, Completely connected graph, Bipartite graph.

## I. INTRODUCTION

The ubiquitous presence of the multimedia applications and the tremendous popularity of the World Wide Web have dramatically increased the amount of traffic over the Internet, which results the urgent requirement for high bandwidth links and switches. Due to the progress in DWDM technology, link bandwidth for carrying such traffic is no longer a problem. For DWDM networks, optical cross-connect (XOC) in nodes are key functional elements that steer whole network traffic by simultaneously switching a huge amount of optical flows. To build a large-scale OXC, generally small (e.g.  $2 \times 2$ ) switching elements (e.g. Directional couplers) are used as the basic building blocks, and are interconnected in a particular fashion to satisfy the required connectivity. Here we refer to the interconnection pattern of the optical links, the basic SEs, and the input/output ports of the switch, as optical switch network. Directional couplers (DC) [1] are considered as a promising candidate for the basic SE since it can handle optical signal of some terabits per second using WDM technology. It is notable that DC suffers from an intrinsic crosstalk problem [1][2], in which a portion of optical power in one waveguide of a DC will be coupled into the other waveguide unintentionally when two optical flows pass through the DC at the same time. This undesirable coupling effect is called first-order crosstalk, which may propagate downstream stage by stage, leading to a higher order crosstalk in each downstream stage with a decreasing magnitude.

According to the blocking properties, switches networks are classified as blocking and nonblocking. If a free input cannot be connected to a free output due to internal link-

blocking then it is considered as blocking. However, if multiple inputs intend to be connected with the same output, it causes output contention resulting in blocking to all requests but one, and mainly regarded as the property of the traffic pattern given to the network. Crosstalk in photonic switching networks adds a new dimension of blocking, called crosstalk blocking, which happens when an SE has two active inputs/outputs. A cost-effective solution to the crosstalk problem is to make sure that only one signal passes through each SE of a network at a time. Although this kind of space dilation of the network can eliminate the blocking and crosstalk completely, it may increase the hardware cost significantly if the interconnection pattern of the switching network is not chosen carefully. Since optical memory is not in a matured state to be used in an efficient queuing system, nonblocking networks have been favored in optical switching system. There are three different types of nonblocking networks: strictly nonblocking (SNB), wide-sense nonblocking (WSNB) and rearrangeably nonblocking (RNB). In both SNB and WSNB networks, a connection between a free input and free output can always be established without interrupting existing connections; however there is a difference. In SNB, any of the conflict-free path between a pair of input/output can be chosen, where as in WSNB, a smart algorithm is used to choose the path so that this connection does not result in blocking to any future connections. Usually a SNB network has got dedicated path for every input/output pair, and WSNB shares portion (links) of a path among different connections. Therefore, SNB networks have the higher hardware cost than WSNB networks but the latter have higher time complexity than the former one. RNB networks can also establish connections among idle inputs and outputs but has to allow rearrangements of the existing connections. It has the lowest hardware cost among the three, and the routing time complexity is often in between WSNB and SNB. Banyan networks [3], although a blocking networks, are attractive for constructing DC-based optical switches for their small depth, absolute loss uniformity (each path goes through exactly the same number of DCs), simple switch setting ability (self-routing, and therefore time complexity  $O(\log N)$ ), and for lower hardware cost (switch complexity  $O(N \log N)$ ). However, optical implementation of banyan networks results in severe blocking and crosstalk. To deal with this situation, it is a novel approach of keeping the whole network nonblocking as well as crosstalk-free by vertical stacking multiple copies (planes) of an optical banyan network [4]. This network is called vertically

stacked optical banyan (VSOB) network which preserves all the property of banyan networks except self-routing characteristics. It has been shown that total number of  $T = 2^{\lfloor (\log N + 1)/2 \rfloor}$  planes are required to make the switch network rearrangeably nonblocking with a routing algorithm that has the time complexity  $O(N \log N)$ . This time complexity may be considered too high when  $N$  is large. For optical interconnections where data rates are very high, and has no viable optical memory system, routing decision should be taken as fast as possible. Zheng *et. al.* [5] have proposed a  $O(\log N)$  parallel routing algorithm where  $N$  completely connected processors have been used, and information is exchanged among  $N$  nodes at every computation steps. They have recursively used balanced 2-coloring algorithm of a bipartite graph  $G(N, k, g)$  to get the  $g$ -edge coloring of the graph.  $G(N, k, g)$  is a bipartite graph with  $N/g$  vertices (in each of  $V_1$  and  $V_2$ ) and  $k$  edges where at most  $g$  edges are incident at any vertex. When  $k = N$ , creating such a graph would take  $O(N)$  time if used single processor, but in this paper it has been considered as  $O(1)$  as all  $N$  processors are completely connected. It is practically very difficult to develop a completely connected network when  $N$  is large. Therefore, we have been encouraged to develop a more pragmatic solution to this problem in which  $\sqrt{N}/2$  processors work in pipeline fashion, and therefore, are connected very loosely. Information is exchanged only between two adjacent processors.

In this paper we propose a routing algorithm in which controls are distributed over groups of inputs to achieve parallelism in computing crosstalk free realizable partial permutation in the  $O(N)$  time complexity. All logarithms used in this article are of base 2.

## II. BACKGROUND

### A. Vertically Stacked Banyan (VSB) Networks

Vertically Stacked Banyan (VSB) networks [4][6] are constructed by stacking  $T$  copies of  $N \times N$  optical Banyan networks. If  $T$  is number of banyan networks required to make the network rearrangeable nonblocking as well as crosstalk-free then,

$$T = 2^{\lfloor (n+1)/2 \rfloor} \quad (1)$$

Here  $n$  is the number of stages in the banyan networks, i.e.  $n = \log N$ . Figure 1 shows an  $N \times N$  VSB network. Circles at inputs represents  $1:T$  input switches and circles at outputs represents  $T:1$  combiner. An input request is sent only one Banyan network (plane) at a time. So, only one of the  $T$  links is busy at any time. On the output side, a combiner receives signal from only one plane since the request is considered to be a permutation. Therefore, switching is not required at the output side. The input request is split into partial permutations (CRPP) in such a way that each of those CRPP can be realized in a Banyan networks without

first-order crosstalk. A central control determines  $T$  partial permutations, and sets the input switch accordingly to route all signals of a CRPP to a Banyan plane. Being a Banyan network, each plane is self-routing

Fig. 1. a)  $N \times N$  VSB network. b) A 16x16 Banyan network.

### i) Crosstalk-free Realizable Partial Permutation (CRPP)

A full permutation is split into  $T$  partial permutation in such way that each of them can be realized in a banyan network without any crosstalk and blocking. Each of these partial permutations is called Crosstalk-free Realizable Partial Permutation (CRPP) [4]. Considering the traffic arrives in the form of permutation, routing of the request is being done by (a) Decomposing a permutation into CRPPs (b) sending  $T$  CRPP to  $T$  planes of Banyan networks.

### ii) CRPP Decomposition Algorithm

As indicated in [4], a CRPP decomposition algorithm can easily be obtained by repetition of the simple bipartite graph coloring with two colors. Due to space limitation here we describe the algorithm in short and simple way.

A bipartite graph  $G = (V, E)$  is constructed where each input switch is considered a node in set  $V_1$  (input set) and each output switch is considered a node in set  $V_2$  (output set). An edge represents that there is a connection request from an input switch to an output switch. Since each switch is a  $2 \times 2$  DC, the node degree is always 2. Using Euler's split  $G$  is split into  $G_1$  (consisting of all forward orientation) and  $G_2$  (consisting of all reverse orientation). Each of these bipartite graphs has  $N/2$  input nodes,  $N/2$  output nodes and

$N/2$  edges, and represents a partial permutation. However, these partial permutations only guarantee that they are crosstalk free in the input and the output stage.

In the next iteration,  $G_1$  is reconstructed where adjacent two nodes (from input set and output set) are merged. Therefore, this new  $G_1$  has  $N/4$  input nodes,  $N/4$  output nodes and  $N/4$  edges. The node degree is again 2. Using the

Fig. 2. Illustration of CRPP algorithm. (a) The input request (b) Bipartite graph  $G=(V_1, V_2, E)$  (c) Two partial permutations resulted from G (d) Graph  $G_1'$  for the left partial permutation. (e) Two CRPP resulted from graph  $G_1'$ .

Considering that it takes  $O(\sqrt{N})$  time to send T CRPP to T planes, the time complexity for routing a permutation in VSB networks is  $O(\sqrt{N} + N \log N) = O(N \log N)$ .

### III. DISTRIBUTED CONTROL ALGORITHM

#### A. Problem Formulation

First we show that the input-output request patterns can be represented by a  $2^t$  regular bipartite graph. Then we prove that the graph has such perfect matching which can be routed through a banyan plane without any blocking. We will use few pipelined processors for finding and routing these perfect matching in the  $O(N)$  time complexity.

For a networks having odd number of stages,  $n$ , stage  $(n+1)/2$ -th is the middle stage, and for even  $n$ , stages  $n/2$ -th and  $(n/2+1)$ -th are middle stage switches. Since each SE is connected to two SEs of the previous stage (as well as of the next stage), the number of inputs (outputs) intersects at a middle stage SE is  $2^{\lfloor (n+1)/2 \rfloor}$  i.e.  $T$ . Therefore, we propose input and output groups as per following definitions.

**Definition 1:** Input Groups,  $I_i$ , is defined as the set of inputs that intersect each other in a middle-stage SE. Therefore,

Euler's split algorithm in the same way as mentioned before, the  $G_1$  is split into two graphs.  $G_2$  is also split in the same way. So, we get 4 partial permutations each is represented by a graph. Using this technique recursively,  $T$  partial permutations are generated. Each of these  $T$  partial permutations is a CRPP. Xiang *et. al* [4] has shown that it takes  $O(M \log N)$  time to generate these CRPPs.

$$I_i = \{iT + 0, iT + 1, \dots, iT + (T - 1)\}, \text{ where } 0 \leq i \leq \frac{N}{T} - 1 \quad (2)$$

**Definition 2:** Output groups,  $O_i$ , is defined as the set of outputs that intersect each other at a middle-stage SE. Therefore,

$$O_i = \{iT + 0, iT + 1, \dots, iT + (T - 1)\}, \text{ where } 0 \leq i \leq \frac{N}{T} - 1 \quad (3)$$

**Definition 3:** Two connections,  $xy$  and  $pq$  are said to have group conflict if  $p, x \in I_i$  and/or  $q, y \in O_j$ , where  $0 \leq i, j \leq T - 1$ .

Figure 1 shows the grouping of inputs and outputs for a 16x16 banyan networks.

It is interesting to see that two requests,  $\begin{pmatrix} 2 \\ 0 \end{pmatrix}$  and  $\begin{pmatrix} 4 \\ 7 \end{pmatrix}$

have different input groups and output groups, and they have disjoint paths from input to output. Therefore, these two requests can be routes through a 16x16 banyan network without blocking and crosstalk. We need to know the minimum number of such connections for a Banyan network. We give two essential Lemmas in this regard.

**Lemma 1:** Any middle stage switch can carry connections generated (destined) from (to) only one input (output) group.

Fig. 3. Illustration of IG and OG (a) Even number of stages (b) Odd number of stages

**Proof:** Let's first prove it for inputs. A switch in stage  $i$  is connected to two adjacent switches of stage  $i-1$  (and  $i+1$ ). A switch at stage  $i$  are connected to only  $2^i$  adjacent inputs.

Therefore, a middle stage switch is connected to only  $2^{\lfloor \frac{n+1}{2} \rfloor}$  (i.e  $T$ ) adjacent inputs. For example, first  $T$  inputs are connected to  $0^{\text{th}}$  and  $k \cdot 2^{\lfloor \frac{n}{2} \rfloor}$ -th SEs of the middle stage, where  $0 < k < 2^{\lfloor \frac{n}{2} \rfloor}$  (for odd  $n$ ) and  $0 < k < 2^{\lfloor \frac{n-1}{2} \rfloor}$  (for even  $n$ ). No other connections can pass through these switches. This group of inputs corresponds to an input group. Therefore, any SE in the middle stage carry connections generated from only one input groups.

An SE in the middle stage is connected to two SEs of  $2^{n-\lfloor \frac{n+1}{2} \rfloor} \times 2^{n-\lfloor \frac{n+1}{2} \rfloor}$  banyan networks. Therefore, an SE of the middle stage carry connections destined to these two  $2^{n-\lfloor \frac{n+1}{2} \rfloor} \times 2^{n-\lfloor \frac{n+1}{2} \rfloor}$  networks. The total number of inputs of these two networks is  $2 \cdot 2^{n-\lfloor \frac{n+1}{2} \rfloor} = 2^{\lfloor \frac{n+1}{2} \rfloor} = T = |O_i|$ . So, we conclude that a middle stage SE can carry connections destined to only one output group. *QED*

**Lemma 2:** Connections without group conflicts can be established in a Banyan networks without crosstalk.

**Proof:** Let us consider any two connections  $xy$  and  $pq$  those do not have any group conflict. Since  $x \in I_i, p \in I_j$  and  $i \neq j$ , they belongs to different middle-stage SEs. Therefore, their routes up to middle stage are switch-disjoint. Similarly,  $y \in O_i, q \in O_j$  and  $i \neq j$ , so their routes from output to the middle stage are also switch-disjoint. Since Banyan network is a unique-path network, two sections of a route of the same connection must coincide at one and only one middle-stage SE. Therefore, the whole routes for  $xy$  and  $pq$  are switch-disjoint. Since they are disjoint, all SEs along their paths contain only one signal. Thereby, both  $pq$  and  $xy$  can be established crosstalk-free.

When  $n$  is even, there are two middle stages; stage  $(n/2)$  and stage  $(n/2+1)$ . Two connections generated from different input groups are switch-disjoint up to stage  $n/2$ , and two connections destined to two different output groups are switch-disjoint up to stage  $n/2+1$ . An SE in the  $n/2+1$ -th stage is connected to two SEs in the  $n/2$ -th stage those belong to different input groups. On the other hand two SEs in the  $n/2$ -th stage are connected to two SEs in the  $n/2+1$ -th stage those belong to different output groups. That means there is only one link between these two middle stages for a connection generated in an input group and destined to a particular output group. Therefore if two connections do not have group conflict they pass through different SEs in stages  $n/2$  and  $n/2+1$ , which ensures that both the connections have switch-disjoint paths from input to output. *QED*

Needless to say that if two connections have disjoint paths from input to output they will certainly not produce any blocking. Therefore, a crosstalk free permutation must be nonblocking in the network. Now we give theorem 1 by which we can determine the minimum number of crosstalk-free connections in an  $N \times N$  optical Banyan switch networks.

**Theorem 1:** An  $N \times N$  Optical Banyan networks can establish at least  $N/T$  connections crosstalk-free.

**Proof:** Let  $S$  be the size of input or output groups. Then  $S = |I_i| = |O_i|$ . By Lemma 2, one pair of input-output groups can have at least one connection crosstalk-free. For a switch network of size  $N \times N$ , there are  $N/S$  pairs of input-output groups. Therefore, at least  $N/S$  connections can be established without any crosstalk. Again,  $S = 2^{\lfloor \frac{n+1}{2} \rfloor} = T$ . Therefore, an  $N \times N$  optical Banyan switch network can establish at least  $N/T$  connections crosstalk-free.

Since an  $N \times N$  VSB network has  $T$  vertically stacked  $N \times N$  optical Banyan networks it can establish  $T \cdot \frac{N}{T} = N$  connections simultaneously without any crosstalk. Considering a group as a node we present a bipartite graph  $G(V_1, V_2, E)$ , in which  $V_1$  is the set of input nodes,  $V_2$  is the set of output nodes and  $E$  is the set of edges connecting them. An edge corresponds to a connection request. Therefore,  $E$  represents a request pattern which is essentially a permutation. Figure 2(b) shows a bipartite graph for the connection pattern in Figure 2(a).

Finding a set of  $N/T$  crosstalk-free connections is a problem of finding a perfect matching in  $G$ . To realize all  $N$  connections  $T$  such perfect matching is required to be found. We prove that  $G$  is  $T (=2^t)$  regular bipartite graph and it has  $T$  perfect matchings (PMs). Then we propose an algorithm for calculating these PMs in  $O(N)$  time. Each PM corresponds to a CRPP. First we discuss PM and its properties.

Fig. 4. (a) A connections pattern. (b) Corresponding  $G(V_1, V_2, E)$ .

A matching in  $G$  is a subset of  $E$  such that no two edges share a common vertex. A perfect matching in  $G$  is such that every  $v \in V_1$  is the endpoint of an edge. For example, set of red edges in Figure 2 is a perfect matching in  $G$ .

P. Hall's Theorem [8] states that in a bipartite graph  $G(X, Y, E)$  there exists a perfect matching of  $X$  into  $Y$  if and only if, for any  $S \subseteq X$ ,  $|S| \leq |\Gamma(S)|$ , where  $\Gamma(S)$  is the set of nodes adjacent to nodes in  $S$ .

Our bipartite graph  $G(V_1, V_2, E)$  is a  $T$ -regular graph. For any  $v \in V_1$ ,  $1 \leq |\Gamma(v)| \leq T$ . Therefore,

$$|\Gamma(S)| = \sum_{v \in S} |\Gamma(v)| \geq |S| \quad (3)$$

So,  $G$  has a perfect matching.

## B. Proposed Routing Algorithm

Our algorithm for decomposing a permutation into CFPP is based on Gabow's algorithm for edge coloring of bipartite multigraphs [7] in which author showed that a PM can be found in  $O(m)$  time where  $m$  is the number of edges in the graph. We have introduced parallelization in process of partitioning a  $2^t$  regular graph into  $2^{t-1}$  regular graph. We summarize our algorithm as follows:

Step 1: Construct the graph  $G(V_1, V_2, E)$ .

Step 2: Using Euler orientation, split  $G$  into two  $2^{t-1}$  regular subgraph  $G_1(V_1, V_2, E_1)$  and  $G_2(V_1, V_2, E_2)$ . All forward edges (oriented from  $V_1$  to  $V_2$ ) form  $E_1$  and all backward edges (oriented from  $V_2$  to  $V_1$ ) form  $E_2$ .

Step 3: process each of the subgraphs simultaneously by different processors.

Step 4: Repeat step 2 until all subgraphs are 1-regular bipartite graph.

Step 1 and step 2 require  $O(N)$  time. A processor has to visit all  $N$  edges in the first call of the step 2. In the second call the processor visits  $N/2$ , in the third call  $N/4$  and so on. Therefore the time complexity for one processor is  $O(N + N/2 + N/4 + \dots) = O(2N) = O(N)$ . However,  $2^{\text{nd}}$  processor has to visit  $N/2$  edges,  $3^{\text{rd}}$  processor visits  $N/4$  edges, and so on. Therefore, all the processor ends their operation at the same time. Since all PMs are found at the same time, the overall time complexity is  $O(N)$ .

Each of the  $T/2$  processors takes the responsibility of sending 2 CFPP to 2 planes. First two planes are assigned to first processor,  $2^{\text{nd}}$  two planes to  $2^{\text{nd}}$  processor and so on.

## IV. CONCLUSION

A simple way to parallelizing the routing process of VSOB networks has been proposed. Only  $\sqrt{N}/2$  processor are required to achieve the routing time complexity of the  $O(N)$ . We hope the findings of this paper will help switch designers implement a faster nonblocking optical switch network.

A centralized routing algorithm of the  $O(N)$  is under investigation.

**Abstract**—Crosstalk is an intrinsic drawback of an optical network, and avoiding crosstalk is important for making fruitful application of optical switching network. In this paper, we apply the well-known semi-permutation technique on Generalized Recursive Network (GRN) to make it crosstalk free. GRN has reasonable path independent signal loss and crosstalk. Using the methodology presented in this paper, that reasonable crosstalk is avoided. For the GRN network, we show that any semi-permutation is realizable in one pass and any permutation is realizable in two passes under the constraint of avoiding crosstalk.

**Index Terms**—GRN, Crosstalk, Semi-permutation, and Crosstalk-free routing algorithm.

## I. INTRODUCTION

Two major problems in designing optical switch networks are signal loss and crosstalk. There are two ways in which optical paths can interact in planar switching networks. First, two optical channels on different waveguides may cross each other in order to obtain a particular topology. This is called channel crosstalk. Alternatively, two paths sharing a switching element will experience some undesired coupling from one path to the other. This is called optical crosstalk [1].

Generalized Recursive Non-blocking Network (GRN) is a new approach for building non-blocking optical Multistage Interconnection Networks (MINs) [1]. It can be built from strictly nonblocking to blocking depending on building blocks and thereby it can be traded of cost with performance. It has very easy self routing algorithm [1, 4]. However, using this routing algorithm the network is not crosstalk free. Therefore, the main objective of this paper is to make the GRN crosstalk free using well known semi-permutation [2]. In this paper, a new crosstalk free routing algorithm is proposed for Generalized Recursive Network (GRN). The algorithm is derived based on the idea of the semi-permutation.

The remainder of the paper is organized as follows. In section II, we give an overview idea of preliminaries. In section 4, we discuss details about the crosstalk-free routing algorithm of GRN along with the proposed routing. In section IV, we discuss the performance evaluation of our proposed routing algorithm. Finally, Section V concludes the paper.

## II. PRELIMINARIES

When two optical paths interact to each other, then crosstalk occurs. The number of crosstalk switches along a path of a signal from input to output is a representative measure of crosstalk of the switch architecture. The number of switching elements in a signal path is a measure of signal loss. Clearly signal loss is proportional to the number of switches that has to be crossed by a signal before reaching the output. The total number of switches required, to build a network is a representative measure of the hardware complexity of the network.

Centralized routing control of switches is centralized; the decision about how to send the input signal to its desired output is taken at a central location for any input. Distributed routing, control units may be distributed among several switches. Self-routing, every switching elements in the architecture can decide about the routing without having any information of other switches states [4].

Self-routing reduces the connection complexity for the control lines [1]. As the control function is distributed among different switching modules, the network is less susceptible to faults of a switch. Most of the existing switch networks are not self-routing for all permutations. Banyan and its equivalent networks are self-routing, but they cannot route all  $N!$  permutations. Benes network with more than five inputs are not self-routing. Clos network whose first stage contains more than two switches are not self-routing. Crossbar network is self-routing for all permutations but it requires the header of size  $O(N)$ .

### A. Generalized Recursive Network (GRN)

GRN has better performance than any other indirect interconnection networks. Because it has low signal loss and crosstalk. In this architecture, any  $M \times N$  non-blocking switch network can be built with building blocks of given size  $m \times n$ , where  $M, N, m, n$  are all powers of integers. GRN is self-routing for all  $N!$  permutations and the propagation delay is  $O(\log N)$ . The switches of GRN maintains the connection pattern of shuffle-exchange fashion. If the size of the building blocks is  $m \times n$ , then the number of building blocks required is  $\frac{M}{m}$  and the

number of switching elements required is  $(n(\frac{M}{m} - 1))$ . The number of recursions in GRN is  $\log(N/n)$ .

An  $M \times N$  GRN constructed from  $m \times n$  strictly non-blocking building blocks is also a strictly non-blocking network and the parameters switch count ( $T_N$ ), maximum signal loss ( $S_N$ ) and maximum crosstalk ( $C_N$ ) are given by the following equations, respectively [1]:

$$T_N = \left( \frac{MN}{m} + \frac{MN}{n} - M - N \right) + \frac{MN}{mn}$$

where  $\frac{MN}{mn}$  represents the total number of building blocks of size  $m \times n$

$$S_N = \log\left(\frac{M}{m}\right) + \log\left(\frac{N}{n}\right) + S_m$$

where  $S_m$  is the maximum signal loss of the building block.

$$C_N = C_m$$

where  $C_m$  is the maximum crosstalk of the building block. It means that the crosstalk is only available in the building block.

### B. Limitation of GRN

There are three stages in GRN. The stages are input stage, output stage, and building-block-stage. In  $M \times N$  GRN, with building block size of  $m \times n$ , a signal has to cross  $\log(N/n)$  input stage switches, and  $\log(M/m)$  output stage switches in addition to one building block. Since the input stage switches are  $1 \times 2$  switches, they do not contribute to crosstalk. Likewise, the output stage switches are  $2 \times 1$  and they do not have to bear signals at both of their inputs at the same time. So, they do not contribute to crosstalk as well. The only possible elements that contribute to crosstalk are the building blocks. And our work is concentrate on this issue to avoid the crosstalk.

## III. OUR APPROACHES TO SOLVE THE CROSSTALK OF GRN

One way to solve the crosstalk problem is a space domain approach, where a MIN is duplicated and combined to avoid crosstalk. But this approach uses more than double of the original network hardware to achieve the same permutation capability.

Another way to implement this idea is a time domain approach [2]. A set of connections is partitioned into several subsets such that the connections in each subset can be established simultaneously in a network without crosstalk. In our work, we will consider the idea of time domain approach. Because each switch can only pass one signal at a given time.

There is a nice property for permutation that any permutation can be decomposed into semi-permutations. A

routing algorithm for realizing a semi-permutation in a generalized recursive non-blocking network (GRN) is also presented. Routing is the act of moving information across an inter network from a source to a destination. Semi-permutation, which is a special type of partial permutation and has the maximum potential to be realized in an optical network without crosstalk [2]. This permutation ensures that there is only one active link passing through each input switch and output switch that is it eliminates crosstalk. The semi-permutation concept is accomplished based on the idea of the bipartite graph. Bipartite graph (i.e, a set of graph vertices decomposed into two disjoint sets such that no two graph vertices within the same set are adjacent) such that every pair of graph vertices in the two sets are adjacent.

### A. Semi-permutation

Semi-permutation for a network is a pairing of its inputs and outputs such that each input appears in exactly one pair and each output appears also in exactly one pair. In other words, a permutation is a full one-to-one mapping between the network inputs and outputs. For an  $n \times n$  network, suppose input  $x_i$  is mapped to output  $y_i$ , where  $x_i = i$  and  $y_i \in 0, 1 \dots n-1$  for  $0 \leq i \leq n-1$ , we denote this permutation as,

$$\begin{pmatrix} x_0 & x_1 & \dots & x_{n-1} \\ y_0 & y_1 & \dots & y_{n-1} \end{pmatrix}$$

A crosstalk-free optical network can not realize permutation in a single pass, since at least the two input links on an input switch or the two output links on an output switch cannot be active in the same pass. For an optical network consisting of  $2 \times 2$  switches, it is useful to introduce the following,

A partial permutation,  $\begin{pmatrix} x_0 & x_1 & \dots & x_{n/2-1} \\ y_0 & y_1 & \dots & y_{n/2-1} \end{pmatrix}$  of an  $n$ -element set  $0, 1, \dots, n-1$ , where  $n$  is an even integer,  $x_i, y_i \in 0, 1, \dots, n-1$  and  $x_0 < x_1 < \dots < x_{n/2-1}$ , is referred to as a semi-permutation of the  $n$ -element set, if  $\{\lfloor \frac{x_0}{2} \rfloor, \lfloor \frac{x_1}{2} \rfloor, \dots, \lfloor \frac{x_{n/2-1}}{2} \rfloor\} = \{0, 1, \dots, n/2-1\}$  and  $\{\lfloor \frac{y_0}{2} \rfloor, \lfloor \frac{y_1}{2} \rfloor, \dots, \lfloor \frac{y_{n/2-1}}{2} \rfloor\} = \{0, 1, \dots, n/2-1\}$

### B. Number of Semi-permutation in GRN

Total number of semi-permutation for the GRN is  $\#semi-permutation = 2 \times \log 2^{\lfloor \log_2 buildingblock \rfloor}$ . Our proposed crosstalk free routing algorithm of GRN is properly crosstalk free at building block. For an  $8 \times 8$  GRN network with  $2 \times 2$  building block, maximum number of semi-permutation is  $\log_2^2 = 1$ . For a  $4 \times 4$  building block, maximum number of semi-permutation is  $\log_2^4 = 2$ . Thus, we can find out the total number of semi-permutation in GRN network. But if we replace the building block by  $4 \times 4$  wide-sense non-blocking Benes network then the number of semi-permutation is reduced.

### C. Bipartite Graph

A bipartite graph is a graph whose vertices can be divided into two disjoint sets  $V_1$  and  $V_2$  such that every edge connects a vertex in  $V_1$  and one in  $V_2$ ; that is, there is no edge between two vertices in the same set [1].

Now if we considered an undirected bipartite graph  $G = (V_1, V_2, E)$ . The vertex sets of  $G$  are defined as  $V_1 = \{A_0^{[1]}, A_1^{[1]}, \dots, A_{n/2-1}^{[1]}\}$ ,  $V_2 = \{A_0^{[2]}, A_1^{[2]}, \dots, A_{n/2-1}^{[2]}\}$  and the edge set  $E$  of  $G$  is defined as: for any one-pair mapping  $\begin{pmatrix} x_i \\ y_i \end{pmatrix}$  in the permutation. If  $x_i \in A_{j_1}^{[1]}$  and  $y_i \in A_{j_2}^{[2]}$ , then there is an edge between vertex  $A_{j_1}^{[1]}$  and vertex  $A_{j_2}^{[2]}$  in  $E$ . We also assign each edge in  $E$  a label representing the corresponding one-pair mapping in the permutation. Here  $n$  is an integer value.

This bipartite graph has some properties. This graph may have parallel edges and each vertex of this graph has even degree. This graph may consist of more than one connected component and each edge traversed exactly once. It's vertices  $|V_1| = |V_2| = n/2$  and edges  $|E| = n$ . Each bipartite graph is a perfect graph. In this case, we considered cyclic bipartite graph, that each vertex of this graph has degree two.

### D. Decomposition algorithm of Bipartite Graph

Any permutation can be decomposed into two semi-permutation. Here we considered  $8 \times 8$  network, with  $2 \times 2$  switching building block. The input and output can be decomposed into two semi-permutation as follows,

$$\begin{pmatrix} 0 & 1 & 2 & 3 & 4 & 5 & 6 & 7 \\ 1 & 0 & 7 & 5 & 3 & 4 & 6 & 2 \end{pmatrix}$$

$$\begin{pmatrix} 0 & 3 & 4 & 6 \\ 1 & 5 & 3 & 6 \end{pmatrix} \begin{pmatrix} 1 & 2 & 5 & 7 \\ 0 & 7 & 4 & 2 \end{pmatrix}$$

- First: Construct a bipartite graph  $G$  for the given permutation.
- Second: We started from a vertex of this component in  $V_1$ , traverse through an unvisited edge to the neighbor vertex in  $V_2$ , back and forth until return to the starting vertex. If the traverse direction is from  $V_1$  to  $V_2$ , is called "forward" edges and marked "backward" if the direction is opposite.
- Third: take all one-pair mappings corresponding to the edges marked with "forward", to form one semi-permutation and "backward" to form another semi-permutation.

The above algorithm is correct because this algorithm maintains the properties of the bipartite graph  $G$ . Now if we apply the above decomposition algorithm in one permutation that decomposed into two semi-permutation,

then the bipartite graph and edge traverses are shown in below,

$$e_0 = \begin{pmatrix} 0 \\ 1 \end{pmatrix}, e_1 = \begin{pmatrix} 1 \\ 0 \end{pmatrix}, e_2 = \begin{pmatrix} 2 \\ 7 \end{pmatrix}, e_3 = \begin{pmatrix} 3 \\ 5 \end{pmatrix}, e_4 = \begin{pmatrix} 4 \\ 3 \end{pmatrix}, e_5 = \begin{pmatrix} 5 \\ 4 \end{pmatrix}, e_6 = \begin{pmatrix} 6 \\ 6 \end{pmatrix}, e_7 = \begin{pmatrix} 7 \\ 2 \end{pmatrix},$$

Then we find the "forward" pairs  $e_0, e_3, e_4$ , and  $e_6$  to form,

$$\begin{pmatrix} 0 & 3 & 4 & 6 \\ 1 & 5 & 3 & 6 \end{pmatrix} \quad (1)$$

and the "backward" pairs  $e_1, e_2, e_5$ , and  $e_7$  to form,

$$\begin{pmatrix} 1 & 2 & 5 & 7 \\ 0 & 7 & 4 & 2 \end{pmatrix} \quad (2)$$

which completes the decomposition shown in Figure 1,

Fig. 1. The bipartite graph and edge traverses of the decomposition

The set of all edges marked with "forward" is a perfect matching of the bipartite graph  $G$ , and so is that marked with "backward". The time to construct the bipartite graph is proportional to the number of pairs in the permutation, i.e.  $O(n)$ , and the time to traverse all edges is  $O(|E|) = O(n)$ . The complexity of the decomposition algorithm is  $O(n)$  [3]. Now we can again decompose the "forward" pair from Eq. 1, according to bipartite graph and we get "forward" pairs  $e_0$  and  $e_3$  and "backward" pairs  $e_1$  and  $e_2$ .

Forward =  $\begin{pmatrix} 0 & 6 \\ 1 & 6 \end{pmatrix}$ , Backward =  $\begin{pmatrix} 3 & 4 \\ 5 & 3 \end{pmatrix}$ , and the bipartite graph for the semi-permutation shown in Eq. 1 is depicts in figure 2.

Similarly, we can also decompose the backward pair of equation 2, according to bipartite graph, we get again the "forward" pairs  $e_0$  and  $e_2$  and "backward" pairs  $e_1$  and  $e_3$ .

Fig. 2. Forward and backward edges of Eq. 1 traverse along the decomposition

Forward =  $\begin{pmatrix} 1 & 5 \\ 0 & 4 \end{pmatrix}$ , Backward =  $\begin{pmatrix} 2 & 7 \\ 7 & 2 \end{pmatrix}$ , and the bipartite graph for the semi-permutation shown in Eq. 2 is depicts in figure 3.

Fig. 3. Forward and backward edges of Eq. 2 traverse along the decomposition

#### E. Routing Mechanism of GRN

GRN networks maintain self-routing principle. The whole routing mechanism of GRN from an input to an output is divided into three steps:

- 1) Routing in the input stage
- 2) Routing in the building-block-stage, and
- 3) Routing in the output stage

Each input and output switches uses 1 bit to decide it's state. Each building block has its own routing strategy. It can route a signal properly with the given source and destination addresses. The input switch uses the first tag bit arriving at the switch, sets the state of the switch accordingly and sends rest of the tag bits to the next switch along the path up to the building block. Starting from the left, the first  $\log(N/n)$  bits are used by the input stage switches. In this stage the signal is routed from the leaf to the root of the output tree. The last  $\log(M/m)$  bit is used by the output stage switches. Building block use the remaining middle bits for it's own routing.

#### F. Proposed Routing Algorithm of GRN

In GRN, crosstalk occurs only at building block. To remove this crosstalk, we propose a new crosstalk free routing algorithm of GRN. The proposed routing algorithm is given below:

**Routing Algorithm** (integer  $N$ , SEMI-PERM semi-perm)

**Step 1:** If  $N$  is 2, compute only the routing mechanism of GRN and exit, no semi-permutation is needed.

**Step 2:** Construct a bipartite graph  $G = (V_1, V_2, E)$  from a given permutation, when  $N > 2$ , where  $N$  is the number of inputs/outputs.

**Step 3:** Decompose the permutation according to the decomposition algorithm of bipartite graph.

**Step 4:** Obtain forward and backward edges from the bipartite graph.

**Step 5:** Then apply, the routing mechanism of GRN upon the obtaining semi-permutations for a particular permutation.

**Step 6:** Recursively call Routing Algorithm (integer  $N$ , SEMI-PERM semi-perm) until reach  $\#Semi-permutation = 2 \times \log_2^{[Building-block]}$

**End**

#### IV. REALIZATION OF A ROUTING

In this section, we have shown the simulation result using an example of routing proposed in this paper. The routing paths for various sets of inputs-outputs are clearly shown in Figure 4 with different colors. The messages to be sent are directed from all input ports to its corresponding output ports.

Let us consider a input and output sequence, where the output sequence is generated randomly. An example is shown below:

$$\begin{pmatrix} \text{Input Sequence} = & 0 & 1 & 2 & 3 & 4 & 5 & 6 & 7 \\ \text{Output Sequence} = & 0 & 6 & 1 & 2 & 3 & 4 & 7 & 5 \end{pmatrix},$$

Then we decompose, these sequences according to proposed routing algorithm of Generalized Recursive Non-blocking Network (GRN) and we get "forward" and "backward" pairs as below.

$$\text{Forward} = \begin{pmatrix} 0 & 3 & 5 & 6 \\ 0 & 2 & 4 & 7 \end{pmatrix}$$

$$\text{Backward} = \begin{pmatrix} 1 & 2 & 4 & 7 \\ 6 & 1 & 3 & 5 \end{pmatrix}$$

In Figure 4, only one signal comes in a building block for a particular time for both forward pair and backward pair. Therefore, there is no possibility to occur crosstalk at its building block. The input and output trees are cross-talk free [1]. Therefore, the whole network is crosstalk free in two passes.

Now, we consider  $8 \times 8$  GRN network with  $(4 \times 4)$  building block, for the same input and output sequences, as mentioned earlier. In Figure 5, at the same time two signals pass in a building block switch. Therefore, it is possible to occur crosstalk in the building block switch. To overcome this problem, we have decomposes this semi-permutation again into forward pair and backward pair.

(a)

(b)

Fig. 4. Routing of various input-output combination with (a) forward pair (b) backward pair

$$\text{Forward} = \begin{pmatrix} 0 & 5 \\ 0 & 4 \end{pmatrix} \quad (3)$$

$$\text{Backward} = \begin{pmatrix} 3 & 6 \\ 2 & 7 \end{pmatrix} \quad (4)$$

The realization of this decomposed permutation is shown in Figure 6. Figure 6(a) is for forward pair shown in Eq. 3 and Fig. 6(b) for backward pair shown in Eq. 4. It is shown that the only one signal passes through the building block. Therefore the network is crosstalk free.

Fig. 5. Routing in  $8 \times 8$  GRN with  $4 \times 4$  building block for forward pair

Fig. 6. Routing in  $8 \times 8$  GRN with  $4 \times 4$  after second decomposition. (a) forward pair (b) backward pair

Figure 7 shows the realization of the backward decomposition. Here, it is shown that only one signal is pass through the building block. Thus the building block, and hence the whole network crosstalk-free.

But if we replace the building block by the  $4 \times 4$  wide-sense non-blocking Benes network, then only one signal comes in a building block switch at a time, and there is no possibility to occur crosstalk in the building block switch. Again for backward pair only one signal comes in a building block switch at a time, and it is shown above.

We have shown an example of crosstalk-free routing. In our study study all the input-output permutations, where the output is generated randomly, the GRN is deadlock free with the number of Semi-permutation =  $2 \times \log_2^{[Building-block]}$ .

## V. CONCLUSION

We have proposed a new crosstalk-free routing algorithm of GRN. Each switch can only pass one signal at a given time. Therefore, there is no possibility to occur crosstalk in a building block switch. This algorithm is derived based on the idea of the semi-permutation, and the main advantage of our proposed routing algorithm is

Fig. 7. Routing in  $8 \times 8$  GRN with  $4 \times 4$  building block for backward pair

that it reduces the number of passes of a permutation under the constraint of avoiding crosstalk.

**Abstract** — Vertical stacking of multiple copies of an optical banyan network is a novel scheme for building nonblocking optical switching networks. The resulting network, namely vertically stacked optical banyan (VSOB) network, preserves all the properties of the banyan network, but increases the hardware cost significantly under first order crosstalk-free constraint. Therefore, blocking behavior analysis could be an effective approach to studying network performance, and finding a graceful compromise between hardware costs and blocking probability with different degree of crosstalk constraint. However, lower bound on number of planes for such networks with zero crosstalk constraint has been determined previously. In this paper, we present the simulation results for lower bound on blocking probability with given degree of crosstalk. The results show that blocking probability decreases to low value if we allow some CSEs to the network. The simulation results presented in this paper can guide network designer in finding a tradeoff among the blocking probability, and the degree of crosstalk of VSOB networks.

**Index Terms** — Lower bound, blocking probability, crosstalk.

## I. INTRODUCTION

Optical mesh networks are considered more capacity-efficient and survivable for serving as the backbones for next generation internet. A key network element equipped with a switching node of optical mesh networks is the optical switch, which has the capability of switching huge data at an ultra-high speed. The main factors those have to be considered while designing any optical switching networks are hardware cost, blocking probability, crosstalk, switching speed etc. The basic  $2 \times 2$  switching element (SE) in a large optical switching network is usually a directional coupler (DC) [1,7]. DC's can switch multiple wavelengths at the same time, which is important for the future optical cross-connects (OXC's).

Crosstalk is an intrinsic shortcoming of the DC. It is the effect of the undesirable coupling between the signals carried in the two waveguides of the coupler [1,2]. When two optical signals meet at a DC, a small portion of the signal power will be directed to the unintended output channel. Crosstalk suppression becomes particularly important in networks, where a signal propagates through many nodes and accumulates crosstalk from different elements at each node from the system view. In order to obtain an approximate idea of the crosstalk

requirements, suppose that a signal accumulates crosstalk from  $N$  sources, each with crosstalk level  $\alpha$ . This neglects the fact that some interfering channels may have higher powers than the desired channel. Networks are very likely to contain amplifiers and to be limited by signal-spontaneous beat noise. For example, if we have 10 interfering equal-power crosstalk elements, each producing intrachannel crosstalk, then we must have a crosstalk suppression of below 35dB in each element, in order to have an overall penalty of less than 1dB [7]. Thus, Crosstalk reduction is an important issue in designing the systems that are based on DC's. The crosstalk issue can be tackled at either the device level or the system level. The two methods complement each other. The focus of this paper is on the system-level approach. As will be seen, crosstalk adds a new dimension to the theory of building a nonblocking and negligible blocking switching network.

Banyan networks [8,4,3,5] are a class of attractive switching structures for constructing DC-based optical switches, because they have a smaller and exactly the same number of SEs along any path between an input-output pair such that an absolutely loss uniformity and smaller attenuation of optical signals are guaranteed in this class of switching networks. However, with the banyan topology only a unique path can be found from each network input to each network output, in which the network is degraded as a blocking one. The general scheme for building banyan-based nonblocking optical switching networks is to vertically stack the multiple copies of regular optical banyan network [6,10] as illustrated in Fig.1. We use VSOB to denote the optical switching networks built on vertical stacking scheme of banyan network.

Numerous result are available for VSOB networks, such as [6], and their main focus has been on determining the maximum and minimum number of stacked copies (planes) required for a nonblocking VSOB networks if conservative routing algorithm is used for routing a request to a plane. These results indicate that VSOB structure, although is attractive, usually requires either a high hardware cost or a relatively larger depth for building a nonblocking network. In paper [11], the maximum number of planes required for nonblocking a VSOB

networks with link-failures and the blocking probability of VSOB networks for given failure probability & load have been determined. In paper [12], the lower bound on number of planes for VSOB networks with link-failures have been determined. In this paper, we analyze the blocking behaviour of VSOB networks with allow some CSEs to the networks. The simulation results can guide networks designers to initiate a compromise among the hardware cost, and the blocking probability of a VSOB network under different degree of crosstalk.

Fig. 1. Vertically stacked optical banyan (VSOB) network.

The rest of the paper is organized as follows: Section 2 provides preliminaries that facilitate our further discussions. Section 3 presents our contribution. Section 4 concludes the paper.

## II. PRELIMINARIES

In VSOB network, blocking happens when two connections intend to use the same link, which is referred to as link-blocking. However, there is another type of connection-related blocking, which occurs when some paths (including the new one) violate the crosstalk-free constraint after adding the new connection. In such a situation, the connection is not allowed to be allocated even if the path is available. We refer to this second type of blocking as crosstalk-blocking throughout the paper. It is the combination of the two types of blocking that makes the design principle different.

For A typical  $N \times N$  banyan network consists of  $\log_2 N$  stages, each containing  $N/2$   $2 \times 2$  SEs. Regular banyan network has a unique path between an input-output pair, and a basic technique for creating multiple paths between an input-output pair is the vertical stacking of multiple copies of the banyan network. In this paper, we focus on the banyan network that has  $m$  multiple copies as shown in fig.2.

Fig. 2. 16x16 banyan network.

Due to the topological symmetry, all paths in banyan networks have the same property in terms of blocking. We define the blocking probability to be the probability that a feasible connection request is blocked, where a feasible connection request is a connection request between an idle input port and an idle output port of the network. Without loss of generality, we focus on the path between the first input and the first output (which is termed as the tagged path hereafter). All the SEs and links on the tagged path are called tagged SEs and tagged links respectively. The stages of SEs are numbered from left (stage 1) to right (stage  $\log N$ ) and the stages of links are also numbered from left (stage 1) to right (stage  $\log N + 1$ ). For the tagged path, an input intersecting set  $I_i = \{2^{-i}, 2^{-i+1}, \dots, 2^{-i-1}\}$  at stage  $i$  is defined as the set of all inputs that intersect a tagged SE at stage  $i$ . Likewise, an output intersecting set  $O_i = \{2^{-i}, 2^{-i+1}, \dots, 2^{-i-1}\}$  associated with stage  $i$  contains all the outputs that intersect a tagged SE at stage  $\log N - i + 1$ .

When two light signals go through an SE simultaneously, crosstalk is generated at the SE. Such SE is referred to as a crosstalk SE (CSE). The degree of crosstalk of the switching system is defined as the number of CSE's allowed along a path.

A restricted SE (RSE) is a  $2 \times 2$  SE which carries only one light signal at a time. Although crosstalk at an RSE is very small, it may not be entirely zero. For example, when a light signal passes through an RSE, a small portion of the signal will leave at the other unintended output channel. This stray signal can arrive at the input of the next stage SE and generate some crosstalk. Since crosstalk generated by the stray signal is much smaller than the regular crosstalk, we will ignore it in our analysis.

Following the typical assumption as in [6,9] on probabilistic analysis of multistage interconnection networks, we neglect the correlation among signals arriving at input and outputs ports, and consider that the statuses (busy or idle) of individual input and output ports in the network are independent. This assumption is justified by the fact that the correlation among signals at inputs and outputs, though exists for fixed communication

patterns, and becomes negligible for arbitrary communication patterns in large size networks, which is the trend of future optical switching networks that can switch huge data at high speeds.

#### A. Lower Bound on Number of Planes

The lower bound on the number of planes required to make VSOB networks nonblocking is shown in Fig.3.

Fig. 3. Nonblocking condition for VSOB network.

### III. VSOB NETWORKS WITH ALLOW CROSSTALK

In this section, we analyzed the blocking behavior of VSOB networks with given crosstalk constraint.

#### A. Network Simulator

The network simulator we developed consists of four major modules as shown in fig. 4.

Fig. 4. Block diagram of network simulator.

We consider here the permutation request as the traffic. Due to the symmetric architecture of VSOB  $(N, T)$  network, every connection request has the same probability to be blocked. In our simulation, we fix the connection request of input-output pair 0-0 and investigate the blocking probability of this connection request only that may result by other contentious connections.

**Module 1:** This module randomly generates a permutation request for the VSOB  $(N, T)$  network based on the workload  $r$  (here workload  $r$  is defined as the occupancy probability of a port).

In this section we present some definitions, which are used in the discussion of our algorithm:

**Definition 1 Blocking connections,  $C_{bc}$ :** The connections those are potential to blocking the tagged path.

**Definition 2 Crosstalk-blocking connections,  $C_{cbc}$ :** The connections those are potential to crosstalk-blocking the tagged path.

**Definition 3 Maximum allowed crosstalk,  $C_m$ :**  $C_m$  is defined the maximum allowed crosstalk along the tagged path.

**Definition 4 Allowed crosstalk,  $c$ :**  $c$  is defined the allowed crosstalk along the tagged path at any time.

**Module 2:** This module finds  $C_{bc}$  which is determined by the following relation:

$$I_i + O_j < \log_2 N + 2 \quad (1)$$

Here, input  $i$  has originated from input intersecting group  $I_i$  and destined to output  $j$  that belongs to output intersecting group  $O_j$  (see Fig.2).

We find  $C_{cbc}$  that must satisfy the following relation

$$I_i + O_j = \log_2 N + 1 \quad (2)$$

**Module 3:** This module assigns connection requests to different planes in the following way. The tagged path is assigned first to a plane randomly chosen. Then a connection from the list of  $C_{cbc}$  is assigned to the plane in which tagged path assign and allow one  $c$ . If  $c$  less than  $C_m$  then the next connection from the list of  $C_{cbc}$  is picked and assigned to the plane as mentioned above. When  $C_m$  reached then the other connections from the list of  $C_{bc}$  are assigned to the other free planes. The connections share the planes without conflicting each others. This plane assignment algorithm ensures the use of minimum number of planes for routing a permutation request. At last if there is a connection for which no such plane is available then the connection request pattern is recorded as a blocked connection pattern.

**Module 4:** In this module the blocking probability is estimated by the ratio of number of connection requests in which the 0-0 request is blocked to the total number of connection requests generated.

#### A.1. Lower Bound on Number of Planes Given Crosstalk Constraint

The simulation result for lower bound on blocking probability of VSOB networks under crosstalk constraint is given below:

Fig 5. Number of planes vs blocking probability for different crosstalk of VSOB (256,m) networks.

It is shown from Fig.5 that for  $N=256$ ,  $r=1.0$ ; if we allow 2 CSEs to the network then blocking probability decreases 52% for  $m=6$  and 60% for  $m=8$ . It is also shown from Fig.5 that for  $N=256$ ,  $r=1$ ; if we allow 3 CSEs to the network then BP decreases by 72% than  $c=0$  and if we increase the number of planes from 6 to 7 then BP decreases by 62%. This picture derives the fact that if we allow small amount of crosstalk then the blocking probability decreases rate is high compare the number of planes.

Fig. 6. Number of planes vs blocking probability for different crosstalk of VSOB (512,m) networks.

It is shown from Fig.6 that for  $N=512$ ,  $r=1.0$ ; if we allow 2 CSEs to the network then blocking probability decreases 54.6% for  $m=9$  and 56% for  $m=10$ .

Fig.7. load vs blocking probability for different Crosstalk.

The effect on blocking probability with load for various crosstalks for a fixed network size and number of planes is shown in Fig.7. If we decreases load from 1.0 to 0.8 then BP decreases 78.4% for  $c=0$  and 83% for  $c=1$ .

Fig. 8. Crosstalk vs blocking probability for different network size.

It is observed from fig.8 that for  $m=10$  &  $\text{load}=1$ ; if we allow 2 CSEs to the network then blocking probability decreases to 59% for  $N=256$  and 56% for  $N=512$ .

Fig.5 & 6 shows that the trend of variation of the blocking probability remains the same for different network size.

The simulation results show that blocking probability decreases for allowing CSEs because if we allow some CSEs to the network then the network SEs can be shared by more connections.

#### IV. CONCLUSION

We have presented approximate results of lower bound on blocking probability for VSOB networks with given certain degree of crosstalk constraint. The simulated results in section 3 can provide network developers with a guidance of quantitatively determining the effects of various degrees of crosstalk and reduction in number of planes on the overall blocking behaviors of VSOB networks. The results show that if we allow some CSEs which are negligible for higher network size then blocking probability decreases to approximate zero. The results can also show how crosstalk adds a new dimension to the performance analysis of VSOB networks and effects of crosstalk on hardware cost and blocking probability. A mathematical model for blocking probability of this network is under research.

**Abstract** — For faster connection establishment, previously proposed Pruned Vertically Stacked Optical Banyan (P-VSOB) networks used plane fixed routing (PFR) algorithm, and has  $O(\log_2 N)$  routing complexity. Blocking probability has also been analyzed for these kinds of networks with given amount of crosstalk. In EP-VSOB networks, a few regular banyan planes are added with the P-VSOB networks. Necessary routing algorithm, namely, PFR\_LS and PFR\_RS show that this switching network can reduce the blocking probability to very low value while keeping the hardware cost almost the same as that of P-VSOB networks. Both these algorithm also have the time complexity  $O(\log_2 N)$ . This paper deals with the blocking behavior of EP-VSOB (Extended pruned VSOB) networks having link-failures and allows crosstalk constraint. Our simulation results show that crosstalk adds a new dimension to the performance analysis of practical EP-VSOB networks where some links are failed. The results show that if we allow some CSEs to the network then blocking probability decreases to low value for both PFR\_LS and PFR\_RS algorithm. The results also show that the blocking probability of the EP-VSOB networks does not always increase with the increase of link-failures; blocking probability decreases for certain range of link-failures, and then increases again.

**Index Terms** — EP-VSOB network, crosstalk, link-failure.

## I. INTRODUCTION

Photonic switching networks play an important role within wavelength-division multiplexing (WDM) networks, where optical cross-connects (OXC) are greatly preferable to electronic switches. The main factors those have to be considered while designing any photonic switching networks are hardware cost, blocking probability, crosstalk, switching speed etc. Researchers have proposed many switching architectures having different merits in the literature. A few important works have been listed in the references.

Directional-coupler (DC) [1,2] can handle the optical signals of some terabits per second and with multiple wavelengths, and this make it ideal for serving as the basic  $2 \times 2$  switching element (SE) in high-speed optical switches. However, one of the major shortcomings of a DC is crosstalk. When two light signals go through an SE

simultaneously, crosstalk is generated at the SE. Such SE is referred to as a crosstalk SE (CSE). The degree of crosstalk of the switching system is defined as the number of CSE's allowed along a path.

Banyan networks [3,4,5,6] are attractive for constructing DC-based optical switches for their small depth, absolute loss uniformity, lower hardware cost and a simple switch setting ability (self-routing). With banyan structure, only a unique path exists between input-output pair in which the network is simply degraded as a blocking one. The blocking probability of banyan network is high. The whole network can be made nonblocking by vertically stacking multiple copies of an optical banyan network [7], known as vertically stacked optical banyan (VSOB) network. The VSOB network increases the hardware cost but decreases the blocking probability, and has  $O(N \log_2 N)$  time complexity. Due to high hardware cost and routing complexity of VSOB network, researchers proposed Pruned VSOB (P-VSOB) networks [8]. In P-VSOB network, PFR routing algorithm is used in which a plane of the VSOB network is fixed for a group of inputs and achieved  $O(\log_2 N)$  time complexity. Although P-VSOB networks guarantee considerably low blocking probability, but for some high performance applications, this blocking probability may be considered too high. In paper [12], the blocking probability of P-VSOB networks with given crosstalk have been determined. Khandker *et. al.* have proposed Extended-Pruned-VSOB (EP-VSOB) network [9] that has the potential to reducing the blocking probability while keeping the crosstalk constraint to zero. Necessary routing algorithm, namely PFR\_LS and PFR\_RS modifying the PFR algorithms have also been proposed. The EP-VSOB network has almost the same routing complexity as that of the P-VSOB network with significantly lower blocking probability. This switch network achieves the speed close to P-VSOB networks and blocking probability close to VSOB networks.

Due to the increasing importance and requirement for fault-tolerance in optical switches for large mesh WDM networks, performance analysis of VSOB networks at the

presence of probability of link failures becomes critical for the practical adoption of the VSOB networks in the current internet applications. Paper [10] deals the blocking behavior analysis of VSOB networks with link-failures and the author showed that VSOB network is a fault tolerant network. In paper [11], the blocking probabilities of P-VSOB networks having link failures have been determined. P-VSOB networks can accommodate some link failures safely without degrading the performance. In this paper, we analyze the blocking behavior of EP-VSOB networks with given some crosstalk constraint when some links are failed or broken in the network.

The rest of the paper is organized as follows. We discuss the published work briefly in section 2; especially EP-VSOB networks. Section 3 presents our contribution. We conclude this paper in section 4.

## II. PRELIMINARIES

A connection request may be blocked by link failures in a faulty VSOB network, which is referred to as the *failure-blocking*. We assume that the links in VSOB networks may fail independently and these failures are permanent. Thus, both crosstalk-blocking and failure-blocking should be fully considered in the blocking analysis of a faulty VSOB networks as illustrated in Fig.1 for a  $8 \times 8$  network.

Fig. 1. Blocking in a VSOB network. (a) Failure-blocking. (b) Crosstalk- blocking. (c) Combination of failure-blocking and crosstalk-blocking.

Due to their topological symmetry, all paths in a banyan network have the same property in terms of blocking. Through out this paper, we will select the path between the first input and the first output and try to set up a connection between them. We call the path between this input-output pair the tagged path. In this paper, we consider the banyan networks that support one-to-one communication. We define the blocking probability to be the probability that a feasible connection request is blocked, where a feasible connection request is a connection request between an idle input port and an idle output port of the network

### A. Pruned-VSOB network

P-VSOB  $(N,T)$  denotes an  $N \times N$  Pruned-VSOB network that has  $T$  fixed planes. In P-VSOB network, plane fixed

routing (PFR) algorithm is used for routing input signals to requested outputs. In PFR algorithm, we select one input from each input group  $I_i$  and tie them with a plane of VSOB  $(N, T)$  network permanently. Input groups  $I_i$  is defined as the set of inputs  $\{i, i+1, i+2, \dots, i+T-1\}$  as shown in Fig.2. We first define the following subsets of input taking on from each input sets:

$$G_i = \left\{ i, i+T, i+2T, \dots, i + \left( \frac{N}{T} - 1 \right) T \right\}; 0 \leq i \leq T-1$$

$$T = 2^{\lceil (\log_2 N + 1) / 2 \rceil}$$

In PFR algorithm all  $N$  inputs are always evenly distributed among the planes and each plane has only  $N/T$  connections. Since these  $N/T$  connections are fixed at their corresponding inputs in the plane, only 1 input of a group will be active; all other inputs will remain unused. Therefore, input switches connected to unused inputs and switches in the successive stages corresponding to these unused inputs are redundant. All these redundant switching elements are eliminated. Fig.3 explains the idea.

Fig. 2. Illustration of inputs and outputs grouping.

Fig. 3. The structure of a P-VSOB  $(16,4+2)$  network.

### B. Extended Pruned VSOB ( $N, T+K$ ) network

In this section, we describe previously proposed Extended-Pruned-VSOB network. EP-VSOB ( $N, T+K$ ) denotes an  $N \times N$  EP-VSOB network that has  $T$  fixed planes (pruned banyan) and  $K$  extra planes (regular banyan). The main idea of the EP-VSOB is to add a small number of regular banyan planes to the P-VSOB( $N, T$ ) network such that the connections blocked in the fixed  $T$  planes of the P-VSOB( $N, T$ ) network have more chances to be established through these extra  $K$  planes.

Depending on how a plane is chosen from the extra planes, we propose two routing algorithm for fast connection establishment in an EP-VSOB( $N, T+K$ ) network, namely PFR with linear search algorithm and PFR with random selection algorithm.

#### B.1. PFR with Linear Search (PFR\_LS)

In the PFR\_LS algorithm for an EP-VSOB( $N, T+K$ ) network, each connection now has  $(1+K)$  chances to be established through the network. Whenever a request arrives at an input, first it is sent to the fixed plane of that input. If the request cannot be established in the fixed plane, the input searches for a free plane among the extra  $K$  planes. The searching starts with the first plane and continues orderly up to the last one so that each plane is being searched at most one time by an input. If the connection request still fails to find a free plane among all  $K$  extra planes, it is considered as a blocked request. The time complexity of the PFR\_LS algorithm  $O(\log_2 N)$  when  $K$  is constant and much smaller compared to  $T$ .

#### B.2. PFR with Random Selection (PFR\_RS)

In the PFR\_RS algorithm for an EP-VSOB( $N, T+K$ ) network, each connection has two chances to be established through the network. The first chance is to establish the connection through its fixed plane. If the connection request is blocked in its fixed plane, it still has a second chance to be established through another plane selected randomly from  $K$  extra planes. If the connection request still could not be established through the randomly selected plane, it is considered as a blocked request. It is easy to see that the time complexity of the PFR\_RS algorithm remains the optimum  $O(\log_2 N)$ .

The simulation results of EP-VSOB networks without link failures are given below:

Fig. 4. Blocking probability of EP-VSOB networks without link-failures.

### III. EP-VSOB NETWORKS WITH LINK FAILURES AND GIVEN CROSSTALK

In this section, we analyzed the blocking behaviour of EP-VSOB networks having link-failures with allow some CSEs to the network using PFR\_LS and PFR\_RS algorithm.

#### A. Network simulator

The network simulator we developed consists of six major modules as shown in figure 5.

Fig. 5. Block diagram of the network simulator.

We consider here the permutation request as the traffic since a permutation does not have output contention, and therefore, gives real blocking probability of the switch network only. Due to the symmetric architecture of P-VSOB  $(N,T)$  network, every connection request has the same probability to be blocked. In our simulation, we fix the connection request of input-output pair 0-0 and investigate the blocking probability of this connection request only.

**Module 1:** This module randomly generates a permutation request for the VSOB  $(N,T)$  network based on the workload  $r$  (here workload  $r$  is defined as the occupancy probability of a port).

**Module 2:** This module generates link failures based on the given  $pfr$  (here  $pfr$  is defined as the probability that a link is failed or broken) and then assign those failures randomly to different links.

**Module 3:** This module initializes the switches with the permutation request.

**Module 4:** This module attempts to assign connection requests to different planes using PFR algorithm. We only consider the plane that contains the tagged path. We try to establish the tagged path in the selected plane with allow  $C_m$  (maximum allowed crosstalk) CSEs along the tagged path to the network. If the tagged path is not established, then we try to assign other connections in their selected planes.

**Module 5:** If the tagged path is not established in the selected plane then we try to establish the tagged path (along with other connections that are not established in their selected plane with allow  $C_m$  CSEs) in the extra planes with allow  $C_m$  CSEs along all connections path to the network. In case of PFR\_LS algorithm, the searching starts with the first plane and continues orderly up to the last one. If the tagged path still fails to find a free plane among all extra planes, it is considered as a blocked request. In case of PFR\_RS algorithm, we randomly selected a plane from extra planes. If the tagged path still could not be established through the randomly selected plane, it is considered as a blocked request.

**Module 6:** In this module the blocking probability is estimated by the ratio of number of connection requests in which the 0-0 request is blocked to the total number of connection requests generated.

#### A.1. PFR\_LS algorithm

The simulation results of EP-VSOB networks using PFR\_LS algorithm with link failures and allow CSEs are given below:

Fig. 6. Blocking probability decreases for certain range of link-failures and then increases again.

It is also interesting to note from Fig.6 that the blocking probability not always increases with the increase of link failures; blocking probability also decreases for certain range of link failures and then increases again. For  $N=128$ ,  $r=1$ , extra planes=2 &  $c=0$ ; if we introduce 0.015 link failure to the networks then BP increases 96.6%. Now if we allow 2 CSEs to the network then BP decreases 96.3%. That means the amount of performance degradation caused by link failures can be compensated by introducing CSEs. This may help switch designer choose a switch networks for different degree of performance with comparably low hardware cost.

The effect on blocking probability with load for different crosstalk is shown in Fig.7. If we reduce load 1 to 0.8 then BP decreases 31.5% for crosstalk=1, BP decreases 45.7% for crosstalk=2.

Fig. 7. Load vs blocking probability for different crosstalk.

Fig. 8. Blocking probability decreases dramatically with crosstalk.

It is shown from Fig.8 that for  $N=128$ ,  $pfr=0.01$ ,  $r=1$ ; if we allow 1 CSEs to the network then blocking probability decreases to 60% for extra planes=2 and 81% for extra planes=3.

## A.2. PFR\_RS algorithm

The simulation results of EP-VSOB networks using PFR\_RS algorithm with link failures and allow CSEs are given below

Fig. 9. Link failure vs blocking probability for different crosstalk.

It is shown from Fig.9 that for  $N=128$ ,  $pfr=0.01$ ,  $r=1$ , extra planes=2; if we allow 2 CSEs to the network then BP decreases by 89% than  $c=0$

Fig. 10. Blocking probability increases linearly with load.

Blocking probability increases linearly with load as shown in fig.10. If we reduce load 1 to 0.8 then BP

decreases 25% for crosstalk =2, BP decreases 37% for crosstalk=3.

Fig. 11. Crosstalk vs blocking probability for different extra planes.

It is shown from Fig.11 that for  $N=128$ ,  $pfr=0.01$ ,  $r=1$ ; if we allow 1 CSEs to the network then blocking probability decreases to 57.6% for extra planes=2 and 75% for extra planes=3.

From fig. 6 & 9 we can say that for  $N=128$ ,  $r=1$ , extra-planes =2 &  $pfr=0.01$ ; if we allow 2 CSEs to the network then blocking probability decreases to 96.5% for PFR\_LS algorithm and 89% for PFR\_RS algorithm.

From fig. 8 & 11 we observe that for  $N=128$ ,  $r=1$ ,  $c=1$  &  $pfr=0.01$ ; if we add 3 extra-planes to the network then blocking probability decreases to 81% for PFR\_LS algorithm and 75% for PFR\_RS algorithm.

#### IV. CONCLUSION

In this paper, we have presented simulation results of the blocking probability of EP-VSOB networks with link-failures and given crosstalk constraint. To guarantee the fast connection setup in the EP-VSOB networks, we use two PFR based routing algorithm, namely PFR\_LS & PFR\_RS algorithm. The results in section 3 shows that only allow 3 CSEs along a connection can reduce the blocking probability to negligible value. The result also shows the effects of crosstalk on hardware cost and

blocking probability. The performance of PFR\_LS algorithm is better than PFR\_RS algorithm. The simulation results presented in this paper can guide network designer in finding a tradeoff among the blocking probability, the degree of crosstalk, and link failures of EP-VSOB networks. A mathematical model for blocking probability of this network is under research.

**Abstract** — The bit error rate (BER) performance for quadrature amplitude modulation (QAM) with different diversity combining scheme is derived for Rayleigh fading channel using Log-likelihood ratio (LLR). Three combining techniques, maximal ratio combiner (MRC), selection combining (SC), and Equal Gain Combiner (EGC) are considered for the BER analysis in this paper. The average BER performance of QAM symbol through a flat fading channel is derived from the individual bits forming the QAM symbol with MRC, SC, and EGC space diversity. The analytical and simulation of BER performance of the QAM symbol through the fading channel with MMC, SC, and EGC combiner is compared. The both analytical and simulation result shows that the probability of bit error decreases with the order of diversity for all the cases of MRC, SC, and EGC. It is also seen from the results that MRC provides better BER performance than the other two combiners (SC and EGC) for the same environment of the fading channel.

**Index Terms** — Rayleigh Fading Channel, QAM, Diversity, Diversity Combiner, LLR.

## I. INTRODUCTION

The radio propagation in Doppler spread environment can be classified by three effects such as multi-path fading or fading, shadowing, and path loss. The signal transmitted from the transmitter to receiver via different path; the path may be line-of-sight (LOS) or Non-line-of-sight (NLOS). In a typical land mobile radio system, the LOS propagation path follows many NLOS reflected propagation paths. This type of propagation path is called multi-path. The channel impulse response of different paths cause individual signals of the corresponding paths arrives at the receiver with different amplitudes, phases and delays [1]. The fading causes the BER degradation of the transmitted symbol. The signal from different paths is added at the receiver. The signals are added constructively if all the incoming signals from different paths are in phase and the signals are added destructively if all the signals are out of phase. The constructive interference increases the signal strength and the destructive interference decreases the signal strength. Equalizer is used to increase the signal strength of the faded signal. The design complexity of the Equalizer is increased with the data rate [2]. The next generation wireless communication (3G and beyond) requires high data

rate, and equalizer is not suitable to minimize the effect of multi-path fading. Diversity is a technique to search for the strongest signal from the multi-path; this property of the diversity technique increases the demand of this technique for digital mobile radio services. The difficulty to send high-speed data is to achieve the limitation of channel capacity for multi-path fading effect. Two types of diversity are used in digital land mobile system, a) transmit diversity and b) receive diversity. Transmit is more efficient than receive diversity to reduce noise and multi-path fading effects [3]. In the proposed diversity technique, modulated complex symbols are transmitted as Space Time Block Code (STBC). In receive diversity one transmitter transmit symbol and two or more antennas received the transmitted symbols that arrive via different multi-path, and in transmit diversity two or more antennas are used to transmit symbol and one antenna is used to receive the multi-path signal. The BER increases when such symbols transmitted through the fading channel and for this reason the transmission channel has bandwidth limitation. The diversity branches carry the same information at the same time period but have uncorrelated multipath fading; the diversity combiner circuit combines those fading signals or selects the path having the highest signal strength. The multi-path fading appearing in the diversity branches becomes uncorrelated if the spacing between the adjacent antennas at receiver site are properly selected.

There are a number of diversity combiner circuits, usually classified into the three categories, such as, Maximal Ratio Combiner (MRC), Selection Combiner (SC), and Equal Gain Combiner (EGC). In MRC, the signal received from different branches are weighted, co-phased and then summed to obtain the highest received signal strength [4]. In SC, the signal having the highest instantaneous signal to noise (SNR) is selected from the multi-path. The EGC receives all the multi-path signals, co-phased and summed but not weighted. The MRC provides highest BER improvement of the multi-path fading channel but SC is more suitable for mobile radio applications because of its simple implementation. The quadrature amplitude modulation (QAM) is one of the effective techniques among all other modulation techniques to achieve highest spectral efficiency for the next broadband wireless communication

system through Rayleigh fading channel under the condition when the receiver is capable to estimate the channel state information (CSI) [2]. Space diversity is used to combat multi-path fading in mobile radio communications, and diversity gain is achieved at the desired level without increasing the corresponding transmission power [5]. The individual bit in QAM symbol is affected independently by the faded channel (frequency selective or frequency non-selective) and noisy channel i.e. Additive White Gaussian Noise (AWGN). The overall BER of QAM symbol is affected by the channel noise because the individual bits are affected independently. The Log-likelihood Ratio (LLR) for individual bit of QAM symbol is derived for flat fading channels [6]. In this paper, we derived the BER expression of each bit in QAM symbol based on LLR approach for a Rayleigh fading channel with MRC, SC and EGC combiner circuits. The MRC weighed each diversity branch in a co-phased manner and for this we obtain the highest SNR at the receiver site. The SNR expression for MRC is applied to find the BER expression based on LLR analysis of each bit. The average BER for QAM in Rayleigh fading channels can also be determined [4]. The SC and EGC use the average SNR for determining the average BER of QAM. A simulation work is done to find the BER performance of M-ary QAM for a Rayleigh fading channel for MRC, SC and EGC. Here, the BER expression of individual bits of QAM is used to find the average BER of the QAM symbol through a fading channel. Finally, we compare the analytical and simulated average BER performance of QAM symbol for Rayleigh fading channel for MRC, SC and EGC.

## II. PROBABILITY OF BER USING LLR SCHEME

Let us consider 16-QAM, where the 4 bits ( $r_1, r_2, r_3, r_4$ ) are mapped on to a complex symbol  $a = a_1 + ja_0$ . If the modulated symbol undergoes multi-path fading, then the received signal  $y$  can be written as

$$y = ha + n \quad (1)$$

where  $h$  is complex channel impulse response, which is assumed to be Rayleigh distributed, and  $n = n_1 + jn_0$  is a complex noise of zero mean and variance  $\sigma^2/2$ .

The LLR of bit  $r_i = 1, 2, 3, 4$  of the received symbol can be given as [6] is:

$$LLR(r_i) = \log \left( \frac{\sum_{\alpha \in S^{(1)}_i} P_r \{a = \alpha | y, h\}}{\sum_{\beta \in S^{(0)}_i} P_r \{a = \beta | y, h\}} \right) \quad (2)$$

For independent symbol using Bayes' rule, we have

$$LLR(r_i) = \log \left( \frac{\sum_{\alpha \in S^{(1)}_i} f_{y|h,a} \{y|h, a = \alpha\}}{\sum_{\beta \in S^{(0)}_i} f_{y|h,a} \{y|h, a = \beta\}} \right) \quad (3)$$

$$f_{y|h,a} \{y|h, a = \alpha\} = \frac{1}{\sigma\sqrt{\pi}} \exp \left( -\frac{1}{\sigma^2} \|y - h\alpha\|^2 \right), \text{ Now,}$$

Eq.(3) can be written as:

$$LLR(r_i) = \log \left( \frac{\sum_{\alpha \in S^{(1)}_i} \exp \left( -\frac{1}{\sigma^2} \|y - h\alpha\|^2 \right)}{\sum_{\beta \in S^{(0)}_i} \exp \left( -\frac{1}{\sigma^2} \|y - h\beta\|^2 \right)} \right) \quad (4)$$

Using the identity  $\log \left( \sum_j \exp(-X_j) \right) \approx -\min_j (X_j)$ ,

we can write Eqn. (4) as:

$$LLR(r_i) = \frac{1}{\sigma^2} \left\{ \min_{\beta \in S^{(0)}_i} \|y - h\beta\|^2 - \min_{\alpha \in S^{(1)}_i} \|y - h\alpha\|^2 \right\} \quad (5)$$

We define a variable,  $z = \frac{y}{h} = a + \frac{n}{h} = a + \hat{n}$ , where  $\hat{n}$

is Gaussian complex random variable and normalizing

$LLR(r_i)$  by  $4/\sigma^2$ , we get:

$$LLR(r_i) = \frac{\|h\|^2}{4} \left\{ \min_{\beta \in S^{(0)}_i} \|z - \beta\|^2 - \min_{\alpha \in S^{(1)}_i} \|z - \alpha\|^2 \right\}$$

$$LLR(r_i) = \frac{\|h\|^2}{4} \left\{ \min_{\beta \in S^{(0)}_i} \left\{ \|\beta\|^2 - 2z_I\beta_I - 2z_Q\beta_Q \right\} - \min_{\alpha \in S^{(1)}_i} \left\{ \|\alpha\|^2 - 2z_I\alpha_I - 2z_Q\alpha_Q \right\} \right\} \quad (6)$$

where  $z = z_I + jz_Q$ ,  $\alpha = \alpha_I + j\alpha_Q$  and  $\beta = \beta_I + j\beta_Q$ . The LLR for bit  $r_1, r_2, r_3$ , and  $r_4$  becomes-

$$LLR(r_1) = \left\{ \begin{array}{l} -\|h\|^2 z_I d, \forall |z_I| \leq 2d \\ 2\|h\|^2 d(d - z_I), \forall z_I > 2d \\ -2\|h\|^2 d(d + z_I), \forall z_I < -2d \end{array} \right\} \quad (7)$$

$$LLR(r_2) = \left\{ \begin{array}{l} -\|h\|^2 z_Q d, \forall |z_Q| \leq 2d \\ 2\|h\|^2 d(d - z_Q), \forall z_Q > 2d \\ -2\|h\|^2 d(d + z_Q), \forall z_Q < -2d \end{array} \right\} \quad (8)$$

$$LLR(r_3) = \|h\|^2 d \{ |z_I| - 2d \} \quad (9)$$

$$LLR(r_4) = \|h\|^2 d \{ |z_Q| - 2d \} \quad (10)$$

Here,  $2d$  is the minimum Euclidean distance, and can be computed according to [7]

$$d = \sqrt{\frac{3m.E_b}{2(M-1)}} \quad (11)$$

where  $m=\log_2 M$ ,  $M$  represents the number of bits per symbol and  $E_b$  represents the average energy per bit.

The probability of error for bit  $r_1$ ,  $P_{b1}$ , is according to [3]:

$$P_{b1} = P_{b1|a_I=-d} P_r\{a_I = -d\} + P_{b1|a_I=-3d} P_r\{a_I = -3d\} + P_{b1|a_I=d} P_r\{a_I = d\} + P_{b1|a_I=3d} P_r\{a_I = 3d\} \quad (12)$$

$$\text{where, } P_{b1|a_I=-d,h} = Q\left(\sqrt{\frac{4E_b\|h\|^2}{5N_0}}\right)$$

It can be written as

$$P_{b1|a_I=-d} = Q\left(\sqrt{\frac{4E_b\|h\|^2}{5N_0}}\right) = \frac{1}{\sqrt{2\pi p_1}} \exp\left(-\frac{1}{2} p_1\right), \quad (13)$$

$$p_1 = \sqrt{\frac{4E_b}{5N_0}}$$

Similarly  $P_{b1|a_I=-3d}$  can be written as:

$$P_{b1|a_I=-3d} = Q\left(\sqrt{\frac{36E_b\|h\|^2}{5N_0}}\right) = \frac{1}{\sqrt{2\pi p_2}} \exp\left(-\frac{1}{2} p_2\right), \quad (14)$$

$$p_2 = \sqrt{\frac{36E_b}{5N_0}}$$

Therefore  $P_{b1}$  is

$$P_{b1} = \frac{1}{2\sqrt{2\pi p_1}} \exp\left(-\frac{1}{2} p_1\right) + \frac{1}{2\sqrt{2\pi p_2}} \exp\left(-\frac{1}{2} p_2\right) \quad (15)$$

For 16-QAM,  $P_{b1}=P_{b2}$ , and the error probability  $P_{b3}$  and  $P_{b4}$  are:

$$P_{b3} = \frac{1}{2} \left( 2P_{b1|a_I=-d} + P_{b1|a_I=-3d} - \frac{1}{\sqrt{2\pi p_3}} \exp\left(-\frac{1}{2} p_3\right) \right) \text{ where,} \quad (16)$$

$$p_3 = \sqrt{\frac{100E_b}{5N_0}}$$

The average bit error rate of 16QAM symbol

$$P_b = \frac{1}{2} (P_{b1} + P_{b3}) \quad (17)$$

### III. SYSTEM MODEL

If a signal  $S(t)$  is transmitted at symbol period  $T$ , the received signal for a postdetection diversity receiver can be written as [9]

$$r_k(t) = h_k S(t) + n_k(t), \quad k=1, 2, \dots, L \quad (18)$$

where  $h_k(t)$  is the channel impulse response for the  $k^{\text{th}}$  diversity branch and  $n_k(t)$  is the AWGN noise for the  $k^{\text{th}}$  fading channel.

#### A. MAXIMAL RATIO COMBINING (MRC)

With MRC, each diversity branch is weighted by their respective fading gain, co-phased, and added. The received signal vectors

$$\bar{r} = (r_1, r_2, \dots, r_L) \quad (19)$$

from each of the  $L$  diversity branch are added to provide maximum SNR. If each branch has fading gain  $h_k$ , then the diversity combiner generates the sum [8]

$$\bar{r} = \sum_{k=1}^L h_k^* r_k \quad (20)$$

The envelope of the composite signal is

$$\alpha_M = \sum_{k=1}^L \alpha_k^2 \quad (21)$$

where  $h_k = \alpha_k \exp(-j\theta_k)$ . The weighted sum of the branch noise power of each branch has the same average noise power  $N_0$  expresses by:

$$N = N_0 \sum_{k=1}^L \alpha_k^2 \quad (22)$$

The SNR at the detector device is,  $\gamma_M = \frac{r^2_M}{2N_T}$

The maximum value of  $\gamma_M$ , according to [9] is:

$$\gamma_M = \frac{1}{2} \sum_{k=1}^L \frac{r_k^2}{N_0} = \sum_{k=1}^L \gamma_k \quad (23)$$

The individual average SNR for each diversity branch is given by

$$SNR = \Gamma = \frac{E_b}{N_0} \alpha^2$$

where  $\alpha^2=1$ .

The average SNR ( $\bar{\gamma}_M$ ) equals to the sum of the individual average SNR [8]:

$$\bar{\gamma}_M = \sum_{k=1}^L \gamma_k = \sum_{k=1}^L \Gamma = L\Gamma \quad (24)$$

The probability of error for distance  $-d$  ( $P_{b1|a_I=-d}$ ) for MRC space diversity is given by applying the average SNR from (24) into (12), and then we get:

$$P_{b1|a_I=-d} = Q\left(\sqrt{L \frac{4E_b}{5N_0}}\right)$$

$$= \frac{1}{\sqrt{2\pi p_1}} \exp\left(-\frac{1}{2} p_1\right), p_1 = \sqrt{L \frac{4E_b}{5N_0}} \quad (25)$$

Similarly, the error for distance  $-3d$  ( $P_{b1|a_I=-3d}$ ) from (13), we have:

$$P_{b1|a_I=-3d} = Q\left(\sqrt{L \frac{36E_b}{5N_0}}\right) = \frac{1}{\sqrt{2\pi p_2}} \exp\left(-\frac{1}{2} p_2\right), p_2 = \sqrt{L \frac{36E_b}{5N_0}} \quad (26)$$

Hence, the probability of error for 1<sup>st</sup> bit in the QAM symbol is  $P_{b1} = \frac{1}{2}(P_{b1|a_I=-d} + P_{b1|a_I=-3d})$ . Using Eqs. (25) and (26) the bit error is expressed as:

$$P_{b1} = \frac{1}{2\sqrt{2\pi p_1}} \exp\left(-\frac{1}{2} p_1\right) + \frac{1}{2\sqrt{2\pi p_2}} \exp\left(-\frac{1}{2} p_2\right) \quad (27)$$

Now, we know  $P_{b3}=P_{b4}$ . Similarly, by the similar argument as above, the probability of error for 3<sup>rd</sup> and 4<sup>th</sup> bit can be given as

$$P_{b3} = \frac{1}{2} \left( 2P_{b1|a_I=-d} + P_{b1|a_I=-3d} - \frac{1}{\sqrt{2\pi p_3}} \exp\left(-\frac{1}{2} p_3\right) \right),$$

where  $p_3 = \sqrt{L \frac{100E_b}{5N_0}}$  (28)

From (27) and (28), the average bit error for MRC space diversity is given as:

$$P_b = \frac{1}{2}(P_{b1} + P_{b3}) = \frac{3}{4\sqrt{2\pi p_1}} \exp\left(-\frac{1}{2} p_1\right) + \frac{1}{2\sqrt{2\pi p_2}} \exp\left(-\frac{1}{2} p_2\right) - \frac{1}{4\sqrt{2\pi p_3}} \exp\left(-\frac{1}{2} p_3\right) \quad (29)$$

## B. SELECTION COMBINING

In SC the detector select the highest SNR path, in this case the diversity combiner performs the operation

$$\bar{r} = \max_{|h_k|} |r_k| \quad (30)$$

The instantaneous SNR ( $\gamma_k$ ) of  $k^{\text{th}}$  branch has the probability density function [8] is expressed as:

$$p(\gamma_k) = \frac{1}{\Gamma} \exp\left(-\frac{\gamma_k}{\Gamma}\right) \quad (31)$$

where  $\Gamma$  is the mean SNR of each branch [9] is:

$$\text{SNR} = \Gamma = (E_0/N_0) \bar{\alpha}^2 \quad (32)$$

We assume  $\bar{\alpha}^2 = 1$ . The average SNR with SC [8] is:

$$\bar{\gamma} = \Gamma \sum_{k=1}^L \frac{1}{k} \quad (33)$$

Let us define the average SNR by  $\beta = \bar{\gamma} = \frac{E_b}{N_0} \sum_{k=1}^L \frac{1}{k}$ ,

then from Eq.(27), we have the bit error for 1<sup>st</sup> bit with SC expressed as:

$$P_{b1} = \frac{1}{2\sqrt{2\pi q_1}} \exp\left(-\frac{1}{2} q_1\right) + \frac{1}{2\sqrt{2\pi q_2}} \exp\left(-\frac{1}{2} q_2\right),$$

where  $q_1 = \sqrt{\beta \frac{4E_b}{5N_0}}$  and  $q_2 = \sqrt{\beta \frac{36E_b}{5N_0}}$

Now from (28) the error for 3<sup>rd</sup> and 4<sup>th</sup> bit of QAM symbol with the assumption  $P_{b3} = P_{b4}$  can be given as:

$$P_{b3} = \frac{1}{2} \left( 2P_{b1|a_I=-d} + P_{b1|a_I=-3d} - \frac{1}{\sqrt{2\pi q_3}} \exp\left(-\frac{1}{2} q_3\right) \right), \text{ where}$$

$$q_3 = \sqrt{\beta \frac{100E_b}{5N_0}}$$

The average probability of bit error for SC space diversity through Rayleigh fading channel can be given as

$$P_b = \frac{1}{2}(P_{b1} + P_{b3}) = \frac{3}{4\sqrt{2\pi q_1}} \exp\left(-\frac{1}{2} q_1\right) + \frac{1}{2\sqrt{2\pi q_2}} \exp\left(-\frac{1}{2} q_2\right) - \frac{1}{4\sqrt{2\pi q_3}} \exp\left(-\frac{1}{2} q_3\right) \quad (34)$$

## C. EQUAL GAIN COMBINER (EGC)

The EGC is same as MRC but different from it that the diversity branches are not weighted. The combiner generates the sum [8]

$$\bar{r} = \sum_{k=1}^L \exp(-\theta_k) \bar{r}_k \quad (35)$$

The envelope of the composite signal is

$$\alpha_E = \sum_{k=1}^L \alpha_k \quad (36)$$

The resulting SNR is

$$\bar{\gamma}_M = \frac{\alpha^2 E_b}{L N_0} = \frac{1}{L} \sum_{k=1}^L \gamma_k = \frac{1}{L} \times L \Gamma = \Gamma \quad (37)$$

The probability of error due to distance  $-d$  ( $P_{b1|a_i=-d}$ ) for EGC space diversity is given by applying the average SNR from Eq.(37) into Eq.(12), we have

$$P_{b1|a_i=-d} = Q\left(\sqrt{\frac{4E_b}{5N_0}}\right) = \frac{1}{\sqrt{2\pi p_1}} \exp\left(-\frac{1}{2} p_1\right), p_1 = \frac{4E_b}{5N_0} \quad (38)$$

Similarly, the error probability for distance  $-3d$  ( $P_{b1|a_i=-3d}$ ) from Eq.(13), we have:

$$P_{b1|a_i=-3d} = Q\left(\sqrt{\frac{36E_b}{5N_0}}\right) = \frac{1}{\sqrt{2\pi p_2}} \exp\left(-\frac{1}{2} p_2\right), p_2 = \frac{36E_b}{5N_0} \quad (39)$$

Hence, the probability of error for 1<sup>st</sup> bit in the QAM

symbol is  $P_{b1} = \frac{1}{2} (P_{b1|a_i=-d} + P_{b1|a_i=-3d})$ . Using

Eqs.(38) and (39) the bit error is expressed as:

$$P_{b1} = \frac{1}{2\sqrt{2\pi p_1}} \exp\left(-\frac{1}{2} p_1\right) + \frac{1}{2\sqrt{2\pi p_2}} \exp\left(-\frac{1}{2} p_2\right) \quad (40)$$

The probability of error for 3<sup>rd</sup> and 4<sup>th</sup> bit can be given with the assumption  $P_{b3}=P_{b4}$  as:

$$P_{b3} = \frac{1}{2} \left( 2P_{b1|a_i=-d} + P_{b1|a_i=-3d} - \frac{1}{\sqrt{2\pi p_3}} \exp\left(-\frac{1}{2} p_3\right) \right),$$

$$\text{where } p_3 = \frac{100E_b}{5N_0} \quad (41)$$

Using Eqs. (40) and (41), the average bit error for EGC is as:

$$P_b = \frac{1}{2} (P_{b1} + P_{b3}) = \frac{3}{4\sqrt{2\pi p_1}} \exp\left(-\frac{1}{2} p_1\right) + \frac{1}{2\sqrt{2\pi p_2}} \exp\left(-\frac{1}{2} p_2\right) - \frac{1}{4\sqrt{2\pi p_3}} \exp\left(-\frac{1}{2} p_3\right) \quad (42)$$

#### IV. RESULTS

The simulation results for the BER performance of MRC, SC and EGC space diversity with 16-QAM for  $2 \times 2$  diversity system for Rayleigh fading channel is shown in

Fig.1. The simulation results show that MRC provides better BER performance than SC and EGC. The analytical BER performance of 16-QAM for Rayleigh fading channel with MRC space diversity is obtained from Eq.(29), and is shown in Fig. 2 for  $L = 1$  to 8. It is seen from Figs. 1 and 2 that at  $E_b/N_0 = 10$  dB with 2 transmit and 2 receive antenna system, the simulated and analytical BER is 0.0015 and 0.0028 respectively. The analytical BER performance of 16-QAM symbol for Rayleigh fading channel with SC space diversity is obtained from Eq.(34), and is shown in Fig. 3 for  $L = 1$  to 8.

Fig.1. Simulated BER performance of MRC, SC, and EGC with 2 transmits and 2 receive antennas.

It is seen from Figs. 1 and 3 that for  $E_b/N_0 = 10$  dB with 2 transmit and 2 receive antenna system for Rayleigh fading channel, the simulated and analytical values of BER are 0.13 and 0.2 respectively. Similarly, the analytical BER performance of 16-QAM symbol for  $L = 1$  to 8 for Rayleigh fading channel with EGC space diversity is obtained from Eq.(42), and is shown in Fig. 4.

The simulated and analytic BER values of EGC are 0.193 and 0.212 respectively at  $E_b/N_0 = 10$  dB with  $2 \times 2$  space diversity. The theoretical BER performance results of MRC, SC, and EGC from Figs.2, 3, and 4 show that the BER for MRC space diversity are higher than those of SC and EGC values, because MRC weights and adds all branch signals while SC selects one branch having the highest SNR and EGC does not weight each branch but the only co-phased signal.

Fig. 2: The analytical BER Performance of 16-QAM with MRC space diversity in Rayleigh fading channels evaluated using (29).

Fig. 3: The BER Performance of 16-QAM with SC space diversity in Rayleigh fading channels according to (34).

## V. CONCLUSION

In this paper, we compare the BER performance of different diversity combiners specially MRC, SC and EGC. The theoretical and simulated BER performance values are shown in this work. The theoretical values are calculated using LLR approach and the simulation values are found by sending a 16-QAM symbol through Rayleigh fading channel.

Both theoretical and analytical BER performance values show that the MRC provides the highest BER performance than those of the other two combiners. The BER performances are also calculated for MRC and SC space diversity for Rayleigh fading channel in work [5]. The simulation results in Fig.1 show that the BER values at  $E_b/N_0 = 10$  dB for MRC and SC are 0.0015 and 0.13 respectively for  $2 \times 2$  diversity. In work [5], the BERs for MRC and SC at  $E_b/N_0 = 10$  dB are 0.03 and 0.24 respectively. We get the BER values at  $E_b/N_0 = 10$  dB to be 0.0028 and 0.2 for MRC and SC from the LLR based BER

derivation as in Eqs.(29) and (34). The key contribution of our paper is that our LLR based BER calculation and simulated BER performance are more accurate than the BER derivation in work [5].

Fig. 4: The BER Performance of 16-QAM with EGC space diversity in Rayleigh fading channels based on (42).

# Learning Intrusion Detection Based on Adaptive Bayesian Algorithm

Dewan Md. Farid, Mohammad Zahidur Rahman

Department of Computer Science and Engineering, Jahangirnagar University, Savar, Dhaka-1342, Bangladesh. Emails: [dmfarid@uiu.ac.bd](mailto:dmfarid@uiu.ac.bd), [rmzahid@juniv.edu](mailto:rmzahid@juniv.edu)

**Abstract** — Recent intrusion detection have emerged an important technique for information security systems. It's very important that the security mechanisms for an information system should be designed to prevent unauthorized access of system resources and data. Last few years, many intelligent learning techniques of machine learning applied to the large volumes of complex and dynamic audit data for the construction of efficient intrusion detection systems (IDS). This paper presents, theoretical overview of intrusion detection and a new approach for intrusion detection based on adaptive Bayesian algorithm. This algorithm correctly classify different types of attack of KDD99 benchmark intrusion detection dataset with high detection accuracy in short response time. The experimental result also shows that, this algorithm maximize the detection rate (DR) and minimized the false positive rate (FPR) for intrusion detection.

**Index Terms** — Intrusion detection, Bayesian algorithm, classification, detection rate, false positive rate.

## I. INTRODUCTION

Development of interconnection of computer systems have increased the number of threats to information security systems. To defend various cyber attacks and computer viruses, lots of computer security technique have been introduced in the last few years, which include cryptography, firewalls, and intrusion detection systems (IDS) etc. Among all IDS become more promising for defending complex and dynamic intrusion behaviors. IDS was introduced by Anderson in 1980 [1]. He coined an intrusion as an attempt or a threat to be the potential possibility of a deliberate unauthorized attempt to access information, manipulate information, and render a system unreliable. The main goal of an IDS is to detect computer security incidents accurately in real-time and process the appropriate actions. The most popular IDS uses audit data to detect both pattern-based and anomaly-based detection [2]. An audit data is a record of activities generated by the operating system that are logged to a file in chronologically sorted order. Thus, one of the important problems for IDS is to built patterns to distinguish normal behaviors from abnormal behaviors by observing collected audit data. Because the behavior of an IDS is highly dependent on its environment, it is hard to program an IDS using ordinary procedural programming languages in a constantly changing environment. On the other hand,

large sizes of audit data generated everyday by the computer system makes manual analysis impossible. To solve this problem, earlier IDS usually rely on security experts to analyze the audit data and construct intrusion detection rules manually [3].

Due to the above deficiencies of IDS, intrusion detection techniques are using machine learning algorithms, such as Neural Networks, SVMs, Genetic algorithm, and Naïve Bayesian Classifier, and Decision Tree etc. [4], [5] to detecting known and unknown intrusions. IDS based on machine learning aims to solve the problems of analyzing huge volumes of audit data and realizing performance optimization of detection rules. By making use of machine learning algorithms, intrusion detection models can be automatically constructed based on labeled or unlabeled audit data. Despite of many advances that have been archived, existing IDS still have some difficulties, such as low detection accuracy, unbalanced performance on different attack types and long response time. It is also difficult to improve detection abilities for complex or new attacks without increasing false alarms. Another difficulty of current IDS is to detect high speed network traffics in real time. Because in high speed networks, IDS have to deal with large volumes of data in a short time. So, it is another challenging problem for IDS research to maintain high detection accuracy for high speed networks. In host-base IDS, there still exist other difficult problems for sequential behavior prediction.

The Bayesian algorithm is an efficient method for performing supervised learning [6], [7]. It provides an optimal way to predict the class of an unknown example. It is widely used in many fields of data mining, image processing, bio-informatics, and information retrieval etc. In the basic Bayesian algorithm, conditional probabilities for each attribute value are calculated from a given training set. These conditional probabilities are then used to find out the probabilities of belongingness to different classes. The unseen example is then categorized to that class, which assumes the maximum value. In this paper, based on a comprehensive analysis for the current research challenges in intrusion detection, a new method for intrusion detection using adaptive Bayesian algorithm is presented. Experiment on benchmark data such as KDD99 dataset show that this algorithm correctly classify different

types of attack with high detection accuracy in short response time. Also this algorithm maximize the detection rate (DR) and minimize false positive rate (FPR) for intrusion detection.

In this paper a brief introduction of intrusion detection is presented in section II. In section III our proposed algorithm is presented. Finally experimental result and conclusion are presented in section IV and V.

## II. OVERVIEW OF THE INTRUSION DETECTION

Intrusion detection is the process of identifying unauthorized usage of a computer system. It is an important skill for computer system administrators. It is difficult to learn on the job because it is needed only occasionally but can be critical. The most popular IDS uses audit data to detect intrusions. IDS collect information from a variety of systems and analyze the information for signs of intrusions. In general, there are seven types of IDS that are discussing bellow:

- 1) Network IDS detects intrusions by reading all the incoming packets and trying to find suspicious patterns. It monitors multiple hosts and investigates network traffic by connecting with network devices, like: hub, switch, and router. It also inspects the outgoing or local network traffic as well to identify the internal intruders (who abuse their privileges).
- 2) Protocol-based IDS is installed on a server and analysis the protocol that is use by the server. It sit at the front end of a server, monitoring and analyzing the dynamic behavior and state of the communication protocol between a connected device (a user/PC or system) and the server.
- 3) Application protocol-based IDS normally sits between a group of services/ process, monitor and analysis the behavior and state of the application protocol in use by the system between two connected devices.
- 4) Anomaly-based IDS or misuse intrusion detection detects computer intrusions and misuse by monitoring system activity and classifying it as either normal or anomalous. It attempts to characterize normal operation, and try to detect any deviation from normal behavior. The advantage of anomaly detection is a relatively high detection rate for new types of intrusions.
- 5) Signature-based IDS performs simple pattern matching for match a pattern corresponding to a known attack type. It is also known as pattern-based IDS. The main advantage of

signature-based IDS is that it has a relatively low rate of false alarms, which means is has a relatively high precision. And the main disadvantage of this IDS is that the detection rate of attacks is relatively low, because attacker will try to modify the basic attack signature in such a way that it will not match the known signatures of that attack and it cannot detect a new attack for which a signature is not yet installed in the database.

- 6) Host-based IDS identifies intrusions by analyzing system calls, application logs, file-system modifications, and other host activities. It installed on individual systems to examine the internal interfaces. It monitor the operating system and write data to log files and/or trigger alarms.
- 7) Hybrid IDS combines one or more approaches. Host agent data is combined with network information to form a comprehensive view of the network.

### A. Intrusion Detection Data

Intrusion detection data set was built a predictive model or classifier capable of distinguishing between “bad” connections, called intrusion or attacks, and “good” normal connections. In 1998, to compare the performance of various intrusion detection methods, a simulated environment was set up by the MIT Lincoln Lab. The objective was to survey and evaluate research in intrusion detection. A standard set of data to be audited, which includes a wide variety of intrusions simulated in military network environment. The KDD99 benchmark data set for intrusion detection uses a version of this data set. In KDD99 data set, each data record corresponds to the features of a connection in the network data flow. A connection is a sequence of TCP packets starting and ending at some well defined times, between which data flows to and from a source IP address to a target IP address under some well defined protocol. Each connection is labeled either as normal or as an attack, with exactly one specific attack type. The data records are all labeled with one of the following five classes:

- 1) Normal is a class that generated by simulated daily user normal behavior.
- 2) Probing is a class of attacks where an intruder scans a network to gather information or find known vulnerabilities. An intruder with a map of machines and services that are available on a network can use the information to look for exploits.

- 3) Denial of service is a class of attacks where an intruder makes some computing or memory resource too busy or too full to handle legitimate requests, thus denying legitimate users access to a machine.
- 4) User to root exploits are a class of attacks where an intruder starts out with access to a normal user account on the system and is able to exploit vulnerability to gain root access to system.
- 5) Remote to user attack is a class of attacks where an intruder sends packets to a machine over a network, then exploits machine's vulnerability to illegally gain local access as a user.

### III. PROPOSED METHOD

Correct classification for different types of attack is one of the central problems for intrusion detection. Supervised or unsupervised learning algorithms are using to classify different types of attack in intrusion detection, but their performance are not very satisfactory due to the challenging problem of detecting novel attacks with low false alarms. In this section, we proposed a new algorithm to classify the different types of attack for intrusion detection, using adaptive Bayesian algorithm.

#### A. Naïve Bayesian Algorithm

The naïve Bayesian (NB) algorithm is used for learning task, where a training set with target class is provided. Training set is described by attributed  $A_1$  through  $A_n$  and each attribute is described by attribute values  $a_1, a_2, \dots, a_n$  associated with class  $C$ . The objective is to classify an unseen example, whose class value is unknown but attribute values are known. The Bayesian approach to classifying the unseen example is to assign the most probable target class,  $C_{MAP}$  given the attribute values ( $a_1, a_2, \dots, a_n$ ) that describe the example.

$$C_{MAP} = \underset{C_j}{\operatorname{argmax}} \sum C^P(C_j | a_1, a_2, \dots, a_n)$$

The expression can be rewrite using Bayesian theorem as  $C_{MAP} = \underset{C_j}{\operatorname{argmax}} \sum C^P(a_1, a_2, \dots, a_n | C_j) P(C_j)$  (1) It is easy to estimate each of the  $P(C_j)$  simply by counting the frequency with which each target class  $C_j$  occurs in the training set. The naïve Bayesian algorithm is based on the simplifying assumption that given the target class of the example, the probability of observing the conjunction  $a_1, a_2, \dots, a_n$  is just the product of the probabilities for the individual attributes:  $P(a_1, a_2, \dots, a_n | C_j) = \prod_i P(a_i | C_j)$ . Substituting this into equation 1, we get

$$C_{NB} = \underset{C_j}{\operatorname{argmax}} \sum C^P(C_j \cdot \prod_i P(a_i | C_j)) \quad (2)$$

Where  $C_{NB}$ , denote the target class predicate by the naïve Bayesian classifier. In naïve Bayesian algorithm, the

probability values of equation 2, are estimated from the given training data. These estimated values are then used to classify unknown examples.

#### B. Improved Adaptive Bayesian Algorithm

In our improved Bayesian algorithm, we estimate the class conditional probabilities for each attribute value based on their frequencies in the training dataset. We calculate the sum of weights for each class from the training dataset. Initially all the training dataset have unit weight. Then we calculated the sum of weights for each attribute value with respect to same class. Finally, we calculate the class conditional probabilities for each attribute value from the training dataset by dividing the sum of weights for each attribute value by the sum of weights for each class. After calculating the class conditional probabilities for each attribute value from the training dataset, we classify the test dataset. If any test example is misclassified, we update the weights of training dataset. We compare each of test example with every of training examples and compute the similarity between them (out of four attributes two attribute values are same then similarity becomes 0.5 or one attribute value is same then similarity is 0.25 and so on), and then weights of training dataset are increased by a fixed small value multiplied by the corresponding similarity measure. If the test example is correctly classified, then the weights of training set will remain unchanged. After weights adjustment, the class conditional probabilities for attribute values are recalculated from the modified training dataset. If the new set of probabilities correctly classifies all the test examples, the algorithm terminates. Otherwise, the iteration continues until all the test examples are correctly classified or the target accuracy is achieved. At this stage the algorithm terminates, the class conditional probabilities are preserved for future classification of seen or unseen intrusions.

Algorithm I: Improved Adaptive Bayesian Algorithm (IABA)

Input: training set, test set, weight

Output: intrusion detection model

Procedure:

1. Initialize the weights  $W_1, W_2, \dots, W_n$  of training set:  
 $\text{for } (i = 1 \cdot N)$   
 $W_i = 1.0;$
2. Calculate the sum of weights for each class is training set:  
 $\text{for } (i = C_i \cdot C_N)$   
 $\text{for } (j = 1 \cdot N)$   
 $\text{if } (W_j \cdot C_i) \text{ then } (W_{Ci} = W_{Ci} + W_j);$
3. Calculate the sum of weights for each attribute value in training set:  
 $\text{for } (i = A_i \cdot A_N)$

$for(j = a_i \bullet a_n)$   
 $for(k = C_i \bullet C_n)$   
 $W_{a_{ij}} = W_{a_{ij}} + W_k;$

4. Calculate the class conditional probabilities for each attribute value for training set:

$for(i = A_i \bullet A_n)$   
 $for(j = a_i \bullet a_n)$   
 $P_{a_{ij}} = W_{a_{ij}} / W_{C_i}$

5. Classify the each testing examples:  
 $TargetClass, C_{TC} = \underset{C_j}{\operatorname{argmax}} \sum C_{C_i}^W \bullet_i P_{a_{ij}};$
6. If any test example is misclassified then update the weights of training set: Similarity,  $S = 0.5$  (out of four attributes two attributes values are same)  
 $W_i = W_i + (S * 0.01);$
7. If weight update, go to step (2);
8. If all test examples are correctly classified then the algorithm terminates;

#### IV. EXPERIMENTAL RESULTS

In our experiments, we perform 5-class classification for intrusion detection. The training and test examples are taken from the benchmark KDD99 dataset. In this experiments, 10 percent of the whole KDD99 dataset used for the training examples and 10 percent whole KDD99 dataset used for the testing examples. The training and test examples are taken randomly. This is done with different ratios of positive versus negative instance. In the KDD99 dataset, the normal data belongs to class1, probe belongs to class2, denial of service (Dos) belongs to class3, user to super user (U2R) belongs to class4, and remote to local (R2L) belongs to class5. Table I shows the distribution of connection types for 10% training and 10% testing dataset in the KDD99 dataset, which has a total number of 494021 and 311028 examples respectively.

TABLE I

NUMBER OF CONNECTIONS FOR TRAINING AND TESTING DATASET IN KDD99 DATASET

Class in KDD99	10% Training Examples	10% Testing Examples
Normal	97277	60592
Probe	4107	4166
DoS	391458	237594
U2R	52	70
R2L	1126	8606
Total	494021	311029

In our experiments, firstly we use standard naïve Bayesian algorithm and then our improved adaptive Bayesian algorithm to perform classification and compare their results. The training examples are used to train the

algorithms, and the test examples are used to evaluate the performance of the algorithms. Table II shows the comparisons of training and testing speed of algorithms.

TABLE II

PROCESSING SPEED COMPARISON

Classifiers	Training Time (m)	Testing Time (m)
Naïve Bayesian Algorithm	106.7	26.4
Adaptive Bayesian Algorithm	52.8	13.2

It is clear that that the proposed adaptive Bayesian algorithm is approximately 2 times faster in training and testing than conventional naïve Bayesian algorithm. To evaluate the performance of our improved adaptive Bayesian algorithm for intrusion detection, we are interested in two major indicators of performance: detection rate (DR) and false positive rate (FPR). Detection rate (DR) is defined as the number of intrusion examples detected by the system divided by the total number of intrusion examples present in the dataset. And false positive rate (FPR) is defined as the total number of normal examples. The performance comparison between naïve Bayesian algorithm and our improved adaptive Bayesian algorithm are shown in Table III and Table IV.

TABLE III

PERFORMANCE OF NAÏVE BAYESIAN ALGORITHM

Attack type in KDD99	Training Time (m)	Testing Time (m)
DoS	99.68	0.04
Probe	98.47	0.42
R2L	98.34	7.03
U2R	98.91	0.13

TABLE IV

PERFORMANCE OF ADAPTIVE BAYESIAN ALGORITHM

Attack type in KDD99	Training Time (m)	Testing Time (m)
DoS	99.81	0.03
Probe	99.23	0.39
R2L	99.45	5.96
U2R	99.07	0.11

We also compare the intrusion detection performance among Neural Network (NN), Support Vector Machines (SVM), Naïve Bayesian Classifier, and our improved adaptive Bayesian algorithm (IABA) on KDD99 dataset. The comparative results are summarized in Table V.

TABLE V: COMPARISON OF SEVERAL LEARNING ALGORITHM

Attack type in KDD99	NN(%)	SVM(%)	NB(%)	IABA(%)
DoS	91.82	99.43	99.67	99.78
Probe	97.27	98.53	99.39	99.49
R2L	94.43	96.44	99.01	99.47
U2R	49.05	64.07	64.45	99.35

## V. CONCLUSION

Recently research on machine learning for intrusion detection has received much attention in the computational intelligence community. In intrusion detection algorithm, huge volumes of audit data must be analyzed in order to construct new detection rules for increasing number of novel attacks in high speed network. Intrusion detection algorithm should consider the complex properties of attack behaviors to improved the detection speed and detection accuracy. Analyze the large volume of network dataset and improve the performance of detection accuracy, intrusion detection become an important research field for machine learning. This paper presents a new algorithm for intrusion detection based on machine learning. The future works focus on applying the domain knowledge of security to improve the detection accuracy, visualizing the procedure and result of intrusion detection to promote the understandability of intrusion detection. Also apply machine learning techniques in real commercial intrusion detection systems.

# Analytical Performance Evaluation of Space Time Coded MIMO OFDM Systems Impaired by Timing Jitter

M. R. H. Mondal<sup>1</sup> and S. P. Majumder<sup>2</sup>

<sup>1</sup>IICT, BUET, rubaiyat97@iict.buet.ac.bd, Bangladesh

<sup>2</sup>Department of EEE, BUET, spmajumder@eee.buet.ac.bd, Bangladesh

**Abstract** — An analytical approach is presented to determine the impact of time selective fading, timing jitter and AWGN on the bit error rate performance of an OFDM system with DQPSK and QPSK modulation. The expression for the conditional BER conditioned on a given timing error and fading, is derived and the average BER is evaluated. The BER performance results are evaluated for different values of fading and jitter variances. The performance of the OFDM system in Rayleigh and Rician fading channels is also compared. Analytical approach is also developed to evaluate the BER performance of a quasi-orthogonal space-time block coded (STBC) OFDM system having multiple transmitting and single receiving antennas. The analysis is extended for a MIMO-OFDM system using the “selection method” for combining multiple receiving antennas, which offers significant improvement in the system performance. The effects of increase in number of OFDM subcarriers and increase in Doppler frequency are also investigated.

**Index Terms** — Convolutional coding, intersymbol interference, MIMO, OFDM, Rayleigh fading, STBC, timing jitter.

## I. INTRODUCTION

Orthogonal frequency division multiplexing (OFDM) is effective in avoiding intersymbol interference caused by multipath delay. However, it is sensitive to time-selective fading which destroys the orthogonality among different subcarriers in one OFDM symbol leading to intercarrier interference. OFDM signal is also degraded by timing jitter caused by time synchronization errors at the receiver. Several research works have been carried out during the last few years on the performance evaluation of an OFDM system over fading channels in [1]-[5]. The effect of timing jitter on the performance of an OFDM system without considering multipath fading is also reported [6], [7]. The performance of quasi-orthogonal-space-time coded (QOSTC) system over fast fading channel is investigated for single-carrier systems in [8]. The performance of QOSTC-OFDM system over fading channel is reported in terms of carrier to interference (C/I) and signal to interference and noise ratios [9]. The BER is also evaluated through simulations. However in [9] the jitter effect is ignored and only a single receiving antenna is used.

In this paper, we develop an analytical approach in order to find the BER of an OFDM system and a STBC-OFDM system considering all three channel impairments like AWGN, fading and jitter in fading environment. We extend the analysis for a MIMO-OFDM system with switching/selection method for combining multiple receiving antennas. We also apply convolution coding to evaluate the effectiveness of coding in minimizing the effect of system impairments.

## II. SYSTEM MODEL

The STBC-OFDM system model considered for analysis is shown in Fig. 1.

Fig. 1. Block diagram of the system

Binary input data is mapped to modulation symbols. These symbols are serial-to-parallel converted and then mapped to a matrix by using a quasi-orthogonal STBC with constellation rotation scheme. An inverse Fourier transform is used to find the corresponding time waveform. The guard period is then added to reduce the intersymbol interference (ISI). This guard period is a cyclic extension of the symbol to be transmitted. After the guard has been added, the symbols are then converted back to a serial time waveform. This is then the base band signal for the OFDM. The symbols are transmitted from the multiple transmitting antennas simultaneously during every OFDM symbol period.

The receiver basically does the reverse operation to the transmitter. The signal is received in two receiving

antennas. Diversity combiner at the receiver selects the best instantaneous signal of the two antennas. The received signal can be detected through differential or coherent scheme.

### III. THEORETICAL ANALYSIS OF BER

For a stand alone OFDM system the STBC Encoding block and Linear Combiner block in Fig. 1 will not exist. Considering such an OFDM system, the expression of signal-to-noise plus interference power ratio (SNIR) without timing error can be expressed as [5]:

$$\text{SNIR} = \frac{1}{\frac{(k+1)(1+\delta_c)}{2E_b} + \frac{(\pi F_d T_s)^2}{2} + \frac{(\pi F_d T_s)^2}{6(1+\delta_c)^2}} \quad (1)$$

where  $F_d$  is the maximum Doppler frequency,  $N_0$  is the Gaussian noise (AWGN),  $E_b$  is the bit energy, and  $k$  is the Rician parameter/factor. In (1)  $T_s$  is the symbol duration and  $\delta_c$  is the guard interval ratio of an OFDM symbol. Here intra-symbol interference ( $I_s$ ) and intercarrier interference ( $I_c$ ) are considered as:

$$I_s = \frac{(\pi F_d T_s)^2}{2}$$

$$I_c = \frac{(\pi F_d T_s)^2}{6(1+\delta_c)^2}$$

By expressing the intercarrier interference component in terms of number of OFDM subcarriers ( $N_s$ ), the expression of SNIR in (1) is modified as follows:

$$\text{SNIR} = \frac{1}{\frac{(k+1)(1+\delta_c)}{2E_b} + \frac{(\pi F_d T_s)^2}{2} + \sum_{n=1}^{N_s} \frac{1}{n^2} (F_d T_f)^2} \quad (2)$$

where  $T_f$  is the effective symbol period deducting guard period. To incorporate the jitter effect along with fading and AWGN, the jitter term is added in the equation of SNIR. In any communication system timing jitter causes the signal power to degrade by a factor of  $(1-\varepsilon)$  over a time slot. The jitter also causes interference which is added as  $E_b \varepsilon$ . Here  $\varepsilon$  is the timing error normalized by  $T_s$  i.e. ( $\varepsilon = \Delta / T_s$ ) and  $E_b$  is the bit energy. However in fading environment, the received signal energy is random depending on random fade but the noise energy remains unchanged. The received bit energy  $E_b$  is the product of input bit energy  $E_m$  and the multiplicative fade  $\alpha^2$ , i.e.  $E_b = E_m \alpha^2$ . So with this modification the expression of SNIR for a stand alone OFDM system is as follows:

$$\text{SNIR}(\varepsilon, \alpha) = \frac{1}{\frac{(k+1)(1+\delta_c)}{2(E_m \alpha^2)(1-\varepsilon)} + \frac{(\pi F_d T_s)^2}{2} + \sum_{n=1}^{N_s} \frac{1}{n^2} (F_d T_f)^2 + (E_m \alpha^2) \varepsilon} \quad (3)$$

In the presence of time-varying fading, SNIR for quasi-orthogonal STBC-OFDM system has an expression as [9]:

$$\text{SNIR} = \frac{4 \sum_{l=0}^{L-1} [N_s + 2 \sum_{i=1}^{N_s-1} (N_s - i) J_0(2\pi F_d T_s)] e^{-\frac{\tau_l}{\tau_{rms}}}}{4 \sum_{k'=1}^{N_s-1} \sum_{l=0}^{L-1} [N_s + 2 \sum_{i=1}^{N_s-1} (N_s - i) J_0(2\pi F_d T_s) \cos(\frac{2\pi}{N_s} k' i)] e^{-\frac{\tau_l}{\tau_{rms}}} + \sigma^2} \quad (4)$$

The above expression is considered for unit symbol energy and four number of transmitting antennas. In (4)  $\tau_l$  is the delay of the  $l$ th path normalized with respect to the OFDM symbol duration  $T_s$  whereas  $\tau_{rms}$  represents the root-mean square (rms) delay spread. In the expression  $\sigma^2$  represents the variance of AWGN. Now we consider  $E_s$  symbol energy with guard interval ratio  $\delta_c$  and Rician parameter  $k$ . For DQPSK and QPSK symbol energy is twice the bit energy i.e.  $E_s = 2E_b$ . So for DQPSK and QPSK modulation the equation of SNIR for a quasi-orthogonal STBC-OFDM system in (4) can be modified as follows:

$$\text{SNIR} = \frac{N_T \sum_{l=0}^{L-1} \left\{ \frac{2E_b}{(k+1)(1+\delta_c)} \right\} [N_s + 2 \sum_{i=1}^{N_s-1} (N_s - i) J_0(2\pi F_d T_s)] e^{-\frac{\tau_l}{\tau_{rms}}}}{N_T \left\{ \frac{2E_b}{(k+1)(1+\delta_c)} \right\} \left[ \sum_{k'=1}^{N_s-1} \sum_{l=0}^{L-1} \left\{ N_s + 2 \sum_{i=1}^{N_s-1} (N_s - i) J_0(2\pi F_d T_s) \cos(\frac{2\pi}{N_s} k' i) \right\} e^{-\frac{\tau_l}{\tau_{rms}}} \right] + \sigma^2}$$

where  $N_T$  is the number of transmitting antennas. For STBC-OFDM, jitter has the same effect as in OFDM systems. So by simultaneously considering AWGN, jitter and fading the expression of SNIR for a quasi-orthogonal STBC-OFDM system can be expressed as follows:

$$\text{SNIR}(\varepsilon, \alpha) = \frac{N_T \sum_{l=0}^{L-1} \left\{ \frac{(2E_m \alpha^2)(1-\varepsilon)}{(k+1)(1+\delta_c)} \right\} [N_s + 2 \sum_{i=1}^{N_s-1} (N_s - i) J_0(2\pi F_d T_s)] e^{-\frac{\tau_l}{\tau_{rms}}}}{N_T \left\{ \frac{(2E_m \alpha^2)(1-\varepsilon)}{(k+1)(1+\delta_c)} \right\} \left[ \sum_{k'=1}^{N_s-1} \sum_{l=0}^{L-1} \left\{ N_s + 2 \sum_{i=1}^{N_s-1} (N_s - i) J_0(2\pi F_d T_s) \cos(\frac{2\pi}{N_s} k' i) \right\} e^{-\frac{\tau_l}{\tau_{rms}}} \right] + (\sigma^2 + E_m \alpha^2 \varepsilon)}$$

Following [5], the bit error rate (BER) performance for DQPSK/OFDM system over multipath fading channels can be evaluated in presence of jitter as:

$$P_e(\varepsilon, \alpha) = \frac{\{1 - J_0(2\pi F_d T_s)\} \left\{ \frac{SNIR(\varepsilon, \alpha)}{2} \right\} + 1}{2 \left\{ \frac{SNIR(\varepsilon, \alpha)}{2} + 1 \right\}} \exp \left\{ -\frac{k \frac{SNIR(\varepsilon, \alpha)}{2}}{\frac{SNIR(\varepsilon, \alpha)}{2} + 1} \right\}$$

Here  $J_0(2\pi F_d T_s)$  is the time correlation function. Following [10], The BER performance for QPSK/OFDM system can be expressed as follows:

$$P_e(\varepsilon, \alpha) = 0.5 \operatorname{erfc} \sqrt{SNIR(\varepsilon, \alpha)}$$

For a fixed value of  $\alpha$  the probability of bit error is  $P_e(\alpha)$ . This  $P_e(\alpha)$  is considered as a conditional probability of error for a given value of channel attenuation  $\alpha$ . For Rayleigh fading channel,  $\alpha$  is Rayleigh distributed. Then the pdf of  $\alpha$  is:

$$p(\alpha) = \frac{\alpha}{\sigma^2} \exp\left(-\frac{\alpha^2}{2\sigma^2}\right)$$

Here  $\sigma$  is Rayleigh parameter. The mean and variance value of the Rayleigh density function is a function of  $\sigma$ . Mean =  $1.25 \sigma$  and variance =  $0.655 \sigma$ . For Rician fading channel,  $\alpha$  is Rician distributed. Then the pdf of  $\alpha$  is:

$$p(\alpha) = \frac{\alpha}{\sigma^2} \exp\left(-\frac{(\alpha^2 + m^2)}{2\sigma^2}\right) I_0\left(\frac{m\alpha}{\sigma^2}\right)$$

Here  $I_0$  is the zeroth order Bessel function and  $m^2 = 2k\sigma^2$ . The pdf of zero mean Gaussian distributed jitter is

$$p(\varepsilon) = \frac{1}{\sqrt{2\pi\sigma_\varepsilon^2}} \exp\left(-\frac{\varepsilon^2}{2\sigma_\varepsilon^2}\right)$$

where  $\sigma_\varepsilon^2$  is the variance of jitter. The unconditional/average BER ( $P_e$ ) can be calculated by averaging the conditional BER,  $P_e(\varepsilon, \alpha)$ , over all possible values of  $\alpha$  and  $\varepsilon$

$$P_e = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} P_e(\varepsilon, \alpha) p(\alpha) p(\varepsilon) d\alpha d\varepsilon$$

STBC-OFDM with transmitting diversity is transformed into MIMO-OFDM by addition of receiving diversity. For receiving diversity scheme, "selective" diversity combining method is utilized in wireless systems. Considering the average bit error probability without diversity as  $P_{e1}(A)$ , the average BER with diversity can be derived as [10]:

$$P_{e2}(A) = 2P_{e1}(A) - P_{e1}(A/2)$$

where  $A$  denotes the average SNIR.

#### IV. RESULTS AND DISCUSSION

Following the analytical approach, the bit error rate performance results are evaluated at a data rate of 1 Mbps per OFDM subcarrier with maximum Doppler frequency of

60 Hz in fading channel. Keeping number of subcarriers to sixteen and fading variance to 0.1 we compare the performance of the system with and without jitter. Fig. 2 shows the plots of BER vs.  $P_{in}$  (dBm) for DQPSK-OFDM system. From Fig. 2 it is noticed that the BER slightly degrades with increase in jitter. Fig. 3 shows the plots of BER vs.  $P_{in}$  (dBm) for QPSK system. The plots show that OFDM is robust against lower values of jitter variance but the BER is highly degraded when jitter is substantially high and results in BER floor. At a BER of  $10^{-9}$ , the jitter effect is negligible for jitter variance  $\sigma_\varepsilon^2 < 0.125$  with QPSK modulation. It is found that the jitter effect is more pronounced in QPSK than in DQPSK system. The amounts of penalty suffered by the OFDM systems due to timing jitter are shown in Table I. Fig. 4 shows the plots of BER vs.  $P_{in}$  (dBm) for DQPSK system in Rayleigh and Rician channels. It is noticed that BER performance is better in Rician fading channel. This is because in Rician channel there exists one dominant line-of-sight path that is absent in Rayleigh channel. From Fig. 4 it is also revealed that BER performance improves with increase in Rician factor. For example, at 0 dBm input power and DQPSK modulation, the BER of a Rayleigh fading channel is  $10^{-4}$  while Rician channels have a BER in the order of  $10^{-5}$ ,  $10^{-6}$  and  $10^{-7}$  for  $K=0$  dB, 3 dB and 6 dB respectively. This result can be explained from the fact that higher Rician factor indicates more dominant line-of-sight path.

Fig. 5 shows the effect of timing jitter in a DQPSK STBC-OFDM system with one receiving antenna and fading variance of 0.1. From Fig 5, it is revealed that with the increase in jitter the BER performance degrades and results in BER floor for higher values of jitter variance. At a jitter variance  $\sigma_\varepsilon^2$  of 0.2, the BER floor occurs at about  $10^{-3}$  compared to  $10^{-4}$  for the case of without timing error. We also evaluate the similar performance of the system employing QPSK modulation as shown in Fig. 6 and noticed that the jitter causes BER floor. Fig. 7 illustrates the performance comparison of STBC-OFDM with and without receiver diversity. The plot shows that the BER reduces from  $10^{-3}$  to  $10^{-6}$  in presence of jitter  $\sigma_\varepsilon^2 = 0.2$  by deploying diversity combining in receiving side with two receiving antennas. It shows two pair of curves, one without jitter and another with jitter variance of 0.2.

Fig. 8 shows the plots of Space time block coded MIMO-OFDM with DQPSK modulation system with and without convolutional coding in presence of jitter considering four transmitting and two receiving antennas. For convolution code of rate  $1/2$ , the coding gain is 26 dB for constraint length  $K=6$  and 28 dB for  $K=7$  at an uncoded BER of  $10^{-7}$ . It is also noticed that for higher amounts of input power, the coding gain is substantially higher in  $K=7$  than in  $K=6$ . Fig. 9 shows the plots of BER vs. number of subcarriers ( $N_s$ )

for different values of Doppler frequency normalized by symbol period. It is noticed that with the increase in Doppler frequency the BER increases. From Fig. 9 it is also revealed that with increase in  $N_s$ , the BER decreases and becomes minimal and then increases for a particular value of Doppler frequency. It is observed that BER is minimal when number of subcarriers ( $N_s$ ) is 12.

Fig. 2. BER vs.  $P_{in}$  (dBm) in presence of timing jitter for DQPSK-OFDM ( $N_s=16$ ,  $F_d=60$  Hz,  $\sigma_f^2=0.1$ ,  $T_s=10^{-6}$  s)

Fig. 3. BER vs.  $P_{in}$  (dBm) in presence of timing jitter for QPSK-OFDM ( $N_s=16$ ,  $F_d=60$  Hz,  $\sigma_f^2=0.1$ ,  $T_s=10^{-6}$  s)

TABLE I

Power penalty (in dB) due to jitter for OFDM system at  $BER=10^{-6}$

Modulation	$\sigma_e^2 = 0.2$	$\sigma_e^2 = 0.15$	$\sigma_e^2 = 0.125$
DQPSK	0.85	0.65	0.5
QPSK	1.5	0.8	0.6

Fig. 10 shows the plots of BER vs.  $P_{in}$  (dBm) for the analysis presented by Zhang in [9] and the proposed analysis of this paper. The plots are considered for Rayleigh channel with  $F_d=60$  Hz,  $T_s=10^{-6}$  s, four number of transmitting and single receiving antennas. The proposed analysis shows more BER than the previous analysis presented by Zhang [9], because the proposed analysis considers additional impairments of timing jitter ( $\sigma_e^2=0.1$ ) and channel attenuation ( $\sigma_f^2=0.1$ ). From the findings of the evaluation we can propose an optimum system with following design parameters:

1. DQPSK as modulation scheme as it is more robust against jitter.
2. STBC-OFDM with  $T_x=4$ ,  $R_x=2$
3. Number of OFDM subcarriers 12
4. Convolutional coding of rate  $1/2$  and  $K=7$

Fig. 4. BER vs.  $P_{in}$  (dBm) for Rayleigh and Rician channels for DQPSK-OFDM ( $N_s=16$ ,  $F_d=60$  Hz,  $\sigma_e^2=0.2$ ,  $\sigma_f^2=0.1$ ,  $T_s=10^{-6}$  s)

Fig. 5. BER vs.  $P_{in}$  (dBm) in presence of timing jitter for STBC-OFDM (DQPSK) ( $N_s=16$ ,  $F_d=60$  Hz,  $\sigma_f^2=0.1$ ,  $T_s=10^{-6}$  s,  $T_x=4$ ,  $R_x=1$ )

Fig. 6. BER vs.  $P_{in}$  (dBm) in presence of timing jitter for STBC-OFDM (QPSK) ( $N_s=16$ ,  $F_d=60$  Hz,  $\sigma_f^2=0.1$ ,  $T_s=10^{-6}$  s,  $T_x=4$ ,  $R_x=1$ )

Fig. 7. Plots of BER vs.  $P_{in}$  (dBm) with & without receiving diversity for STBC-OFDM (DQPSK)

Fig. 8. BER vs.  $P_{in}$  (dBm) with and without coding for MIMO-OFDM (DQPSK) ( $N_s=16$ ,  $F_d=60$  Hz,  $\sigma_e^2=0.2$ ,  $\sigma_f^2=0.1$ ,  $T_s=10^{-6}$  s,  $T_x=4$ ,  $R_x=2$ )

Fig. 9. BER vs.  $N_s$  (number of subcarriers) for MIMO-OFDM (DQPSK) ( $F_d=60$  Hz,  $\sigma_e^2=0.01$ ,  $\sigma_f^2=0.1$ ,  $T_s=10^{-6}$  s,  $T_x=4$ ,  $R_x=2$ )

Fig. 10. BER vs.  $P_{in}$  (dBm) for previous and proposed analysis ( $F_d=60$  Hz,  $T_s=10^{-6}$  s,  $T_x=4$ ,  $R_x=1$ )

## V. CONCLUSION

We have analyzed the combined effects of timing jitter, time selective fading and AWGN on the BER performance of an OFDM system. For DQPSK the jitter effect is less pronounced than coherently detected QPSK system. For example, at a jitter variance of 0.2, the penalty at a BER of  $10^{-6}$  is 1.5 dB for QPSK and 0.85 dB for DQPSK. We also observe that the BER of an OFDM system is much higher in Rayleigh fading channel than Rician channel. We compute the BER of OFDM in Rician fading channels with different Rician parameters and numerical results show that the performance is improved with higher values of Rician parameters. It is noticed that STBC-OFDM shows better BER performance than OFDM system. Numerical computations indicate that BER becomes higher with increase in Doppler frequency and increase in number of subcarriers. We extend the analysis for a MIMO-OFDM system with selection method for combining multiple

receiving antennas and find substantial improvement in the system performance. As coded MIMO-OFDM successfully achieves outstanding performance, it can be used in practical applications where fading, jitter and AWGN strongly exist.

# Performance Comparison of IPv4 and IPv6 on Various Windows Operating Systems

Shaneel Narayan, Samad S. Kolahi, Yonathan Sunarto, Du D. T. Nguyen, Paul Mani

School of Computing and Information Technology, UNITEC New Zealand  
snarayan@unitec.ac.nz

**Abstract** — Internet is a ubiquitous part of businesses and individuals worldwide. With its popularity on an incline, operating system vendors are developing end-systems that support the new version of Internet Protocol (IPv6) that eventually will replace IPv4. The new version resolves issues that IPv4 has and takes the Internet into the 21st century. Performance of the IP stack and how it associates with operating systems is critical to the efficiency of all network related activities on any computing infrastructure. Hence it is essential to evaluate performance of IP stack with different operating systems. In this paper, two Microsoft operating systems namely, Windows XP and Windows Server 2003 are configured with the two versions of IP and empirically evaluated for performance difference. The experimental results demonstrate that theoretical and practical performance values are different. It also shows that network performance depends not only on IP version and traffic type, but also on the choice of the operating system.

**Index Terms** — Internet Protocol, IPv4, IPv6, network performance, Windows operating system.

## I. INTRODUCTION

Internet has become the default communication channel for businesses and it continues to grow exponentially beyond technical capacity anticipated by the original engineers and designers. There is now an expectation among experts that the currently used version of Internet Protocol, IPv4, will run out of previously unallocated address space in 2010 or 2011, as only 16% of the total address space remains unallocated in early 2008 [1]. Eventual depletion of Internet addresses in the current schema was foreseen in the late 1990s and Internet Engineering Task Force (IETF) began work on the development of a new version of Internet Protocol, IPv6. This new version not only substantially expands the address space, but also has a raft of additional benefits that were lacking in the predecessor. Today, new versions of popular end-user operating systems come fully integrated with IPv6. Hardware vendors, software developers and Internet Service/Exchange Providers are moving towards offering support for IPv6 [2]. However the overall uptake of this new technology is slower than anticipated and there are considerable challenges that need to be addressed. Performance degradation of network with IPv6 is one such challenge. IPv4 has a 20-Byte header and IPv6 header is

40 Bytes, therefore theoretically the latter has higher overhead. This overhead varies with data payload size -for example, with no fragmentation of datagrams a payload of 128 Bytes has performance difference of 10.3%, and for payload of 1408 Bytes the difference is 1.3% approximately. In this paper, we compare TCP and UDP traffic performance theoretical values with data from test bed experiments for Windows operating systems with IPv4 and IPv6. Our results show that theoretical and practical values are dissimilar. Further, it demonstrates that performance of TCP and UDP varies for different operating systems.

The rest of the paper is organized as follows: Section II discusses some of similar work undertaken by other researchers in evaluating performance of protocols on operating systems. Section III describes Internet Protocols mainly focusing on IPv6 and Section IV outlines the experimental setup used in this research to evaluate the performance of IPv4 and IPv6 on different operating systems. We present the results and discuss the findings in Section V. Finally, conclusions from the research are drawn in Section VI.

## II. RELATED RESEARCH

Research related to performance evaluation of protocols with different operating systems has been undertaken by a number of researchers [Table 1]. Early research focused mostly on one operating system implemented with IPv6 beta (or prototype) and compared performance with IPv4. Results indicated that IPv6 experiences slight performance degradation when implemented on a network (for example, Windows NT with IPv6 downgraded by 2% in [3] and FreeBSD with IPv6 performed slightly inferior in [4], [5] and [6]). In [7], it is shown that both protocols performed the same on FreeBSD. Recent researchers have evaluated the performance of protocols on two or more operating systems comparatively. Windows 2000 and Solaris 8 have been compared in [8] and this work was extended to include Redhat 7.3 in [9]. And Windows 2000 with Linux has been evaluated in [10]. Windows 2003 and Redhat 9.0 have been evaluated with FreeBSD 4.9 in [11], and with FreeBSD 5.3 in [12]. All these researchers have

empirically shown that there are performance differences of various degrees between operating systems with same Internet Protocols. Both TCP and UDP traffic also show interesting patterns when tested on various operating systems.

RESEARCHER(S)	OPERATING SYSTEM(S)
Draves, Mankin & Zill (1998)	Windows NT (MSR IPv6)
Xie (1999)	Windows NT (MSR IPv6 Beta)
Ariga, et al. (2000)	FreeBSD (KAME IPv6)
Ettikan (2000)	FreeBSD (KAME IPv6)
Anand (2000)	Linux kernel 2.4.17 (IPv6)
Zeaddally & Raicu (2003)	Windows 2000, and Solaris 8 (IPv4, IPv6)
Zeaddally, Wasseem & Raicu (2004)	Windows 2000, Solaris 8 & Redhat 7.3 (IPv4, IPv6)

Table 1: Research on Performance Evaluation of Operating Systems

The related work indicates that comparative performance analysis of Internet Protocols with different operating systems is imperative. In this undertaking, we extend the list of operating systems examined by other researchers to include Windows XP Professional and Windows Server 2003. At the time of this research, Windows operating systems had approximately 90% market share [13] and the two operating systems evaluated were the current desktop and server versions. We examine their performance with both versions of Internet Protocols. These protocols are discussed next.

### III. INTERNET PROTOCOL OVERVIEW

IPv6 is the communication protocol which is the successor of IPv4. It has been designed to offer improvements over the short comings of the IPv4. The biggest problem with IPv4 is it is running out of the IP addresses, and with the ever increasing number of computers worldwide, this creates a need for a much longer address space. IPv6 offers an answer by increasing the addresses from 32 to 128 bits (an increase from approximately  $4.3 \times 10^9$  binary to  $3.4 \times 10^{38}$  hexadecimal addresses).

IPv6 addresses other inadequacies of IPv4. Being plug-and-play, IPv6 allows novice users to connect nodes to network and be able to use devices instantly without any additional configuration. This is possible due to stateful or stateless auto-configuration features that enable devices to generate link-local address for network interface -this uses Neighbor Discovery (ND) protocol. Secondly, security features that were optional in IPv4 are mandatory in IPv6. Authentication Header (for authentication and integrity) and Encapsulated Security Payload (for integrity and confidentiality) implement security below application layer

in protocol stack and are used to provide deferring levels of security to users and applications. Thirdly, IPv6 has an added scope field to multicast addresses which gives improved multicast routing. Also included is a new type of address called anycast, which is used to send packets to any one of a group of nodes. Fourthly, end-to-end transparency is achieved, which eliminates the need for address translation technologies. And finally, Quality of Service (QoS) guarantees in accomplished in IPv6 by introduction of a flow field. This field identifies IP packets from a particular traffic stream and assigns different priorities to the packets prior to network transmission. QoS when introduced with Internet will provide support for real time services such as IP video and voice.

The challenge of converting from IPv4 to IPv6 is enormous. By design, IPv4 to IPv6 transition is evolutionary and there are a number of mechanisms that can be employed in current interim period [14]. These mechanisms allow for co-existence of both IPv4 and IPv6 networks (maintaining complete compatibility), and the techniques can be broadly grouped into three categories: dual stack, protocol translation, and tunneling:

A. Dual Stack: This is a straightforward transition mechanism where network nodes are stacked with both IPv6 and IPv4 protocols. These IPv6/IPv4 nodes use IPv6 stack to communicate with IPv6 nodes, and IPv4 for communicating with IPv4 networks. Although this solution is practical, all network devices (such as routers, switches, bridges, gateways, etc) end up being dual stacked as well. The additional burden makes network devices inefficient and does not reduce the demand for global routable IPv4 addresses.

B. Protocol Translation: This mechanism works for pure IPv6 network when communicating with nodes on an IPv4 network. Protocol translation techniques solves the problems that dual stack mechanisms exhibit, and depends on some intermediary device or service that convert packet headers at network border. Three protocol translation techniques are prevalent:

i. Dual Stack Application Level Gateway (DS-ALG): A dual stack IP device is used which can access both IPv4 and IPv6 services natively. This is a simple and robust solution, however requires all clients to be configured to use ALG and will work for specific ALG-supported applications only.

ii. Network Address Translator – Protocol Translator (NAT-PT): This is similar to traditional IPv4 NAT; however it also has protocol translation. This uses a pool of IPv4 addresses for assignment to IPv6 nodes on a dynamic basis as sessions are initiated across IPv4-IPv6 boundaries [15]. The IPv6 address binds to IPv4 address to give transparent routing for datagrams traversing

between address realms. Assignment of IPv4 addresses is done by the border router.

iii. Dual Stack Transition Mechanism (DSTM). A DSTM server provides a temporary IPv4 address to dual stack nodes on needs to have basis when IPv6 node wishes to correspond with a node on IPv4 network. The IPv6 node configures its IPv4 stack with the allocated address and tunnels the packets to the DSTM gateway at the edge of the network. The gateway has the responsibility to encapsulate or decapsulate packets as traffic transits through network border.

C. Tunneling: This provides a method to carry IPv6 traffic to other networks using current IPv4 routing infrastructure. IPv6 datagram are encapsulated within IPv4 packets and routed through IPv4 regions of the internetwork. The begin and the end points of the tunnel has to be IPv6/IPv4 dual stacked nodes. Router-to-router, host-to-router, router-to-host and host-to-host are the four possible configurations and there are several types of tunnels:

i. Configured Tunnel: IPv6 data is encapsulated within IPv4 packet at the originating end point and then transported through a tunnel. At the exit point of the tunnel, the packet is decapsulated. The tunnel endpoint addresses are determined from the configuration information that is stored at the encapsulating endpoint (hence named configured tunnel). Configured tunnels can be defined to go between router-to-router, host-to-router, host-to-host or router-to-host. Normally a tunnel broker (a server that manages tunnel requests from users) is employed with this technique.

ii. Automatic Tunnel: IPv6 packet is tunneled all the way to the final destination. There are no pre-configured tunnels and the nodes that perform automatic tunneling are assigned an IPv4-compatible IPv6 address. Since IPv6 packet's destination is the tunnel endpoint, IPv6 packet's destination address determines the tunnels endpoint. This technique is named automatic tunneling because the endpoint address is automatically determined from the embedded IPv4 address of the data's IPv6 address.

iii. 6 to 4: This allows communication from one IPv6 site to another over an IPv4 network without the need for an explicitly configured tunnel or requiring IPv4-compatible IPv6 addresses. There is no end node configuration and edge router configuration is minimal. When transporting data, node sends IPv6 packets to the destination and these packets are tunneled in IPv4 between the edge 6 to 4 routers of the two networks.

iv. 6 over 4: This is an automatic mechanism for establishment of a tunnel that is used to provide unicast and muticast connectivity between IPv6 nodes via an IPv4 network. A virtual link is created between the two

networks and IPv6 multicast addresses are mapped to IPv4 addresses to enable network discovery.

The above discussed techniques are all good, but only in transition period where there is coexistence of both Internet Protocols. Performance evaluation of above mentioned transition mechanisms have been undertaken by numerous researchers, including [16], [17], [18], and [19]. They have comparatively analyzed different traffic types to gauge performance with various mechanisms. In this research, we undertake to compare data transfer rate differences between pure IPv4 and IPv6 networks with Windows operating systems –experimental setup used for analysis is described next.

#### IV. EXPERIMENTAL SETUP

To measure performance of Internet Protocols on various Windows operating systems, two computers with identical hardware (CPU: Intel P4 3GHz, RAM: 1GB, Network card: PCI Intel Pro 100, Hard drive: Seagate Barracuda 7200 [20GB]) were connected point-to-point using a 100Mbps cross-over cable. Connecting test computers such a way eliminate effects that intermediary devices (switches, routers, etc) have on network performance. This testbed setup remained constant for all experiments conducted.

Figure 1: Network test bed

Initially, both computers were loaded with Microsoft Windows Server 2003 SP2. They were configured as application servers (i.e. not as part of a Domain) and no additional services such as DHCP or DNS were installed. Since Windows Server 2003 has by default both IPv4 and IPv6 protocol stacks, only one version was enabled and configured on both computers simultaneously. In the second set of experiments, operating systems were changed to Microsoft Windows XP Professional SP2. Windows XP natively has IPv4 only, therefore IPv6 had to be explicitly installed and enabled when required. For both operating systems, default configurations as per vendor instructions, were configured and no performance optimizations were tweaked. No additional third party software or vendor updates/patches were installed except service packs. The IPv4 and IPv6 parameters were statically configured.

IP Traffic 2.4.2 [20] was used as the primary tool to evaluate performance of protocols on operating systems. IP Traffic generates, receives, captures and replays TCP,

UDP and ICMP traffic end-to-end and measures performance over IP network. These three traffic types are used by mail exchanges, file transfer, ping program, and World Wide Web transmissions. Since IP Traffic uses Windows TCP/IP stack (Winsock2 interface) of the end computers, IP Traffic works independent of transmission link between the nodes. Test bed Computer 1 was configured as IP Generator (node that generates IP traffic) and Computer 2 was IP Answering (node that receives IP traffic). The Generator sends packets through the cable to the Answering, and the Answering echoes the packet back to the Generator. Payload sizes ranging from 128 Bytes to 1408 Bytes were used in the experiment. This range caters for most packet sizes on networks and the Internet [21].

To ensure high data accuracy, all tests were executed with multiple runs for sufficient duration. One million packets were sent 20 times for each payload size. The time and amount of transferred data for each run depends on the payload. For small payload (e.g. 128 Bytes), the transferred time was few seconds and approximate 25MB of data was sent. For larger payload size, such as 1028 Bytes, two minutes was taken to transfer the approximate 2GB of data from Generator and Answering. Standard deviation for data generated for each payload size was calculated and if the results fell outside 95% confidence interval, the experiment was rerun to rule out inconsistencies.

The metric used in the experiment is throughput (measured in Mbps). This metric gives a valuable insight into performance of a system since it is the rate at which data gets transmitted from one node to another over a network. Throughput values were measured for TCP and UDP traffic that was generated and sent between the two nodes. The results are presented and discussed next.

## V. EXPERIMENTAL RESULTS

We present the findings of this research in this section. Data packets were gradually increased in size for TCP and UDP traffic and resulting throughput values were plotted. This was done for both Windows XP and Windows Server 2003 operating systems.

Figure 2 shows TCP throughput results for operating systems with IPv4 and IPv6 protocols for different packet sizes. Also shown are the results for Windows 2000 experiments conducted by Zeadally [8] (indicated by \* in Figure 2). From TCP throughput values, it is observed that for all operating systems there are performance differences between IPv4 and IPv6 throughput. However, the variations in throughput are different for various operating systems.

For Windows Server 2003, IPv4 outperforms IPv6 for all packet sizes. IPv4 throughput range from 61.02 to 76.09, and IPv6 values are from 57.84 to 70.24 Bytes. On an average this indicates a performance difference of 6.2% between the two protocols (lowest difference 3.5% for

Figure 2: TCP Throughput of Windows Operating Systems

packet size 896 Bytes, and highest difference 10.4% for packet size 640 Bytes). For smaller packet sizes (up to 384 Bytes) there is a significant incline in throughput as the pack size increase (a gain averaging 18.5% for both the protocols). However for larger packet sizes, the graphs flatten off, indicating only slight variations in throughput for each protocol. For packet sizes larger than 512 Bytes, throughput means are 75.5 and 71.1 Mbps for IPv4 and IPv6 respectively.

Windows XP throughput exhibits slightly different behavior to Windows Server 2003. For packet sizes up to 256 Bytes, IPv4 outperforms IPv6 by 4.6%. Also, there is a significant incline in throughput (average gain: 17.2%) for both protocols for these packet sizes. For packets sizes between 256 and 1152 Bytes, IPv6 throughput values are higher than IPv4. Average throughput difference for packet sizes in this range is 3.6% (lowest difference 1.7% for packet size 1152 Bytes, and highest difference 5.7% for packet size 1024 Bytes). Also, the graphs flatten off in this range with mean throughput values of 73.6 and 76.2 Mbps for IPv4 and IPv6 respectively. For packet sizes larger than 1152 Bytes, IPv4 outperforms IPv6 by 2.8%. For these packet sizes, throughput performance declines by exactly 11.4% for both the protocols.

Although both Windows Server 2003 and Windows XP evidently show different throughput values for different protocols, there are some similarities in their performance. For small packet sizes, they both incline in performance with similar gains (18.5% and 17.2%); IPv4 outperforms IPv6 for both operating systems; and all throughput values are within +/-7 Mbps of each other. For packet sizes between 384 and 1152 Bytes, all throughput values are

within  $\pm 5$  Mbps, and throughput values for all increase on an average 4.3% ( $\pm 1\%$ ) with increased packet size.

On comparing these results with Zeadally's Windows 2000 throughput values, the following is evident; For packet sizes less than 640 Bytes, Windows Server 2003 and XP throughput values for both protocols are significantly higher than Windows 2000 (more than double for 128 Bytes packet size); IPv6 throughput values are comparatively higher for Windows Server 2003 and XP than Windows 2000; and IPv4 when implemented on Windows 2000 averages the highest throughput (78.4 Mbps).

UDP results obtained from the test bed for Windows operating systems with the two protocols are presented in Figure 3. Also plotted are Windows 2000 results from work of Zeadally [4] (indicated by \*). Like TCP results, UDP throughput values for all operating systems are different for IPv4 and IPv6. And the variations in throughput are also different for various operating systems.

Figure 3: UDP Throughput of Windows Operating Systems

Windows Server 2003 throughput values are higher for IPv4 protocol stack than IPv6. For packet sizes smaller than 384 Bytes, IPv4 outperforms IPv6 by approximately 5%. In this range, there is a throughput gain of almost 170% for both protocols as the packet size increase. For packet sizes between 384 and 640 Bytes, IPv4 throughput values supersede by approximately 5% on IPv6. Also, throughput values for both protocols increase by approximately 16% as packet size increase. The difference in throughput narrows to approximately 1.5% for packet sizes in the range 640 to 896 Bytes. In this range there is throughput gain averaging 4% for both IPv4 and IPv6, peaking to maximum throughput of approximately 80 Mbps. As packet size increases from 896 to 1020 Bytes the throughput values for both protocols decrease; however IPv4 still outperforms IPv6 by 1.7%. For packet sizes larger than 1024 Bytes, throughput values for IPv4 and IPv6 stays constant averaging 75 Mbps. In this packet size range, IPv4 throughput values on average are 3%

Windows XP UDP throughput values show an interesting pattern. For small payload sizes (up to 256 Bytes), IPv4 outperforms IPv6 by 5%, however as the packet size increases to 512 Bytes, IPv4 performance becomes significantly higher than IPv6 – extending to a 35% difference). Throughput values are also substantially small for smaller packet sizes and increases four fold with increased payload. For mid-sized packets (512 to 896 Bytes), IPv6 shows better throughput than IPv4 by approximately 2%. This is the only instance in all experiments where the newer protocol is a better performer than the counterpart. For large packet sizes, IPv4 outperforms IPv6 by almost 12% - with throughput averages of 85 and 75 Mbps respectively for IPv4 and IPv6.

Both Windows Server 2003 and XP show some similarities for UDP throughput. For smaller payload, throughput values are comparatively low and increase in value with increase payload size. For average packet sizes (512 to 896 Bytes) all values band together with an average of 78.5 Mbps with 3% standard deviation. And for large payloads, all values except for Windows XP with IPv4, all throughput values are tightly grouped around 75 Mbps. For packet sizes less than 1000 Bytes, Windows 2000 throughput values are significantly lower than both Windows Server 2003 and XP. For larger payloads, all three operating systems with both the protocols band together in throughput values except Window 2000 with IPv6 – this shows the lowest throughput for most sizes of payloads.

The operating systems evaluated in this research all have at the core the same Window NT kernel architecture and yet portray different throughput performance. In the absence of availability of the operating system source codes, we can only speculate reasons for differences in performance of the protocols. Comparing Windows 2000 IPv4/IPv6 performance for both TCP and UDP protocols with the newer operating systems (Windows XP and 2003), it is observed that Windows 2000 throughput values are significantly lower than both the counterparts for smaller packet sizes. We believe this difference can be attributed to how efficiently an operating system handles TCP/IP packet buffer allocated by the kernel. Packet buffer is a shared memory space on a computer that holds data as it transits between devices. In [8] the authors compared Windows 2000 with UNIX platforms (Solaris and Linux) and concluded that kernel buffer allocation strategies are less efficient in Windows 2000 platform when compared to UNIX counterparts. We see a similar performance difference with Windows XP and 2003 banding together at a higher average throughput value than Windows 2000 for smaller packet sizes. Therefore we believe packet buffer handling strategies have improved

significantly in the newer Windows operating systems, however there may still be differences between Windows XP and Windows 2003. Microsoft has also incorporated changes in newer kernels to improve its overall kernel scalability [22]. This includes improvements in scheduling, memory management, kernel spinlocks, and heap. While discussing how each of these mentioned changes affects performance is beyond the scope of this paper, we believe they have contributed to overall performance enhancement of newer Windows operating systems.

## VI. CONCLUSIONS AND FUTURE WORK

In this paper, we conducted unbiased empirical performance comparison of IPv4 and IPv6 protocol stack on Windows operating systems. We evaluated Windows XP Professional & Server 2003 and compared results with previously studied Windows 2000. Using TCP and UDP traffic between two nodes, and throughput as the metric, we found that:

- For small packet sizes, performance difference between IPv4 and IPv6 is lower than theoretical value of approximately 10.3%. Both Windows XP and Server 2003 have throughput difference of approximately 5% evident for both TCP and UDP traffic.
- For large packet sizes, IPv4 and IPv6 performance difference is higher than the theoretical value of 1.3%. TCP traffic on Windows Server 2003 shows a difference of 10.4% and UDP traffic on Windows XP shows 12%.
- Although two operating systems may have the same kernel, network performance can be different. Comparing throughput values obtained in this research, we conclude that network throughput depends not only on traffic type and Internet Protocol version, but is also governed by the choice of the operating system.

We plan to extend this study by incorporating more operating systems and the range of metrics. Other areas that will be investigated are Internet Protocols with wireless media.

# A New Proposal for Choosing a Deflection Link in a Deflection Network

M. Atiqur Rahman, M. Tanvir Hossain, and Shahed Anwar

Department of Computer Science & Engineering, University of Dhaka, Dhaka - 1000, Bangladesh

**Abstract** — In high-speed networks with greater connectivity, packets can be deflected through a sub-optimal path to reach the destination if the desired path is congested, failed or the buffer is full. However, in a combined store-and-forward and deflection network, packets are deflected when there is congestion in the network. For choosing a link for deflection in such a combined network, currently existing strategy considers only local information to the node in need to deflect a packet. In this paper, a new proposal has been introduced to select an outgoing link for deflection. Under the proposed strategy, packets are guaranteed to traverse through the best cost path available to the destination when they are deflected. Simulation shows better results than that of the existing strategy in terms of packet delivery, discard and average cost per delivered packet.

**Index Terms** — Computer Networks, Routing, Deflection Routing.

## I. INTRODUCTION

Currently computer networks supporting multi-gigabit transmission rates are feasible by using high-speed optical networks. Optical buffering, wave length conversion and deflection routing are technologies that can be used in optical networks for switching purposes to resolve contention [1]. However, as current optical buffers are typically limited to providing a few tens of micro seconds delay; it is not easy to store longer optical bursts. Compared to optical buffering and wavelength conversion, it is relatively easy to optically switching burst data [2]. Accordingly, another technique to control traffic flow and resolve contention in burst optical networks becomes attractive – “deflection routing”.

Because of high connectivity of the routers in current computer networks, there is generally more than one path that can be followed to reach a destination from the same source. With the high transmission rate, the degradation of performance can be kept within a tolerable range, if a packet is deviated from its optimal or shortest path even for real-time applications. In the case of store-and-forward routing, it is natural that, more packets can be stored using larger buffers. However, larger buffers can force packets to wait for longer period of time at each node. These packets could reach the destination through a suboptimal path instead of waiting in the queue for the preferred link. In the worst case, packets could be discarded when the queue or the buffers for the preferred link is full. These

packets could be given a second chance to follow an alternate route to the destination to improve the overall packet delivery or throughput [3]. This type of routing where a packet is intentionally deviated from its optimal path to the destination to a different path that can also lead the packet to its desired destination is known as Deflection routing. Work has been done in [3] to combine the store-and-forward approach of routing with the Deflection approach where nodes are allowed to have limited buffers to work just like store-and-forward routing when the network is in normal condition. But in case of congestion or failure of the preferred link, the combined routing strategy selects another link to deflect the packet exactly in the way the Deflection routing protocols work. But the choice for a deflection link proposed in [3] is not that much efficient in terms of the number of packets delivered, average cost per delivered packet etc. This paper has concentrated on this area of choosing a better link for deflection.

The rest of the paper is organized as follows. Section II explores related works on deflection routing and store-and-forward routing in detail. This section also includes a mixed approach for these two routing styles. In Section III, a new proposal to select a link for deflection in a combined store-and-forward and deflection network is given that results in better performance than that of what proposed in [3]. Section IV is dedicated to simulation and comparative study of the proposed strategy with the existing one. And finally, section V concludes the paper.

## II. EMPIRICAL STUDY

### A. Store-and-Forward Network

In a store-and-forward network, input and output queues (buffers) are attached to each link  $L$ . These buffers are used to temporarily store the incoming packets through link  $L$  and outgoing packets that will be forwarded on the link  $L$ , respectively. Since these buffers are of finite size, the output buffer can become full if the packet incoming rate for the link  $L$  is greater than the packet outgoing rate. Under pure store-and-forward routing, new packets are generally discarded when the output buffer becomes full.

### B. Deflection Network

In a deflection network, if two or more packets choose the same outgoing link  $L$  simultaneously, one packet is forwarded on link  $L$  and the other packet(s) are forwarded on alternate links, if possible. It can be assumed that, if some of the load is distributed among the idle links, the packets will not follow the optimal route, but the overall performance and number of delivered packets will be improved. Deflection is suitable for optical networks with no or limited buffering because, it is difficult to store optical messages [5].

The idea of buffer-less Deflection routing was first suggested by Baran [7]. The focus of Baran's investigation concerned the reliability of a communications network. He suggested that keeping packets "moving" regardless of the optimality of the path was a desirable property of a survivable network.

Lawrie and Padua [8] analyzed the performance of routing with limited buffers in the folded shuffle-exchange network. In this analysis, packets were not routed along shortest paths; a slightly longer path was sometimes chosen to simplify implementation.

### C. Mixed Approach

Deflection routing can be combined with store-and-forward routing in order to achieve certain performance gains from the following perspectives.

- 1) Retransmission and More Loads: Networks having too much buffer space is more harmful than having too little, since the packets or their retransmissions have to be dropped after they have consumed precious network resources [6].
- 2) Real-time application: For real-time applications long buffers should be avoided to satisfy the stringent delay requirements. For example, voice, video-conferencing, movie etc. These types of applications must satisfy some maximum delay [4].
- 3) No or Limited Buffer: Limited buffers can speed up the switching significantly in case of optical networks, so the process can follow the speed of the links as closely as possible.
- 4) Link Failure: In deflection routing, the packets for the failed link can be forwarded through other active idle links to balance the load of the failed link.
- 5) A hop-count bounded adaptive hybrid routing strategy that combines the store-and-forward approach with the deflection approach is proposed in [3].

When the outgoing queue of the link  $L$  is full and a new packet arrives that chooses link  $L$  then in pure store-and-forward routing, the packet is discarded generally. But, in [3] the author gives a proposal which, instead of discarding the packet, gives it a second chance to go to the network again and append it to the outgoing queue of a link chosen for deflection of the packet, if possible. The

author proposes that the datagram is allowed to be deflected no more than  $N$ -times, where  $N$  is the max. hop count value.

In [3], for choosing the deflection link, a scanning is performed among all the idle links and the first underloaded link found was used as the deflection link. When the output queue of the preferred link overflows, the output queue lengths of the available links are checked to find a deflection link. The first such link  $L$  is used as the deflection link. On the other hand, if there is no underloaded link, the packet is discarded.

## III. A NEW PROPOSAL FOR SELECTING A DEFLECTION LINK

Selection of a deflection link in a combined store-and-forward and deflection network is crucial, since it affects the performance of the overall routing strategy. In [3], the load of a link was used to reflect link utilization. As the estimation of the load, the current queue length of the link was used to keep the proposed strategy simple. For choosing a deflection link, [3] considered only information local to a node. The first found link with an underloaded outgoing queue was chosen as a deflection link regardless of the cost of the path the selected deflection link would direct the packet to. It had a potential problem of not forwarding the packet through the best cost path among all the available ones. Thus the probability of following the best cost path via the selected deflection link was,  $1/(k-1)$ , where  $k$  is the connectivity degree of the network.

To raise this probability to exactly 1, while choosing the deflection link, we have considered all the available links having an underloaded outgoing queue. It then selects the link as the deflection link that forwards the packet to the neighbor node with the minimum cost path to the destination of the packet. This definitely improves the performance of the network in terms of the number of packets delivered as well as the average cost per delivered packet. Here is how the proposed strategy selects the best cost path for deflection.

This strategy assumes that the routing tables of the nodes are updated by exchanging information with neighbors or adjacent nodes using Distance Vector Routing (DVR). Usually the routing table of each node contains an entry for each of the destinations in an one dimensional array recording the next hop to the destination with the associated cost to reach that destination as a set of triples of the form as follows -

(Destination, Cost, NextHop)

For example, Table I shows the complete routing table maintained at node B for the network in Fig. 1.

Fig. 1. An example network topology

TABLE I  
ROUTING TABLE MAINTAINED AT NODE B

Destination	Cost	NextHop
A	1	A
C	1	C
D	2	C
E	2	A
F	2	A
G	3	A

Instead of storing information only about the destination nodes, in our proposed strategy, the routing table of a node also stores the routing tables advertised by its directly connected nodes; i.e. its neighbors in a two-dimensional array as follows.

TABLE II  
ROUTING TABLE MAINTAINED AT NODE B ACCORDING TO PROPOSED APPROACH

Destination	Cost	NextHop	Routing Table
A	1	A	Routing table of A
C	1	C	Routing table of C
D	2	C	NULL
E	2	A	NULL
F	2	A	NULL
G	3	A	NULL

For a node, the routing tables of its neighboring nodes can be inserted into its routing table using the same DVR algorithm without increasing the time complexity of the algorithm but with an increase in space complexity. While nodes exchange their routing tables with their neighbors, each node, in addition to computing the costs to the destinations, also stores the advertised routing tables for future reference.

Whenever a node needs to deflect a packet, it scans its entire outgoing queues to find underloaded ones. Whenever such a queue is found, it finds out the link for which this outgoing queue is maintained. It then accesses the routing table of the node to which this node is connected through the link by accessing the appropriate

column of the routing table of the current node. From the accessed routing table, the cost of the best path to the destination of the packet to be deflected is found and stored in a variable called *min\_cost*. At the same time, another variable called *def\_link* is updated to point to the link corresponding to the cost stored in *min\_cost*. Initially *min\_cost* is assigned a very large value and *def\_link* is assigned to NULL. When all the outgoing queues are finished with searching, the current node decrements the deflection count of the packet by 1 and then deflects the packet through the link pointed to by the variable *def\_link*, if it is not NULL. Otherwise, it discards the packet.

In this strategy, the algorithm for routing a packet currently staying at node *i* is as follows –

1. Consult routing table of node *i*
2. Let  $L_{i1}$  be the preferred link to the next hop on the best route to destination.
3. If the queue for  $L_{i1}$  is full then
4. Set *def\_link* = NULL
5. Set *min\_cost* = MAX
6. For each outgoing queue  $q_i$  of node *i*
7. if  $q_i$  is underloaded
8. Consult routing table of *i* and find the cost of the path from the neighbor node for  $q_i$  to the destination node of the packet
9. if the received cost  $C_i < \text{min\_cost}$  then
10. Set *def\_link* = the outgoing link for queue  $q_i$  and *min\_cost* =  $C_i$
11. End of If structure
12. End of If structure
13. End of For
14. If *def\_link*  $\neq$  NULL then
15. Put the packet in the incoming queue of the node connected to node *i* through *def\_link*
16. Else
17. Discard the packet.
18. End of if structure
19. Else
20. Put the packet in the queue of link  $L_{i1}$
21. End of if structure

**Complexity Study of the Proposed Strategy:** A node in need of finding a deflection link, explores all its *k* outgoing links which takes  $O(k)$  time, where *k* is average degree of connectivity. Since  $k \ll n$ , where *n* is the total number of nodes, we can say that the proposed strategy calculates the deflection link in constant time. Again, since it requires for each routing table of a node to store the routing tables of its neighbors, the space complexity of this approach is for storing the routing table is  $O(n^2)$  instead of  $O(n)$ .

#### IV. SIMULATION

In this chapter simulation technique, comparisons and results are discussed. Simulations have been performed for datagram service network based on the approach proposed in [3] and the newly proposed strategy using a program written in Java. Simulation results are observed in terms of number of packets successfully delivered and the total cost.

##### A. Major Parameters Observed

Each Router has queues on its entire links. Queue Capacity specifies the capacity of these queues. In a particular test case all the queues have equal capacities. Maximum Bandwidth specifies the maximum bandwidth of the links in a network. During simulation all links are given a bandwidth value within the range 2 to max. bandwidth. Packets/Timeslot means how many packets are generated on each of the routers in every timeslot. Maximum Deflections Allowed indicates the maximum number of times a packet is allowed to be deflected. Total Packets Generated indicates the total number of packets generated in a particular test case. Average Packet Delivery indicates how many packets on an average could be successfully delivered in a given test case. Average Packet Discards indicates how many packets on an average were discarded in a given test case. All Queues Full (AQF) indicates how many packets were on an average discarded because of the case that all of the outgoing queues in a Router were full. Maximum Deflection Reached (MDR) indicates how many packets were, on an average, discarded due to exceeding the maximum allowed deflections. Each link on the network is assigned a cost randomly. When a packet travels through a link, it adds up the cost of that link to its own cost overhead metric. In this paper, Average Cost specifies the total cost overhead of all of the packets incurred during a particular test case divided by the number of delivered packets.

In all the test cases the following parameters were kept constant:

Total Number of Routers in the Simulated Network: 20;  
Maximum Cost of a Link: 20; Number of Timeslots Simulated in a Test Case: 2000

##### B. Simulation Technique

The simulation technique assumes time as discrete, non-overlapping and consecutive time slots of same duration. Each time slot is considered as unit time. The simulation is performed for the time period T between two consecutive routing updates. It starts after collecting all the required routing information from the other nodes of the network and assumes that, during simulation routing tables do not change. It first computes the routing tables that contain the cost of paths, next hop on that path. Then, it is executed for certain number of timeslots. In each time slot, constant load (fixed number of packets) is generated at each router and the packets waiting in the queues of the nodes advance one hop to their destination.

Result tables are presented below, comparing the outcomes obtained after applying the previous as well as the proposed approach respectively under different test conditions. First of all we have used different Queue Capacities and measured the Average Packet Delivery and Costs, both for the old and proposed approach in Table III. In Table IV you will see the results found by varying the Maximum Bandwidth value. Finally, Table V shows the results found by altering the network load. Each table is also followed by two charts depicting the difference between the two approaches. The first chart shows how better the proposed approach performed in terms of Average Packet Delivery and the second chart shows how much cost savvy the proposed approach is compared to the old approach. In almost all cases the proposed approach has resulted in far better results.

##### Case 1: Varying the queue capacity

In this test case the following parameters were kept constant and only the Queue Capacity was varied:

Maximum Bandwidth = 10; Packets/Timeslot = 20;  
Maximum Deflections Allowed = 5; Total Packets Generated = 8,00,000

TABLE III  
VARYING THE QUEUE CAPACITY

	Queue Capacity	Avg. Packets Delivered	Delivery in Percentage	Avg. Packets Discarded	Discards in Percentage	AQF	MDR	Avg. Cost
Old Approach	1	51157	6.39	748661	93.58	748661	0	139.29
	5	216341	27.04	582801	72.85	555601	27200	137.86
	10	296573	37.07	501633	62.7	412311	89322	123.54
	20	295143	36.89	500993	62.62	393147	107846	139.43
Proposed Approach	1	85633	10.7	714167	89.27	714167	0	85.33
	5	375518	46.94	423554	52.94	383992	39562	75.89
	10	411822	51.48	386400	48.3	303249	83151	80.6
	20	462911	57.86	333351	41.67	225102	108249	74.94

Fig. 2. Impact of varying queue capacity on average packet delivery

Fig. 3. Impact of varying queue capacity on average cost

#### Case 2: Varying the bandwidth

In this test case the following parameters were kept constant while the Maximum Bandwidth of the links was varied:

Queue Length = 5; Maximum Bandwidth = 10;  
Maximum Deflections Allowed = 5

For datagram service, the proposed strategy performs better in terms of number of packets delivered and total

TABLE IV  
VARYING THE MAXIMUM BANDWIDTH

	Max. Bandwidth	Avg. Packets Delivered	Delivery in Percentage	Avg. Packets Discarded	Discards in Percentage	AQF	MDR	Avg. Cost
Old Approach	2	118913	14.86	680077	85.01	680013	64	134.49
	10	216341	27.04	582801	72.85	555601	27200	137.86
	16	267263	33.41	531713	66.46	458298	73415	128.74
Proposed Approach	2	176567	22.07	622476	77.81	622476	0	78.57
	10	375518	46.94	423554	52.94	383992	39562	75.89
	16	429500	53.69	369399	46.17	299670	69729	74.29

Fig. 4. Impact of varying bandwidth on average packet delivery

Fig. 5. Impact of varying bandwidth on average cost

Queue Length = 5; Packets/Timeslot = 20; Maximum Deflections Allowed = 5; Total Packets Generated = 8,00,000

#### Case 3: Varying the load

In this test case the following parameters were kept constant while the Number of Packets Generated per timeslot was varied:

path cost traversed by packets. From the simulations performed above it is understood that the proposed approach gives better results if there is more traffic in the network. Also as in the proposed approach, packets get the opportunity to go through the next possible sub-optimal path, in case an optimal (or sub-optimal) path is engaged, the average cost incurred by all the packets are always less than the previous approach.

TABLE V  
VARYING THE MAXIMUM BANDWIDTH

	Packets/ Timeslot	Total Packets Generated	Avg. Packets Delivered	Delivery in Percentage	Avg. Packets Discarded	Discards in Percentage	AQF	MDR	Avg. Cost
<b>Old Approach</b>	5	200000	188191	94.1	11458	5.73	0	11458	30.15

## V. CONCLUDING REMARKS

In order to select the deflection link, further trick can be applied. Even after choosing the deflection link according to the strategy proposed in this paper it may appear that, the next link has all its outgoing links congested. If it is possible to be aware of this situation well ahead of time, the performance of the routing can be improved even better.

# Design and Construction of Direct Sequence Spread Spectrum CDMA Transmitter and Receiver

M. Habib Ullah, Akhmad Unggul Priantoro, M. Jasim Uddin,  
Department of Electrical and Computer Engineering  
International Islamic University Malaysia  
habib\_ctg@yahoo.com

**Abstract** - Spread Spectrum Communication techniques have been widely accepted in mobile and wireless communications. They have very beneficial and tempting features, like Antijam, security, and multiple accesses. It is the purpose of this paper to describe the features of Spread Spectrum systems. The emphasis will be on the Direct Sequence Spread Spectrum (DS-SS) scheme, Pseudo Noise signals (PN), Modulators and Demodulators, Hardware implementation and illustrate some of the DS-SS system features.

**Index Terms** - CDMA, PN Code, Modulation, Demodulation, DS-SS.

## I. INTRODUCTION

Spread Spectrum Communications is one of the widely used data communication schemes nowadays. It has many features that make it suitable for secure, multiple accesses, and many other properties that are needed in a communication system. Spread Spectrum is defined as: Spread Spectrum is a means of transmission in which the signal occupies a bandwidth in excess of the minimum necessary to send the information. The band spread is accomplished by means of a code, which is independent of the data, and synchronized reception with the code at the receiver is used for despreading, and subsequently data recovery. Basically spread spectrum is a coding technique for digital transmission. It was originally developed for the military under a veil of secrecy. The purpose of coding is to transform an information signal so that it looks more like noise. In the receiver, the incoming signal is decoded, and the decoding operation provides resistance to interference and multi path fading. The spreading or dilution of energy in spread spectrum systems over a wide bandwidth results in several possible advantages, short-range interferences-free overlays on their emissions, and resistance to interference, from other emissions, and low detestability. The low spectral density needed for spread spectrum communication systems, as well as ability of some of these systems

to process signals that are carried far into the noise, offer a potential for shared spectrum use with existing Systems on a non-interference basis. Finally, Spread spectrum systems could be useful in applications to control multi path interference [1].

## II. CDMA OVERVIEW

Spread Spectrum communication techniques provide a new method of multiple access, known as CDMA (Code Division Multiple Access) that is proposed as an interesting alternative with respect to the traditional methods, i.e.: the well-known TDMA (Time Division Multiple Access) and FDMA (Frequency Division Multiple Access) [2]. The main parameter in spread spectrum systems is the processing gain the ratio of transmission and bandwidth has shown in equation 1.

$$G_p = \frac{BW_t}{BW_i} \quad (1)$$

The processing gain determines the number of users that can be allowed in a system, the amount of multi-path effect reduction, the difficulty to jam or detect a signal etc. For spread spectrum systems it is advantageous to have a processing gain as high as possible. A PNcode is a sequence of chips valued -1 and 1 (polar) or 0 and 1 (non-polar) and has noise like properties. This results in low cross-correlation values among the codes and the difficulty to jam or detect a data message. Several families of binary PNcode exist, they are addressed in another. A usual way to create a PNcode is by means of at least one shift-register. When the length of such a shift-register is n, the following equation 2 can be said about the period of the above mentioned code-families:

$$N_{DS} = 2^n - 1 \quad (2)$$

In direct-sequence systems the length of the code is the same as the spreading-factor with the consequence has shown in equation 3:

$$G_p(DS) = N_{DS} \quad (3)$$

This can also be seen from figure 1, where it shows how the PN code is combined with the data signal ( $N_{DS}=7$ ). The bandwidth of the data signal is now multiplied by a factor  $N_{DS}$ . The power contents however stay the same, with the result that the power spectral density lowers.

Figure 1: direct-sequence spreading

The generation of PN codes is a number of shift-registers are all that is required. For this reason it is easy to introduce a large processing-gain in Direct-Sequence systems. The main problem with applying Direct Sequence spreading is the so-called Near-Far effect. This effect is present when an interfering transmitter is much closer to the receiver than the intended transmitter. Although the cross-correlation between codes A and B is low, the correlation between the received signal from the interfering transmitter and code A can be higher than the correlation between the received signal from the intended transmitter and code.

#### A. General model of a spread spectrum digital communication

The input is fed into a channel encoder that produces an analog signal with a relatively narrow bandwidth around some center frequency. This signal is further modulated using the sequence of digits known as spreading code or spreading sequence. Typically, but not always, the spreading code is generated by pseudo noise or pseudo random number, generator. Figure 2 shows General model of a spread spectrum digital communication [1].

I/O  
DATA

Figure 2: General model of a spread spectrum digital communication

The effect of this modulation is to significantly increase the bandwidth (spread the spectrum) of the signal to be transmitted. On the receiving end, the same digit sequence is used to demodulate the spread spectrum signal. Finally, the signal is fed in to a channel decoder to recover the data. Spread spectrum uses wide band, noise-like signals. Because spread spectrum signals are noisy they are hard to detect. Spread spectrum signals are also hard to intercept or demodulate. Further spread spectrum signals are harder to jam (interfere with) than narrow band signals due to the increased bandwidth. To qualify as a spread spectrum signal, two criteria should be met:

1. The transmitted signal bandwidth is much greater than the information bandwidth.
2. Some function other than information being transmitted is employed to determine the resultant transmitted bandwidth.

#### B. Pseudo-Random Noise Codes:

A PNcode used for DS-spreading exists of  $N_{DS}$  units called chips, these chips can have 2 values: -1/1 (polar) or 0/1. As we combine every data symbol with a complete PNcode, the DS processing gain is equal to the code-length.

The sequences must be building from 2-leveled numbers. The codes must have a sharp (1-chip wide) autocorrelation peak to enable code synchronization. The codes must have a low cross-correlation value, the lower this cross correlation, the more users we can allow in the system. This holds for both full-code correlation and partial-code correlation. The latter because in most situations there will not be a full-period correlation of two codes, it is more likely that codes will only correlate partially (due to random-access nature). The codes should be "balanced": the difference between ones and zeros in the code may only be 1. This last requirement stands for good spectral density properties (equally spreading the energy over the whole frequency-band).

#### C. Direct Sequence-spread Spectrum Transmitter and Receiver

In Direct Sequence-Spread Spectrum the baseband waveform is multiplied by the PN sequence. The PN is produced using a PN generator. Frequency of the PN is higher than the Data signal. This generator consists of a shift register, and a logic

circuit that determines the PN signal. After spreading, the signal is modulated and transmitted. The most widely modulation scheme is BPSK (Binary Phase Shift Keying) [10]. Figure 3 shows the PN Generator Block Diagram.

Figure 3: PN Generator Block Diagram

The equation 4 represents this DS-SS signal.

$$S_n = \sqrt{\frac{2E_s}{T_s}} m(t) p(t) \cos(2\pi f_c t + \theta) \quad (4)$$

where  $m(t)$  is the data sequence,  $p(t)$  is the PN spreading sequence,  $f_c$  is the carrier frequency, and  $\theta$  is the carrier phase angle at  $t=0$ . Each symbol in  $m(t)$  represents a data symbol and has a duration of  $T_s$ . Each pulse in  $p(t)$  represents a chip, and has a duration of  $T_c$ . The transitions of the data symbols and chips coincide such that the ratio  $T_s$  to  $T_c$  is an integer. The waveforms  $m(t)$  and  $p(t)$  are shown in fig. 5. Here we notice the higher frequency of the spreading signal  $p(t)$ . The resulting spread signal is then modulated using the BPSK scheme. The carrier frequency  $f_c$  should have a frequency at least 5 times the chip frequency  $p(t)$ . In the demodulator section, there has been simply done reverse the process. We Demodulate the BPSK signal first, Low Pass Filter the signal, and then despread the filtered signal, to obtain the original message. The process has shown in equation 2.1. In the demodulator section, we simply reverse the process. Demodulate the BPSK signal first, Low Pass Filter the signal, and then despread the filtered signal, to obtain the original message. The process has been described in equation 5 [3].

Figure 4: DS-SS Transmitter Block Diagram

Figure 5:  $m(t)$  and  $p(t)$  for a Maximum Length PN

$$m(t) = \sqrt{\frac{2E_i}{T_i}} m(t) p(t) \frac{1}{2} [1 + \cos(4\pi f_c t + 2\theta)] \quad (6)$$

As shown in equation 5 and 6 when we multiply two cosine signals together, we will obtain two expressions, one of which has twice the frequency of the original message. And this part can be removed by a LPF. The output is  $m_{ss}(t)$  as shown in figure 5. This design is based on Coherent Detection BPSK, so we don't have to worry about carrier synchronization issues. Basically we have tried to construct the modulated part in our project. But for receiving data we have designed the Demodulator circuit by the software of 'Electronic Workbench'. As for the PN sequence in the receiver, we mentioned earlier that it should be an exact replica of the one used in the transmitter, with no delays, because this might cause severe errors in the incoming messages. Again, my design is based on the idea that PN sequences are matched, and actually we are going to use the same generator for both to ease the design. There are various techniques that deals with PN delay problems and mismatches, but we are not going to encounter any in this design [4]. After the signal gets multiplied with the PN sequence, the signal despreads, and we obtain the original bit signal  $m(t)$ , that was transmitted. The block diagram of the receiver is shown in figure 6 [5].

Figure 6: DS-SS receiver

This simple straightforward description of DS-SS systems, will allow us to design the Modulator

circuits with some ease. We are going to take advantage of the block diagrams for each one of them.

#### D. The Direct sequence spread spectrum Modulator Design:

In this chapter, we are going to illustrate the circuit design and show the simulation of the DS-SS Modulator (Transmitter). Simulations were conducted using the EWB (Electronics workbench) software and also Hardware. Ideal components were used for the ease of the design, and to try to avoid other factors, that might directly affect the performance of the system. And since we are going to design a simple circuit for educational purposes, we decided to use the ideal components offered inside the software although I constructed it in hardware[9].

#### E. The PN Generator Design

The design of the PN generator is based on the block diagram shown in figure 7. Here we are going to need 4 D-Flip-Flops (FFs), a XNOR gate, and a Clock source. Since we are using 4 FFs,  $m=4$  and the PN signal will repeat every 15 clock cycles. We have chosen the CLK frequency,  $f_{CLK}=100$  KHz. The period of the PN chip is  $TPN_{chip} = 1/100k = 10^{-5}$  seconds. The total period of the PN sequence  $TPN = 15 * TPN_{chip} = 15 * 10^{-5}$  seconds. The period of the Binary Input signal (per bit) is going to be  $T_b = TPN = 15 * 10^{-5}$  seconds, that is a frequency  $f_b = 6.6667$  KHz. The Clock signal was taken from an external source (a Function Generator) [6, 7]. We can design a clock using an oscillator. But we are not going to go into that. The Circuit that resembles this PN is now easily understood. It is shown in figure 7. In our project we used only PN without data. We can let PN is the data. From this design, the output level from the PN is not 1,-1 as was indicated in the signal diagram of  $p(t)$ . The output PN sequence is shown in figure 8.

Figure 7: The PN Generator Circuit Diagram.

Figure 8: The PN Signal

#### F. The Input Word Generator Design:

The Word Generator Circuit design is based on the one designed and illustrated in equation 6. The Word Generator consists of two ICs, an Inverter, a Clock signal with frequency of 6.666KHz, and a DC supply. The 74163 IC is a TTL 4-bit binary counter, and the 74166 is a TTL 8-bit Parallel-In/Serial-Out Shift Register. The Clock signal feeds both ICs as shown in 9. The shift register loads the levels on its inputs when the Parallel Load signal is activated. Then it starts to shift the data, and sends them serially. The Parallel Load signal is taken from a 4-bit binary counter, so that after the counter finishes its count cycle, it will issue the RCO 1 signal, which is used to trigger the shift counter to activate the Parallel Load function. There would be obtaining a controllable 8-bit periodic Word Generator signal. The Signal obtained is shown in figure 10. The 8-bit Word is then multiplied by the PN signal. In the block diagram there has been used a NRZE 2 to adjust the Word level voltages. Now, assuming that we are using the NRZE, the output of the multiplier given the word signal shown in figure 10.

Figure 9: The 8-bit Generator Circuit diagram with a data rate (period of one bit) of 6.666 KHz

Figure 10: The 8-bit word signal.

There has been seen the PN signal affects the incoming word signal that is 1/15 of its frequency.

When a  $\bullet 5$  is multiplied with a  $+5$  the result is  $\bullet 25$ . And when a  $\bullet 5$  is multiplied by a  $\bullet 5$  the result is a  $+25$ . I mentioned in the previous section that the output of the PN is a 0–5 volts, not a  $\bullet 5$ –5 level. Also, the Word levels are 0–5 not  $\bullet 5$ –5. This means that i can't use the multiplication procedure here, because a  $0 \cdot 0$  is not equal to 1. To overcome this problem, and to eliminate the use of a NRZE for the word signal, i substituted the Multiplier with a XNOR gate.

#### G. The BPSK Modulator Design:

This section illustrates the design of the BPSK modulator. The design is directly based on the block diagram shown in figure 9. Figure 11 shown in BPSK Modulator circuit. The design and simulations are based on the use of ideal components. The BPSK Modulator is based on the idea of changing the phase of the carrier signal whenever the incoming Bit changes its state, for example, if the incoming message changes its state from 0–1, the carrier changes its phase by  $+180^\circ$ , and if it changes its state from 1–0 the carrier changes its phase by  $-180^\circ$ .

Figure 11: The BPSK Modulator circuit

For the design of BPSK modulator we used two inverting OP-AMP with the gain 1 and also two analogue switch and one inverter. At operation of the BPSK, the carrier signals are entered into the OP-AMPs through the analog switches which are active at the positive pulse. So switches are controlled by the data. When PN is +ve, the switch one is on and the signal pass and enter into the 1st OP-AMP it inverts this signal [8]. At the same time 2nd switch remains off because it is connected with an inverter. When this signal cross 2nd OP-AMP the signal is inverted again and comes to the original position. On the other hand the 2nd switch will be on when the PN is –ve and it will enter into only the 2nd OP-AMP and invert. In this way it transmits

data. The input carrier frequency used in this design is 5 times f<sub>pn</sub> chip, which is 500 kHz. But in our circuit implementation we used carrier of 100 kHz if we give more as like simulation, it is difficult to find out the phase shift in the oscillator. Though one can rise the frequency of the signal in wireless applications to end up with a shorter antenna for the devices. Anyway, this isn't our concern in this report. The modulation process, we finally get the  $S_{ss}(t)$  which is the signal obtained from the output of the Modulator circuit. The output of the DS-SS Modulator is shown in figure 12 and precise mode figure 13. Here, a couple of the bits from  $S_{ss}(t)$  has illustrate the output signal.

Figure 12:  $S_{ss}(t)$  The DS-SS signal coming out

Figure 13:  $s_{ss}(t)$  The DS-SS signal coming out of of the Modulator (Precise mode).

#### H. Bandwidth consideration of BPSK:

A balance modulator is a product modulator, the output signal is the product of the two input signal. In a BPSK modulator, the circuit output signal is multiplied by the binary data. If +1V is assigned to a logic 1 and -1V is assigned to a logic 0, the input carrier ( $\sin \omega_c t$ ) is multiplied by either a +1 or -1. Consequently, the output signal is either  $+1\sin \omega_c t$  or  $-1\sin \omega_c t$  [9, 10]. This paper described the design of the modulation technique of direct sequence-spread spectrum with its hardware implementation. It also describes the characteristics of BPSK modulator. There has been found the circuit's output characteristics and the BPSK modulated signal's characteristic is same

although a fault was found in our circuit's OP-AMP (at BPSK modulator circuit). As in obvious form the observed out put and simulated out put there is same anomaly. The amplitude of the observed output (fig 14) is not uniform all along. There are sudden jumps in the output wave shape. The cause of these jumps may be manufacturing non uniformly of the integrated circuits.

Figure 14: Circuit's output

In the physical structure, it has been used available components. Firstly there has been first designed it by the simulation software named EWB (Electronics Workbench). There also has been designed the Demodulator circuit with the software and it works successfully.

Figure 15: DS-SS receiver circuit diagram

Figure 14 shows the diagram of the filter (the Sallen-Key second order active filter) and figure 15 shows the full diagram of the demodulator circuit. One who is interested as for Multiplier (Balance Modulator) he can use MC1496 IC. Here all equipments are common and available. Finally, hope that this report has supplied you with some new information, techniques, and ideas. Again, it is intended to be as an educational supplement for any advanced communications course, where the student wants to see a practical application on what is studying.

### III. Conclusion

This paper demonstrated the design of a simplified Direct Sequence Spread Spectrum CDMA system. Design of 8-bit word generator is given. Spreading technique is clearly implemented. Finally, original data are recovered by despreading in receiver.

**Abstract** — Ad hoc wireless networks are decentralized in nature and hence routing is a central challenge in this type of network. In this paper we describe a simulation model to simulate the routing protocols for wireless ad hoc networks and analyze the results from the simulation for performance evaluation. The simulation model incorporates the number of parameter values with changing environmental factors. Specially we have chosen the Dynamic Source Routing (DSR) and Ad-hoc On Demand Distance Vector Routing (AODV) protocol to be implemented in the simulation software with that model. We carried out the extensive simulations and we conclude with the comparative statistical analysis of those two protocols based on mobility factor.

**Index Terms** — MANET, Wireless ad-hoc, routing, DSR, AODV.

## I. INTRODUCTION

Both Dynamic Source Routing (DSR) [1] and Ad-hoc On Demand Distance Vector Routing (AODV) [2] are reactive and on-demand routing protocols [3] where source initiates the route discovery process to find the route to the destination. DSR takes the advantage of route cache, in which it caches source routes that it has learned, maintained by each host in the ad hoc network [4]. In contrast, in AODV the packet header contains only the next hop address for a desired destination.

A packet-level simulation model that was used allowed us to observe and measure the protocols' performance under a variety of conditions. The basic simulation parameters were chosen to model an ad hoc network consisting of a collection of mobile hosts moving around in a certain space. In addition to a number of parameter choices in the protocol, the simulator allows us to vary certain environmental factors such as –

- The number of mobile hosts
- Mobility Pattern of the hosts
- Traffic pattern
- Simulation time and the distribution of the hosts in space.

Each host is initially placed at a random position in the simulation area. As the simulation progresses, each host pauses at its current location for a period (pause time), and then randomly chooses a new location to move with a

velocity in a predefined range. Thus the uses of constantly changing factors gave us an opportunity to analyze the protocol in a wide range of situations.

Some performance metrics were measured from the simulation results and those metrics were analyzed for evaluating the protocols' performance. These performance metrics include -

- Packet delivery ratio – The ratio of data packets delivered to the destinations and data packets originated by the sources.
- Average end-to-end delay of data packets – This includes all possible delays of propagating the packets.

## II. SIMULATION MODEL AND METHODOLOGY

The modeling under the simulating software is divided into 3 levels. The upper level is the network level, and consists in the building of the network topology. The second level is the description of each node that composed this network topology, namely node model. The third and last level is the description of each of these processes that composed a node model. In next section we present the node model for the DSR protocol.

### A. The Node Model

Here is a description of each layer of the DSR node model:

- The physical layer is composed of a transmitter and a receiver. Actually, both the physical and the link layer of this DSR node model come from the Wireless LAN model. Both the transmitter and receiver communicate with upper layers through the 802.11 MAC protocol.
- The link layer used in the model is the 802.11 model. Some small modifications are included in order to link this MAC layer with our DSR routing layer (sending of acknowledgement and error messages, addition of the promiscuous mode). We choose to use 802.11 since this protocol is presently in fashion in the MANET community, and seems to be the protocol that will be used in this kind of network.

1(a)

1(b)

1(c)

1(d)

Figure 1: Pause Time vs Packet Delivery Fraction (PDF)

- The network layer is the core of our node model since it contains our DSR routing process model. As the 802.11 layer, it is divided in two processes. The first one is the DSR routing module, and the second one an interface with the upper layer that chooses for instance a random destination address for each data packet that must be transmitted on the network.
- The upper layers are mainly composed of two processes. The source is a process that generates data packet traffic. The receiver is a sink that just destroys the packet after the reception and processing completion.
- We placed another process model in the upper layers, called mobility. This one is in charge of the node mobility. This process defines the mobility pattern of the node, selects the destination point of that node. Upon reaching this point, the node pauses for a wait timer and then computes a new destination.

We use a detailed simulation model based on ns-2 in our evaluation. In a paper, the Monarch research group

at Carnegie-Mellon University[5] developed support for simulating multi hop wireless networks complete with physical, data link, and medium access control (MAC) layer models on ns-2.

#### B. The Traffic and Mobility Model

Traffic sources are continuous bit rate (CBR). The source-destination pairs are spread randomly over the network. Only 512-byte data packets are used. The number of source-destination pairs and the packet sending rate in each pair is varied to change the offered load in the network.

For the simulations carried out, traffic models were generated for 50 nodes with cbr traffic sources, with maximum connections of 10,20,30,40 at a rate of 4kbps. Now we varied the the no. of sources within the network. For example our simulation ran for each instance with 10, 20, 30, 40 sources.

Mobility models were created for the simulations using 50 nodes, with pause times of 0,20,40,70,100 seconds, maximum speed of 20m/s, topology boundary of 500x500 and simulation time of 100secs.

2(a)

2(b)

2(c)

2(d)

Figure 2: Pause Time vs Average end-to-end Delay

Simulations could be carried out with more complex scenarios using higher traffic rates. However, the simulations take much longer to complete and the trace file generated by each run ends up to more than 50 Mb of user space.

### III. OBSERVATIONS

To analysis any routing protocol we have to measure some performance metrics which are discussed in the previous part. Among those performance metrics we have chosen two important metrics to analyze our concerned protocols. Those are –

- Packet Delivery Fraction
- Average end-to-end delay of data packets

We have measured these four performance metrics based on the *Pause Time* environmental factor that actually represents the mobility pattern.

#### A. Pause Time

Pause time indicates how much time a mobile host keeps stagnant at a particular position. In a mobile adhoc network simulation a host randomly selects a particular direction and goes to that direction. After reaching that position the node waits for a certain amount of time. This time is called pause time. In our simulation we vary this pause time and find the value of different performance metrics for those pause time.

Now we will see the result of the simulation of both DSR and AODV protocol where we vary the pause time as 0,20,40,70,100 and plot the performance metrics against them.

The first set of experiments uses differing numbers of sources with a moderate packet rate and varying pause times. For the 50 node experiments we used 10, 20, 30, and 40 traffic sources and a packet rate of 4 packets/s, except for 40 sources, which use 3 packets/s. We used a slower rate with 40 sources because the network congestion was too high otherwise for a meaningful comparison. The packet delivery fractions for DSR and AODV are significantly different with 10 and 20 sources

(Fig. 1a and b). DSR is likely to perform well in these situations. With 30 and 40 sources, AODV tends to perform almost similarly with DSR (Fig. 1c and d) at lower pause times (higher mobility). For higher pause times (low mobility), however, DSR has a better delivery fraction than AODV. The relative performance of both protocols with respect to delays is similar to that with delivery fractions. DSR and AODV have almost identical delays with 10 and 20 sources (Fig. 2a and b) and with higher mobility. With 30 and 40 sources, AODV has higher end-to-end delay than DSR (Fig. 2c and d) for lower pause times. But for higher pause times, DSR has better (10–20 percent lower) delay than AODV.

One interesting observation is that the delays for both protocols increase with 40 sources with very low mobility (Fig. 2d). This is due to a high level of network congestion and multiple access interferences at certain regions of the ad hoc network. Neither protocol has any mechanism for load balancing, that is, choosing routes in such a way that the data traffic can be more evenly distributed in the network. This phenomenon is less visible with higher mobility where traffic automatically gets more evenly distributed due to source movements.

#### IV. DISCUSSION

##### A. Effect of Mobility

Our simulation results show that mobility affects the performance of AODV and DSR differently. In the presence of high mobility, link failures can happen very frequently. Link failures trigger new route discoveries in AODV since it has at most one route per destination in its routing table. Thus, the frequency of route discoveries in AODV is directly proportional to the number of route breaks. The reaction of DSR to link failures in comparison is mild and causes route discovery less often. The reason is the abundance of cached routes at each node. Thus, the route discovery is delayed in DSR until all cached routes fail. But with high mobility, the chances of the caches being stale are quite high in DSR. Eventually when a route discovery is initiated, the large numbers of replies received in response are associated with high MAC overhead and cause increased interference to data traffic. Hence, the cache staleness and high MAC overhead together result in significant degradation in performance for DSR in high mobility scenarios. Our simulation results show that this effect is more severe with large numbers of sources and for larger networks.

With low mobility, the possibility of link failures is low. However, nodes usually get clustered with low mobility, an artifact of our node movement (random waypoint) model. This leads to network congestion in

certain regions in the presence of high traffic. Congestion in turn causes link layer feedback to report link failures even when the nodes are relatively static and the physical link exists between nodes. Such spurious link failures lead to new route discoveries in AODV. DSR, in contrast, is largely unaffected by this problem at low mobility. DSR caches are nearly up to date in low-mobility cases. Thus, even when a spurious link failure is reported, DSR benefits from caching considerably by salvaging at intermediate nodes and using alternate routes at the sources. Also, the AODV timer-based route expiry mechanism could result in unnecessary route invalidations since the spacing between data packets using a route is critical to refreshing timers associated with that route at different nodes. The above effects of mobility are particularly visible for high traffic scenarios. Also, in reality, a combination of nodes with different mobility (different speeds and different pause times) can form an ad hoc network. In that case, it is hard to predict the relative performance of AODV and DSR.

##### B. Packet Delivery and Choice of Routes

DSR fared comparatively well in our application-oriented metrics (delivery fraction and delay) in more “stressful” situations (i.e., larger numbers of nodes, sources, and/or higher mobility). However, AODV also performed better in less stressful situations. The reason for both of these phenomena is the aggressive use of route caching in DSR. In our observation, such caching provides a significant benefit up to a certain extent. But with extreme loads the extent of caching is deemed too large to benefit performance. The simulation time span was at best 200 sec but in reality more stressful situation can be created with larger time frame. It’s an assumption that AODV will outperform DSR in more stressful conditions. Often, stale routes are chosen since route length (and not any freshness criterion) is the only metric used to pick routes from the cache when faced with multiple choices. Picking stale routes causes two problems:

- Consumption of additional network bandwidth and interface queue slots even though the packet is eventually dropped or delayed
- Possible pollution of caches in other nodes

We have also independently observed that cache expiry using suitable timeouts and wider propagation of route errors can improve the performance of DSR significantly. When compared to AODV, a much smaller number of packets was dropped in DSR for lack of route (e.g., indicating a high cache hit ratio); however, significantly more packets were dropped due to the interface queue being full. An efficient mechanism to “age” packets and

drop aged packets from the network will improve delays in both protocols, particularly DSR.

## V. FUTURE DIRECTIONS

The simulations were not done for larger time span. Actually the ad-hoc network does not exist for only 200 sec which was our highest implementation. An ad-hoc network operates in a larger time span. So if we can increase the simulation time then we can further trace the activities of the nodes and hence analyze the performance in more details and with higher accuracy.

## VI. CONCLUSION

The simulation was done with the specified environmental conditions and with the changing parameters. In cases of high mobility (low pause time), it was found that the DSR protocol produced a higher PDF (packet delivery fraction) than AODV. One important thing to note is that PDF values converge to same values with decreasing mobility i.e. both the protocols tend to perform similarly in stable, non-mobile conditions. Now, for end-to-end delay, it was seen that in highly mobile conditions (when nodes have less pause time) both AODV and DSR performs almost similarly. But, with the

increase of pause time, DSR exhibits notable improvement over AODV, because AODV produces higher end-to-end delay with decreasing mobility. So, in short, DSR is likely to perform better than AODV in more stressful situation.

**Abstract**—Cellular mobile networks use time of arrival (TOA), time difference of arrival (TDOA), angle of arrival (AOA) or received signal strength (RSS) based measurement techniques for mobile position estimation. Each of these measurement techniques has its degree of accuracy and level of complexity. Individual methods are usually not able to give adequate correct position of a mobile user. Therefore, a common trend is to combine these methods with other suitable techniques to attain enhanced performance. There are several algorithms to compensate the position errors by combining different methods. In this paper, a two step least square algorithm for wireless position estimation technique is implemented in WCDMA system where an angle of arrival (AOA) assisted and correlation slope-based time difference of arrival (TDOA) measurement method is considered and their performance is presented in signal to noise ratio conditions

## I. INTRODUCTION

Cellular network based wireless location systems have been researched and successfully deployed for a few decades, but with limitations in accuracy due to multipath and other complications. Code-division multiple access (CDMA) systems overcome [4] this moderately, as their wide bandwidth is able to resolve some of the multipath components. CDMA systems assign each user a unique pseudonoise (PN) spreading code, which makes the identification of multipath components with delay over one PN code chip epoch efficient by signal correlation processing. The correlation peak of a multipath with a delay over one chip does not affect the correlation peak position of the direct signal. One chip epoch in CDMA system is about 800 ns which equals to 240 metres in distance and for WCDMA one chip epoch is about 260 ns [1]. The reflected rays arriving within a chip period of the first ray cannot be resolved by a correlation technique, which is a significant factor limiting the location accuracy. In order to meet the accuracy requirements in handset-based solutions, the mitigation of the effects of intra-chip multipath must be considered.

There are two major methods to implement a cellular network-based location system. In the first approach, the mobile station (MS) receives signals from the base stations

(BS) to calculate its own position, as in GPS. In the second approach, the BS's process the signals from the MS to locate the user. The second approach has the advantage of using the existing receiver. There are several systems using cellular network based or GPS-assisted cellular network-based solution in which a cell phone user receives GPS signals and also connected to a network-based location server which give the actual user location.

The primary objective of this work is to find out the best i.e. the most accurate radio location measurement technique. The target is also to develop a practical signal processing method in mobile based location systems to estimate the AOA and the TDOA for the LOS signal under multipath environments.

This paper is divided into several sections. First mathematical model of AOA/TDOA measurement techniques and a least square algorithm are described. Furthermore a detailed description of the implemented AOA/TDOA algorithms presented with simulation results. Also the results are analyzed and compared the accuracy performance of the explained method.

## II. MEASUREMENT MODELS

As static positioning is considered, a unique single location is estimated from several concurrently taken measurements at each time, which are not dependent with its past or future estimations. And efficient position estimation needs proper utilization of all measured data's in a well defined mathematical model. This mathematical model is pursued by different estimation technique for better position estimation. In this section, the models and assumptions for the TDOA/AOA and hybrid measurements are described.

The system equation of a positioning problem can be written as

$$A(\alpha) + e = b \quad (1)$$

where,  $A(\alpha)$  is the known vector function,  $e$  is the measurement error vector and  $b$  is the collection of all measured values.

For the two-dimensional (2-D) case, if the MS position to be determined is  $\alpha = [x, y]^T$  and the known coordinates

of the  $i$  th BS be  $\alpha_i = [x_i, y_i]^T, i = 1, 2, \dots, N$ , where the superscript  $T$  denotes the transpose operation and  $N$  is the total number of receiving BSs.

The distance between the MS and the  $i$  th BS, denoted by  $d_i$ , is given by

$$d_i = \sqrt{(x_i - x)^2 + (y_i - y)^2} \quad (2)$$

#### A. Time Difference of Arrival (TDOA) measurements

TDOA system uses time difference measurements rather than absolute time measurement as TOA does. It is often referred to as the hyperbolic system [7] because the time difference is converted to a constant distance difference between two base stations to define a hyperbolic curve. The intersection of two hyperbolas determines the position. In this approach at least three base stations are needed.

TDOA method does not require knowledge of the transmit time from the source therefore it doesn't need any strict clock synchronization between the source and receiver. As a result, TDOA techniques do not require additional hardware or software implementation within the mobile unit. Also, this method is able to reduce common errors experienced at all receivers due to the channel.

TDOA are based on range measurements and can directly obtained from the TOA data. In TDOA it is needed to take the difference in TOAs of the MS signal at a pair of BSs. Any BS can be assigned as the reference though in most of the cases nearest BS is fixed as the reference. Now, the range measurements based on the TDOAs without any disturbances is

$$ct_{i,j} = \frac{\sqrt{(x_i - x)^2 + (y_i - y)^2} - \sqrt{(x_j - x)^2 + (y_j - y)^2}}{c}, i, j \in \mathbf{S}; i \neq j \quad (3)$$

where  $i, j = 1, 2, 3, \dots, N$  respectively and  $\mathbf{S}$  is the set of all BS.

Now, in case of disturbances, range measurements of TDOA can be expressed simply as

$$\begin{aligned} r_{TDOA,i,j} &= r_{TOA,i} - r_{TOA,j} \\ &= d_i + e_{TOA,i} - d_j - e_{TOA,j} \\ &= (d_i - d_j) + (e_{TOA,i} - e_{TOA,j}) \\ &= \sqrt{(x_i - x)^2 + (y_i - y)^2} - \sqrt{(x_j - x)^2 + (y_j - y)^2} + e_{TDOA,i,j} \end{aligned} \quad (4)$$

where  $e_{TDOA,i,j}$  is the range measurement error in  $r_{TDOA,i,j}$ .

This equation (4) can be written in vector form as,

$$\mathbf{r}_{TDOA} = \mathbf{A}_{TDOA}(\alpha) + \mathbf{e}_{TDOA} \quad (5)$$

where,  $\mathbf{r}_{TDOA}$  is the collection of range measurement vector,  $\mathbf{e}_{TDOA}$  is the range error vector and  $\mathbf{A}_{TDOA}(\alpha)$  is the actual range measurement vector function from MS to BS, which contains the original MS position. For simplicity lets just assume that BS 1 is the reference then these vectors can be shown in below

$$\begin{aligned} \mathbf{r}_{TDOA} &= [r_{TDOA,2}, r_{TDOA,3}, \dots, r_{TDOA,N}]^T, \\ \mathbf{e}_{TDOA} &= [e_{TDOA,2}, e_{TDOA,3}, \dots, e_{TDOA,N}]^T, \\ \mathbf{A}_{TDOA}(\alpha) &= \begin{bmatrix} \sqrt{(x_2 - x)^2 + (y_2 - y)^2} - \sqrt{(x_1 - x)^2 + (y_1 - y)^2} \\ \sqrt{(x_3 - x)^2 + (y_3 - y)^2} - \sqrt{(x_1 - x)^2 + (y_1 - y)^2} \\ \vdots \\ \sqrt{(x_N - x)^2 + (y_N - y)^2} - \sqrt{(x_1 - x)^2 + (y_1 - y)^2} \end{bmatrix} \end{aligned} \quad (6)$$

#### B. Angle of Arrival (AOA) measurements

The Angle of Arrival measurement technique determines the location based on the direction of arrival of the mobile station signal in base station, by using directive antennas or antennas array. The minimum number of BS's needed for the location process is two, which makes AOA a very attractive method in situations where detect ability of multiple BS signal is a problem. Another advantage is that the AOA method does not need synchronization with the BS clock. The main disadvantages of this method are multipath effects, and that an antenna array is needed. The accuracy of the AOA method is highly dependent on the propagation environment since multipath around the MS will affect the measured AOA. Multipath components affect the angle measurement in a way that the arriving signal may appear to arrive from a different direction.

In adaptive antenna array BS's signals are received with AOA information from MS and these signals are needed for position estimation purpose. MS is at the intersection of several lines corresponding to AOA measurements. The AOA of the transmitted signal from the MS at the  $i$ th BS, denoted by  $\theta_i$  is related to [6]

$$\tan(\theta_i) = \frac{y_i - y}{x_i - x} \quad (7)$$

where,  $\theta_i$  is the angle between the linked object from the  $i$ th BS to the MS and the  $x$ -axis. In presense of angle errors the AOA measurements can be denoted as  $r_{AOA,i}$  and are expressed as

$$\begin{aligned} r_{AOA,i} &= \theta_i + e_{AOA,i} \\ &= \tan^{-1} \frac{y_i - y}{x_i - x} + e_{AOA,i} \end{aligned} \quad (8)$$

where  $e_{AOA,i}$  is the angle measurement error in  $r_{AOA,i}$ . Equation (8) can also be expressed in vector form as

$$\mathbf{r}_{AOA} = \mathbf{A}_{AOA}(\alpha) + \mathbf{e}_{AOA} \quad (9)$$

where,  $\mathbf{r}_{AOA}$  is the collection of angle measurement vector,  $\mathbf{e}_{AOA}$  is the angle error vector and  $\mathbf{A}_{AOA}(\alpha)$  is the actual angle measurement vector function from MS to BS, which contains the original MS position. These vectors can be shown in below

$$\begin{aligned} r_{AOA} &= [r_{AOA,1} r_{AOA,2} \dots r_{AOA,N}]^T, \\ e_{AOA} &= [e_{AOA,1} e_{AOA,2} \dots e_{AOA,N}]^T, \\ A_{AOA}(\alpha) &= \begin{bmatrix} \tan^{-1} \frac{y_1 - y}{x_1 - x} \\ \tan^{-1} \frac{y_2 - y}{x_2 - x} \\ \vdots \\ \tan^{-1} \frac{y_N - y}{x_N - x} \end{bmatrix} \end{aligned} \quad (10)$$

### C. AOA/TDOA Hybrid measurements

In this hybrid measurement technique, several base stations (at least three) receive the target mobile signal, and the target position is determined by combining AOA estimates from each base station and TDOA estimates between multiple base stations. AOA estimates are made using an adaptive array or other adjustable arrangements. Times of signal arrival are measured at each base station and are time stamped with a MS time reference to determine time difference of arrival estimates.

Though multipath fading will occur in this case, still this type of hybrid system is probably the most accurate and reliable type of cellular positioning system that can be used. However, it is an important issue in such systems to make sure that both methods combine synergistically and that the inaccuracies from one method do not adversely affect the overall position estimate.

Now equation (8) can be re-written as

$$\begin{aligned} x \sin(\theta_i + e_{AOA,i}) - y \cos(\theta_i + e_{AOA,i}) &= \\ x_i \sin(\theta_i + e_{AOA,i}) - y_i \cos(\theta_i + e_{AOA,i}) \end{aligned} \quad (11)$$

By simply combining equation (4) and discarding the angle error from (11) we get the combined AOA/TDOA

measurements as follows

$$\begin{bmatrix} x_2 - x_1 & y_2 - y_1 & d_{2,1} \\ \vdots & \vdots & \vdots \\ x_N - x_1 & y_N - y_1 & d_{N,1} \\ \sin(\theta_1) & -\cos(\theta_1) & 0 \\ \vdots & \vdots & \vdots \\ \sin(\theta_N) & -\cos(\theta_N) & 0 \end{bmatrix} \begin{bmatrix} x \\ y \\ d \end{bmatrix} = \begin{bmatrix} \frac{B_2 - B_1 - d_{2,1}^2}{2} \\ \vdots \\ \frac{B_N - B_1 - d_{N,1}^2}{2} \\ x_1 \sin(\theta_1) - y_1 \cos(\theta_1) \\ \vdots \\ x_N \sin(\theta_N) - y_N \cos(\theta_N) \end{bmatrix} \quad (12)$$

where  $B_i$  is the collecting BS's and written as

$$B_i = (x_i + y_i)^2 - 2x_i y_i \quad (13)$$

Equation (12) can also be expressed in vector form as

$$\mathbf{H}_{hybrid} \mathbf{I} = \mathbf{K}_{hybrid} \quad (14)$$

where,  $\mathbf{I}$  contains the original MS position.

### III. TDOA AND AOA BASED POSITIONING ALGORITHM

A two step LS algorithm is applied for individual TDOA/AOA and their combined hybrid estimation measurements. Parameters of TDOA scheme provide a non-linear system of equations. So, it determines the MS position by simply solving (5) via standard LS and the location estimate is found from the following optimization problem [5]

$$\hat{\alpha} = \arg \min_{i,j \in S; i \neq j} \sum (r_{i,j} - ||\alpha - X_i|| - ||\alpha - X_j||)^2 \quad (15)$$

And AOA system also individually determine the MS position by solving (9) LS and the location estimate is found from the following optimization problem

$$\hat{\alpha} = \arg \min_{\alpha} \sum_{i \in S} |- \sin \theta_i (x - x_i) + \cos \theta_i (y - y_i)|^2 \quad (16)$$

To improve positioning accuracy, it is better to use as much information as possible. A hybrid solution is obtained by simply combining TDOA and AOA measurements as stated above and then by solving iteratively an estimation of mobile position can be obtained.

#### IV. RESULTS

In order to evaluate the accuracy of the hybrid mobile position estimation technique, we consider root-mean square (RMS) position estimation error. RMS error is calculated as the square root of mean squared error (MSE). For comparing the performance of the hybrid algorithm, the RMS position estimation errors of TDOA and AOA are also calculated. This section presents the simulation result that is obtained from the hybrid mobile position estimation algorithm for single and multipath path channel.

The performance of TDOA, AOA and hybrid position estimations for single path channel is presented in figure 1. In this figure RMSE values are plotted against SNR values. The red line indicates the performance of TDOA algorithm while the cyan line represents the AOA algorithm and blue line represents the Hybrid algorithm against SNR.

Fig. 1. RMSE performance comparison among TDOA, AOA and hybrid method in single path channel

From the above figure we can find that TDOA is giving lower RMS error than AOA. As the SNR value increases, the error reduced significantly for both cases. At 30 dB SNR, AOA's RMS error is 75 meter whereas TDOA'S RMS error is 52 meters. Error difference in this case is 23 meters, so TDOA is giving much better location accuracy compare to AOA.

Now, we examine the RMSE performance of hybrid algorithm against the SNR values. For low SNR values, the performance is not very impressive as the result is showing quite large RMS error. But as the SNR value increases the RMS error is reduced. Also it can be seen that when SNR value goes above 15 dB then the system is providing quite accurate result. At SNR of 30 dB the RMS error remains 35 meter.

It is clear from the figure that hybrid algorithm provides better result, when TDOA and AOA algorithms are implemented independently. At optimum level (SNR 30 dB) the hybrid method's RMS error is 35 meter which is 17 meter

less than TDOA's and 40 meter less than AOA's RMS error estimation.

For single path channel path delay and power vector of [0] are assumed. But for simulation on 4 path multipath channel the path delay vector of [0 0.3 0.5 0.8] and the power vector of [0 0.7 0.4 0.2] are taken as a channel parameter.

The performance of TDOA, AOA and hybrid position estimation algorithms for multipath path channel is presented in figure 2. It is clear from the figure that, hybrid algorithm gives better performance compare to individual performance of TDOA and AOA, also in case of multipath channel.

Fig. 2. RMSE performance comparison among TDOA, AOA and hybrid method in Multipath channel

#### V. CONCLUSION

In this paper a TDOA/AOA and their hybrid measurement approach is implemented by a two step LS algorithm in WCDMA system. Their implementation shows that this algorithm works quite accurately in WCDMA environment. And also found that this system can combine with GPS system to improve the location accuracy when GPS signal gives poor coverage specially in indoor. Multipath channel mitigation is also tried in the WCDMA channel model.

#### ACKNOWLEDGMENT

This work was the individual interest of the author's. But, we wanted to thank Department of Communication Engineering, Tampere university of Technology, Finland for the supports in simulation period.

**Abstract** — Location management is one of the key issues in wireless networks to provide an efficient and low-cost service. Realistic modeling of user mobility is a critical research area in wireless network. Mobility data based on real human behaviors may give us the opportunity to improve wireless and Mobile services for users in many ways. At present, several mobility models are proposed based on the analysis of real traces [2], [3]. In this paper, we investigate the feasibility of next state prediction using sequences of previously observed state and analyze the efficiency of MARKOV MODEL [1], [4]. The scenario concerns servicing wireless devices by wireless access point in the Dartmouth college [6] campus over some period of time. The performance of the method has been verified for prediction accuracy. It is found that, on average, the choice of training data leads to prediction accuracy of 78.45%, in some cases the accuracy achieves about 95.55%.

**Index Terms** — Location management, state prediction, Markov model, Access Point.

## I. INTRODUCTION

We investigate and predict the number of wireless devices in an Access Point (AP) within the campus of Dartmouth College [6] based on number of devices previously serviced. Our hypothesis is based on the First Order Markov Process. We analyze the Markov O(1) predictor's efficiency based on the training data set size.

The number of devices serviced by an AP is time dependent. Our aim is to see how far the Markov model dynamically predicts the number of devices which will be serviced by the AP. We have done the prediction over the data collected from CRAWAD [6] which includes data of 6202 wireless devices and 624 AP's over 300 days.

## II. MARKOV MODEL

A Markov chain is a stochastic process with Markov property [4]. Markov property means that, given a present state, future states are independent of the past states. The description of the present state fully captures all the information that could influence the future evolution of the process. Future states will be reached through a probabilistic process instead of a deterministic one. At each step the system may change its state from the current state to another state, or remain in the same state, according to a certain probability distribution.

The changes of state are called transitions, and the probabilities associated with various state-changes are called transition probabilities.

A Markov chain is a sequence of random variables  $X_1, X_2, X_3, \dots$  with the Markov property, namely that, given the present state, the future and past states are independent. Formally,

$$\Pr(X_{n+1} = x | X_n = x_n, \dots, X_1 = x_1) = \Pr(X_{n+1} = x | X_n = x_n).$$

The possible values of  $X_i$  form a countable set  $S$  called the state space of the chain. Markov chains are often described by a directed graph, where the edges are labeled by the probabilities of going from one state to the other states. An  $N$ -state Markov (processes) model for a discrete system is defined by a number of parameters. The set of states  $S$  is denoted by

$$S = \{1, 2, 3, \dots, N\}$$

We have interest in initial probability,  $PI_{i,t}$ , probability that the Markov model will be in state  $i$  at time  $t$ . We denote this as

$$PI_{i,t} = \Pr[S_t = i], i = 1, 2, 3, \dots, N$$

$S_t$  denotes the state at time  $t$ . Thus,  $S_t$  ranges over the set  $S$ . The transition probabilities,  $A_{ij}$  [7], denote the probability of going from state  $i$  at time  $t$  ( $S_t = i$ ) to state  $j$  at time  $t + 1$  ( $S_{t+1} = j$ ). In equation form

$$A_{ij} = \Pr[S_{t+1} = j | S_t = i], i, j = 1, 2, 3, \dots, N$$

Here  $t+1$  do not denote a delay of 1 second from time  $t$ .

## III. DATA SETS

CRAWAD (Community Resource for Archiving Wireless Data)[6] places 6202 wireless devices and 624 wireless access points in the Dartmouth campus to observe the behavior of network for 300 days. Total number of Devices: 6202. Total number of Access Points: 624 (include "OFF"). Total time: 300 days. The observed data from the network are placed into several files and saved as follows.

TABLE I  
ACCESS POINT TRACE FILE - NUMBER OF DEVICES ATTACHED TO AN AP AT DIFFERENT TIME INTERVAL

AP	t <sub>0</sub>	t <sub>1</sub>	t <sub>2</sub>	t <sub>3</sub>	t <sub>4</sub>	t <sub>5</sub>	t <sub>6</sub>	...	t <sub>48</sub>
AcadBldg10AP10	0	0	4	24	0	0	0	...	0
AcadBldg10AP11	0	2	0	0	0	0	0	...	0
AcadBldg10AP12	0	0	0	0	0	0	0	...	0
AcadBldg10AP13	0	0	5	0	0	0	23	...	0
AcadBldg10AP14	0	0	0	0	0	0	0	...	0
AcadBldg10AP15	9	0	0	0	8	0	0	...	17
AcadBldg10AP16	0	0	2	0	0	0	0	...	0

**File Name:** day [1...300].csv

These files describe the number of wireless devices associated with one Access Point per day in a 30-minute interval. This file has the tabular form showed in TABLE I. In the above table, the 1<sup>st</sup> column AP showing the location of the wireless access points. The location format for the wireless access points is as follows:

AP location format:

[Building Name][Building Number][AP][AP Number]

The building names are:

Academic Building (AcadBldg), Administration Building (AdmBldg), Athletic Building (AthlBldg), Library Building (LibBldg), Residential Building (ResBldg)

Example: AcadBldg [10] AP [10]

From the 2<sup>nd</sup> to 49<sup>th</sup> column shows the number of wireless devices that accessed a specific AP during a particular period of 30 minutes time interval. Time intervals are taken as t<sub>1</sub> = 1200AM to 1230AM, t<sub>2</sub> = 1230AM to 0100AM ... .. t<sub>47</sub> = 1100PM to 1130PM.

There is a special symbol 'OFF' in the mobility data which means the card is off the wireless network. We determined the time of OFF state by the syslog message "Disauthentication" from the last associated AP with reason of "Inactivity." The Cisco AP sends this message when the card has no activity for 30 minutes. Therefore the time that the card goes to OFF is 30 minutes earlier than the time of the message. For each time interval, count is the number of connections made by wireless devices to each and every access point. A unique wireless device that is connected to the same access point in separate instances during the same time interval will increment the counter in multiple occasions.

#### IV. MARKOV MODEL IMPLEMENTATION

To set the stage for Markov models, we consider a three state model based on the number of wireless devices serviced by the AP. We assume the states low, mid and high for the

number of wireless devices ranges 0 to 5, 6 to 10 and greater than 10 respectively.

$$S = \{\text{low, mid, high}\}$$

As time progresses the AP makes transition between the low, mid and high states. Prior to the transmission of each new interval of time, the environment may change state or remain in the current state. This transition between states takes place with a set of transition probabilities,  $A_{ij}$ . These are conditional probabilities, and for our three-state model there are nine probabilities of interest. Let  $S_t$  and  $S_{t+1}$  denote the state at time  $t$  and at time  $t+1$ , respectively. With this notation, we define the four transition probabilities to be

$$\begin{aligned} A_{\text{low, low}}(t) &= \Pr \{S_{t+1} = \text{low} \mid S_t = \text{low}\} \\ A_{\text{low, mid}}(t) &= \Pr \{S_{t+1} = \text{mid} \mid S_t = \text{low}\} \\ A_{\text{low, high}}(t) &= \Pr \{S_{t+1} = \text{high} \mid S_t = \text{low}\} \\ A_{\text{mid, low}}(t) &= \Pr \{S_{t+1} = \text{low} \mid S_t = \text{mid}\} \\ A_{\text{mid, mid}}(t) &= \Pr \{S_{t+1} = \text{mid} \mid S_t = \text{mid}\} \\ A_{\text{mid, high}}(t) &= \Pr \{S_{t+1} = \text{high} \mid S_t = \text{mid}\} \\ A_{\text{high, low}}(t) &= \Pr \{S_{t+1} = \text{low} \mid S_t = \text{high}\} \\ A_{\text{high, mid}}(t) &= \Pr \{S_{t+1} = \text{mid} \mid S_t = \text{high}\} \\ A_{\text{high, high}}(t) &= \Pr \{S_{t+1} = \text{high} \mid S_t = \text{high}\} \end{aligned}$$

This can be represented by the state transition matrix

$$A(t) = \begin{bmatrix} A_{\text{low, low}} & A_{\text{low, mid}} & A_{\text{low, high}} \\ A_{\text{mid, low}} & A_{\text{mid, mid}} & A_{\text{mid, high}} \\ A_{\text{high, low}} & A_{\text{high, mid}} & A_{\text{high, high}} \end{bmatrix}$$

In the work to follow we will assume that the model is stationary and therefore the state transition matrix  $A(t)$  is fixed so that  $A(t) = A$ . However, if a simulation is performed in which the initial state probability distribution  $PI_0$  is different from the steady-state distribution, some time is required for the state distribution to evolve to the steady-state value  $PI_{ss}$ . The probability of finding the model in a given state is of interest. We define  $PI_t$  as the state probability distribution at time  $t$ . specifically,

$$PI_t = [PI_{t, \text{low}} \quad PI_{t, \text{mid}} \quad PI_{t, \text{high}}]$$

where  $PI_{t,low}$  and  $PI_{t,mid}$  and  $PI_{t,high}$  represent the probabilities of finding the AP in the low state or in the mid state or in the high state at time  $t$ , respectively. By definition of the state transition matrix, the state distribution at time  $t + 1$  is given by

$$PI_{t+1} = PI_t A$$

Fig.1. The transition between the three states

In a similar manner, the state distribution at time  $t + 2$  is

$$PI_{t+2} = PI_{t+1} A = (PI_t A) A = PI_t A^2$$

Thus, in general  $PI_{t+k} = PI_t A^k$

Where  $A^k$  represents the  $k$  step transition matrix. Most, but not all, Markov processes settle to a steady-state probability distribution as time evolves. Assuming that the Markov process converges to a steady-state value distribution  $PI_{t+k} = PI_t$  for sufficiently large  $t$  and arbitrary  $k$ , it follows that

$$PI_{ss} = PI_{ss} A^k = [PI_{ss,low} \ PI_{ss,mid} \ PI_{ss,high}]$$

Fig.2. Steady-state probability of the three state models

The Markov process of order  $m$  (or memory  $m$ ), defined as the probability of the state at time  $t + 1$ ,  $S_{t+1}$ , is given by

$$Pr[S_{t+1} | S_t, S_{t-1}, \dots] = Pr[S_{t+1} | S_t, S_{t-1}, \dots, S_{t-m+1}]$$

Which states that the probability is dependent upon the previous  $m$  states. For a first-order Markov process, the probability of the state at time  $t + 1$  is a function only of the previous state. In other words:

$$Pr[S_{t+1} | S_t, S_{t-1}, \dots] = Pr[S_{t+1} | S_t]$$

For our three state models we will use a first-order Markov model.

Assume that the model is in state  $k$  at time  $t$  and that the next possible states are to be simulated. The first step is to generate uniformly distributed random variable,  $U1$ . The random variable,  $U1$ , is used to determine the new state. Given that the model transition matrix  $A$ . The  $k^{th}$  row of  $A$  is designated by the vector  $A_k$  where

$$A_k = [a_{k1} \ a_{k2} \ \dots \ a_{ki} \ a_{k,i+1} \ \dots \ a_{kN}]$$

The cumulative probabilities associated with  $A_k$  are denoted as  $BI_k$  and are given by

$$BI_k = \sum_{j=1}^k a_{kj}$$

The probability of making a transition from state  $k$  to state  $i$  is, by definition,  $a_{ki}$ , and is given by

$$a_{ki} = BI_i - BI_{i-1}$$

This probability is represented by the shaded area in the figure below:

Fig.3. Determination of the transition probability

The implementation of the simulation procedure is realized using the following pseudo code:

```

A [3] [3] is the transition matrix
N is the total state
STATE ← i
FOR T ← 1 to N
 Begin
 State_Seq [T] ← STATE
 U1 ← Random (1)
 Cum_Sum ← CUMSUM (A (State, :))
 FOR I ← 1 TO Total_States
 Begin
 If U1 >= Cum_Sum(I) AND U1 < Cum_Sum(I+1)
 STATE = I
 END IF
 END FOR
 State_Seq [T] ← STATE
 END FOR

```

Fig.4. Pseudo Code for the simulation procedure

We have run the Markov O(1) predictor on the data set. We deal with the AP name ResBldg101AP1. Accuracy is measured as percentage of correct predictions of the next state of the AP. The result of the predictor's accuracy to predict the next state of AP is tabulated below based on the training data size. We vary the data size and duration to train the predictor to see how well it can predict the state of the AP. We run the predictor for first 100 days, 200 days and 300 days for different training sets. The average accuracy to predict the first 100 days data is 86%, first 200 days data is 76.44% and first 300 days data is 70.38%.

The result for the 100 days, 200 days and 300 days are plotted based on the training data size. We observe that the prediction accuracy increases, if we increase the training data set size for the first 100 days and 200 days. But for the 300 days the predictor shows a different characteristic for the increasing of training data size. For the increasing of data size (shown in TABLE II), the accuracy decreases (No-09 and No-10) and same size of data taken from different time of interval (No-10 and No-11) shows different accuracy.

Fig.6. Markov O(1) predictor's accuracy for 200 days  
Data shown in TABLE II.

Fig.5. Markov O(1) predictor's accuracy for 100 days  
Data shown in TABLE II.

Fig.7. Markov O(1) predictor's accuracy for 300 days  
Data shown in TABLE II.

TABLE II  
TRAINING DATA, PREDICT DATA, AND ACCURACY OF MARKOV O(1) PREDICTOR

No	Training Set	Predicted Set	Accuracy
1	Day 1 to Day 7	Day 8 to Day 100	69.05%
2	Day 1 to Day 25	Day 26 to Day 100	87.61%
3	Day 1 to Day 40	Day 41 to Day 100	91.80%
4	Day 1 to Day 50	Day 51 to Day 100	95.55%
5	Day 1 to Day 25	Day 26 to Day 200	75.05%
6	Day 1 to 40	Day 41 to 200	75.50%
7	Day 1 to Day 25 and Day 100 to Day 125	Day 26 to Day 200	78.77%
8	Day 1 to Day 25	Day 26 to Day 300	69.06%
9	Day 1 to Day 25 and Day 100 to Day 125	Day 26 to Day 300	72.22%
10	Day 1 to Day 25 and Day 100 to Day 125 and Day 200 to Day 225	Day 26 to Day 300	69.86%
11	Day 1 to Day 25 and Day 100 to Day 125 and Day 226 to Day 250	Day 26 to Day 300	84.62%

#### V. CONCLUSION AND FUTURE WORK

We conclude by saying that the choice of training data creates an impact on prediction accuracy, since same size data sets taken in different interval produced an accuracy of even 95.55%. Our findings open the door for improved prediction and modeling of highly mobile users.

**Abstract** - Today's mobile devices are equipped with multiple network interfaces belonging to different access networks, these interfaces may be used in different requirements. A network connection should be established using the best possible interface. During communication, characteristics of a network may change or a new access network is reached by Mobile Node thus an already established connection should be moved from one interface to another or parallel transmission is done over two or more connections. In the last several years' variety of mobility management solutions have been proposed that operate at different layers of the communication protocol stack (e.g link layer, network layer, transport layer and application layer), but the network and transport layer mobility management solutions are more mature. In this paper we have discussed various end-to-end mobility management solutions for TCP. We have also identified a number of evaluation parameters and on the basis of these parameters different mobility management techniques are analyzed.

**Index Terms** - Mobility Management, vertical handover, transport layer, TCP, end-to-end

## I. INTRODUCTION

Next generation mobile communication system (4G) will provide all time access and seamless mobility across different heterogeneous networks like WLAN, WiMAX, UMTS and WWAN etc. In wireless networks, mobility of a Mobile Node (MN) can be defined as "changing the point of attachment without losing its ability to communicate in the network" with correspondent node (CN). Whenever a MN changes its point of attachment, handover occurs. Handover is divided into two types: *horizontal* and *vertical*. A horizontal handover is made between different base stations within the same link layer technology; it is usually due to the geographical movement of a MN in a network. A vertical handover means that MN hand-off from one underlying access network to another. A common goal [1] among all the approaches for mobility management is that mobility should not break the existing connections between two hosts and also the MN should not become unreachable for future connections. Mobility can be handled at different layers [1] of the traditional TCP/IP protocol stack but in any case link layer support is necessary for providing meaningful information to initiate the handover. It can be handled at Network layer (MobileIP [2] etc), Transport layer (SCTP, variants of TCP etc.) and at session layer (SIP, SLM etc.). At each of these layers mobility management schemes have strengths and weaknesses. At Network layer mobility management has several shortcomings [3], e.g. an

intermediate entity is introduced between MN and CN. These approaches (Mobile IP) do not require any changes to be made on the fixed side but require changes in the existing network infrastructure. This is the main problem as service providers are not willing to change the infrastructure due to additional deployment cost, thus end user suffers. Session layer mobility management approaches are quite favorable but they are only for real time data, so cannot be considered as the best technique. Transport layer mobility management techniques are considered strongest despite the fact that they require changes to the existing protocols like TCP. Mobility management scheme operating at any layer should have following characteristics that attempt to keep the Internet infrastructure unchanged by allowing the end hosts to take care of mobility.

- There should be no change in the network infrastructure.
- No need to maintain states in the network [4].
- Low handover latency should be involved [5].
- Direct communication should be done between MN and CN, avoiding the packet redirection [5].
- Application should remain unaware of the handover.
- Authentication should be simple and highly secure and no third parties should be involved.
- Mobility management scheme should not affect the TCP's reliability and in-order delivery features.

In the last several years variety of end-to-end mobility management schemes have been proposed that include variants of TCP for mobility, SCTP [7] based, HIP based mobility management schemes and Session Layer mobility Management (SLM). SCTP based schemes does not use the existing TCP but they are based on SCTP protocol. Host identity protocol (HIP) [8] is a new secure mobility management protocol that handles mobility by separating the dual role [9] of IP address as end point identifier and locator.

In this survey paper we have discussed various end-to-end mobility management schemes for TCP and compared them under common evaluation parameters. We have done an analysis of some selected approaches on the basis of handover delay. Rest of the paper is organized as follows:

In section II related works that has been done so far in this domain are discussed. In section III various evaluation criterions have been identified for mobility schemes. Section IV covers a detailed survey of existing solutions for end-to-end mobility management. In section V a comparison is made among different techniques and in section VI conclusions is made.

## II. RELATED WORK

Mobility management schemes have been discussed and analyzed in the literature at various layers and in varying contexts. For instance in [3] an empirical analysis of handover performance for SIP, Mobile IP, and SCTP Protocols is made but SIP and MobileIP are not based on end-to-end philosophy. In [5] a comprehensive performance analysis of Mobile IP, TCP-Migrate, and SIP is done with the derivation of mathematical model, but the analysis is not made for TCP based connections. [6] has discussed various transport layer mobility management solutions and classified them into different classes on the basis of their functionality. In [10] handover performance is compared for HIP and Mobile IPv6. Different protocols for improving TCP performance during mobility are discussed in [11]. A comparison of host mobility for IP networks using TCP-Migrate, HIP and MobileIP is done in [12] but it does not consider end-to-end mobility. All these works consider some mobility management solutions that are based on different protocols. In this paper we have discussed solutions for end-to-end mobility management for TCP based communication. A comprehensive analysis is made for each solution under some common parameters and strengths and weaknesses are identified on the basis of these parameters.

## III. EVALUATION PARAMETERS

When a MN moves from one location to another then the mobility management scheme should be able to manage communication without disruption. It should handle handover and thereafter sequenced delivery of data. We have selected a number of evaluation parameters and divided them into three classes.

- Handover related issues
- Infrastructure and Design of TCP/IP model related issues
- Performance related issues

### A. Handover related issues

In this class those parameters are included that are related to the type of handover and handover cost etc.

*Soft handover:* A soft handover allows the MN to continue communication without any disruption. Thus soft handover can be defined as make-before-break.

*Handover overhead:* During the handover some control messages have to be exchanged between the two communicating nodes. These messages are transmitted and processed by the communicating parties. The number of these control messages varies from mobility scheme to scheme, and may create overhead.

*Low layers awareness:* A mobility scheme that takes information about signal strengths etc. from the lower layers, for handover decision, is said to be Low layer aware. Usually this information is provided by the link layer through Media Independent Handover (MIH) triggers (802.21) [30].

*Willful handover:* User centric approach [13] can be said as the willful handover. The handover must be according to the requirements of the user. It is possible that there may be an

overlapping area of the two or more networks i.e. strong signals of different access technologies may be received by the MN, but user may not want to do handover.

*Handover latency:* It is the time elapsed after the MN receives the last packet in the old network until it receives the next packet in the new network.

### B. Infrastructure and Design of TCP/IP model related issues

In this class, parameters regarding the network infrastructure and the current implementation of TCP/IP model are included.

*Changes in the current implementation of TCP:* Some mobility management schemes require the changes in the current implementation of TCP means that they do not use the conventional TCP control and data signaling. These schemes may be termed as the TCP-variants for mobility management.

*Requires changes at both ends:* A mobility scheme may require changes in the communication protocol stack at either end or at the both ends.

*Support from Network:* A mobility management scheme may require support from the network for control and data signaling, e.g. use of gateways, proxies, mobility agent etc.

*Cross layer:* Cross layer optimization may be used by some approaches to handle mobility.

### C. Performance related issues

Here the parameters that regard the extra functionality and performance of handover are discussed.

*Location updates:* Whenever a MN moves into a foreign network and gets a new IP address, then the new nodes wanting to communicate with this MN would not be able to locate it. For this purpose location updates are required.

*Multi-homing:* Today's mobile devices come up with multiple network interfaces. Thus it is possible for a mobile device to have multiple IP addresses. These IP addresses may be obtained from different subnets. Using multi-homing [14] an association between MN and CN can be spanned across multiple IP addresses.

*Bandwidth Aggregation:* When a multi-homed MN has access to the coverage areas of different wireless networks, it can use multiple interfaces simultaneously for sending and receiving data [14]. Some mobility management schemes use multiple TCP connections between MN and the CN, in this situation a scheduler is required for efficient bandwidth aggregation on parallel connections.

*Simultaneous movement:* It may be possible that two communicating nodes may move simultaneously. A mobility management scheme is said to be simultaneous movement aware if it supports simultaneous movement of MN and CN.

*Application transparency:* A mobility management scheme is application transparent when applications are unaware of the handover process.

*Security issues:* Different mobility management schemes

have security flaws and/or in some schemes existing security solutions are implemented which do not meet the requirements of that scheme.

#### IV. MOBILITY MANAGEMENT SOLUTIONS FOR TCP

In this section we have discussed various mobility management solutions for TCP. Strengths and weaknesses of each scheme are highlighted. Table.1 shows the comparison among different schemes.

##### A. Freeze TCP

In Freeze TCP [15] an ongoing TCP connection is *frozen* or stopped when the signal strength is fading by advertising a zero window size to CN, thus stopping all transmission before handover. After handover, when MN has moved to some other location and reconnected, the existing TCP *frozen* connection is *unfrozen* by sending a message. As soon as the connection is re-established, MN sends Triplicate ACKs for the last data segment received before handover.

This scheme reduces the chances of packet loss during handover at the cost of higher delays. It does not require any intermediaries like proxy, gateway etc. No changes are required in TCP protocol at CN but needed at MN. It does not support multi-homing but requires support from lower layers for handover. No option for bandwidth aggregation as there are no options for multi-homing and parallel connections.

##### B. TCP-Migrate

In TCP-Migrate [16] [17] for connection migration author has proposed a *Migrate* option for TCP that allows an existing TCP connection to be migrated by either host from an old IP address to a new IP address. This TCP connection migration is done by exchanging newly introduced TCP SYN with Migrate option. In *migrate* option a *token* (identifier) is included that identifies the previously established connection. This *token* is negotiated during initial connection establishment using *migrate-permitted* option.

This scheme is a complete end-to-end mobility management solution but the handover involved is hard handover. Just like *Freeze-TCP* the connection is stopped. It does not require any changes in the network infrastructure but TCP at both ends needs to be changed. No option for multi-homing and bandwidth aggregation. TCP-Migrate handles encrypted traffic and can be implemented with the existing security solutions. This scheme lacks simultaneous movement support and does not preserve location privacy. An enhanced version of TCP-Migrate with simultaneous movement support is proposed in [18].

##### C. TCR-Redirection

For continuous operation on Mobile Node, TCP-R [19] revises the pair of IP addresses and port numbers in the existing connection, whenever there is a change in the MN's IP address. For new connection establishment TCP-R performs two operations:

1. check whether CN is TCP-R aware

2. exchange authentication keys

After getting a new IP address, MN sends a *redirect* message to CN. On receiving the *redirect* message CN sends authentication request to MN. MN replies with *connection-authentication* message. CN checks the connection authenticator, if found correct then revises the pair of addresses of existing TCP connection. In the meanwhile MN also revises its pair of addresses.

The scheme can be implemented as a complete mobility solution and is application transparent. It does not require any support from lower layers for connection migration. DNS is proposed for location management. TCP-R does not support multi-homing and bandwidth aggregation.

##### D. VA-TCP

Vertical handoff Aware-TCP (VA-TCP) [20] is an end-to-end mobility management scheme in which a new abstraction layer is inserted between Network layer and Transport layer for connection continuity. This new layer adds some new messages to support vertical handover and also maintains a Local Connection Translation (LCT) table for maintaining a relationship between original connection information and the new connection. When a MN roams in a new network, then VA-TCP dynamically estimates the connection parameters from the information provided by the lower layers, so that it can fit into the new environment.

VA-TCP is designed to achieve TCP's best performance for end-to-end mobility management that requires changes in the protocol stack by introducing an abstraction layer. Low layer triggers are required for handover initiation. No option for multi-homing and thus no aggregate bandwidth management is required. Handover is not done according to user requirements but is done according to the new network conditions.

##### E. MSOCKS

Maltz et.al proposed MSOCKS [21], Transport layer mobility management architecture based on TCP Splice. MSOCKS is built around a proxy inserted in the path of MN-CN. Connection from MN to CN is split at proxy and two interfaces are made at proxy. Each interface has its own IP address. Scheme introduces a RECONNECT message that is sent to the Proxy upon getting a new IP address in a new network. MSOCKS enabled MN creates a new socket and sends a RECONNECT message to Proxy with connection ID of old session. Proxy establishes new connection and sends a reply message to MN. Upon receiving reply MN resumes transmission.

Mobility in MSOCKS is limited to the coverage area of Proxy as location management is done by Proxy. It also needs low layer information for handover initiation. A node may have multiple IP addresses but communication is done only through one interface so no option for bandwidth aggregation. MSOCKS requires changes in the current implementation of TCP but only at the MN and Proxy. This protocol cannot work with IP layer cryptographic techniques like IP-SEC.

### F. Tsukamoto's scheme with Multiple TCP Connections

Tsukamoto proposed a new mobility management scheme that modifies the transport protocol for handling multiple connections [22] during handover process. A cross layer approach is used that detects any changes in the status of wireless networks and selects the best optimal interface. A Handover Manager (HM) is implemented at transport layer that detects the changes in the status of wireless networks. Link layer information is sent to the HM at transport layer bypassing the intermediate layers. HM using this information can detect a link-up or link-down state of a wireless network. If during communication HM detects a link-up state for a new wireless network on a new interface, then it starts a new TCP connection via that interface and starts parallel transmission using two TCP connections. For each connection end-to-end performance measures are calculated and compared. On the basis of this comparison handover takes place.

In this scheme no details of the control and data flow are given. It is not mature for implementation and a lot of work needs to be done. No provision of willful handover is there. In this scheme bandwidth aggregation can be possible but author has not given any details about this.

### G. pTCP

pTCP [24] [25] is a transport layer solution for multi-homed MN. It creates and maintains one TCP state for each network interface. *TCP-virtual* (TCP-v) pipes are created for each active interface in a pTCP connection. Whenever a new pTCP socket is opened by application for a connection then a TCP-v pipe for that connection using active interface is created. Application in the MN opens a pTCP socket with CN and pTCP creates the first TCP-v pipe. This pTCP with only one pipe behaves as the same as TCP. When MN moves to a new network and gets a new IP address then pTCP creates a new pipe but does not closes the previously

established pipe.

pTCP provides the reliable and sequenced delivery just like the simple TCP. Both ends need to be pTCP aware. No support is required from the network like proxy etc. It does not support willful handovers but bandwidth aggregation is performed [26] for effective throughput.

### H. I-TCP

Indirect TCP (I-TCP) [23] proposes to split the TCP connection at the mobility support station that is typically a gateway/MSR. Two TCP connections are used, one is an I-TCP connection between MN and gateway and the other is regular TCP between gateway and CN. When a MN moves and gets a new IP address then only the TCP connection between MN and gateway is changed and replaced by the new TCP connection. Hard handover is done and protocol requires changes at the MN. No option for multi-homing is available. Network support is required with gateway/MSR.

### I. SLM

Session Layer Mobility management (SLM) [28] is a framework that supports mobility management at session layer. It extends the TCP/IP model by adding session layer. This layer operates above TCP and switches data streams between multiple connections. The end-to-end network path is divided into three separate paths. Two paths are between the applications on the two hosts and socket connectors and the third path between the socket connections of two hosts. Location management is done through User Location server (ULS) in the new network.

In this scheme both ends need to be SLM aware and support is required from the network in the form of proxy / User Location Server (ULS). Multi-homing is available and bandwidth aggregation can be done. This scheme also supports simultaneous movement of two nodes. No option is available for willful handover.

TABLE. 1 Comparison of different mobility management techniques  
Y: Yes N: No

Evaluation Parameters	Freeze-TCP	TCP-Migrate	TCP-R	VA-TCP	MSOCKS	Tsukamoto TCP	pTCP	I-TCP	SLM	HIP based	EMF
Low layers aware	Y	Y	N	Y	Y	Y	Y	Y	Y	Y	Y
Willful handover	N	N	N	N	N	N	N	N	N	N	Y
Requires changes in TCP	Y	Y	Y	Y	Y	Y	Y	Y	Y	N	N
Changes required on both sides	N	Y	Y	Y	N	Y	Y	N	Y	Y	Y
Multi-homing	N	N	N	Y	Y	Y	Y	N	Y	Y	Y
Bandwidth aggregation	N	N	N	N	N	N	Y	N	Y	N	Y
Requires support from network	N	N	N	N	Y	N	N	Y	Y	N	N
Cross layer approach	N	N	N	N	N	Y	N	N	N	N	Y
Location updates	N	Y	Y	Y	Y	Y	Y	N	Y	N	Y
Application transparency	Y	Y	Y	Y	Y	Y	Y	Y	Y	Y	N
Handover	Hard	Hard	Hard	Soft	Hard	Soft	Soft	Hard	Soft	Soft	Soft
Security issues	N	N	N	N	Y	N	N	Y	N	N	N
Handover overhead	N	N	N	N	N	N	N	N	N	N	N
Handover latency	Y	Y	Y	N	Y	N	N	Y	N	N	N
Simultaneous movement aware	N	N	Y	Y	N	N	Y	N	Y	Y	Y

### J. HIP base mobility management techniques

In current Internet IP address is used as both topological locator and an end point identifier. Host Identity Protocol (HIP) [8] separates the dual role of IP address as end point identifier and locator. It introduces a Host Identifier (HI) used as end point name at transport layer and IP address is used as locator at network layer. This is termed as a new layer - Host Identity Layer, which is seen as a 3.5 layer [9].

In this approach multi-homing is allowed but parallel transmission on two links is limited to the fact that when there is data flowing on one link, control packets for handover flow on other link. Therefore no explicit mechanism for bandwidth aggregation has been proposed so far. Willful handover is not considered and both end need to be HIP aware.

### K. EMF

End-to-end Mobility management Framework [29] is a new idea proposed for continuous transmission of data on multiple links between MN and CN. In this scheme cross layer architecture is proposed in which Host Agent gets information from lower layers through MIH triggers [30] and passes to the User Agent on application layer and to Control Agent on transport layer. Host Agent takes handover decision on the basis of information provided by User agent and lower layers. Data handler module is present that is responsible for soft handover and in-order delivery of packets from different TCP connections to the application. In each TCP connection traditional TCP provides reliable data delivery, congestion control and flow control mechanisms. Multiple TCP connections are established under a single EMF association for transmission of single stream of data between MN and CN.

In this approach no support is required from the network but changes are to be made on the both sides in transport layer. Willful handover is also possible that makes this approach unique from others. This scheme inherently provides bandwidth aggregation but no details are given.

## V. ANALYSIS OF DIFFERENT APPROACHES

In any mobility scheme handover delay/latency and throughput degradation are the major factors to be determined. Handover latency depends upon number of handover control messages, their number of retransmissions, and RTT. Throughput degradation depends upon handover latency and the time for TCP slow start.

### TCP slow start time:

Assuming no packet loss and TCP doubles its congestion window on each RTT, [5] has defined the time for TCP to reach steady state as:

$$T_s = [\log_2(CW_s + 1)] RTT \quad (1)$$

Here

$CW_s$  = Congestion window at steady state

$T_s$  = Time to reach steady state

### Handover latency:

Assume that three control messages are being transmitted for handover. Message1 (MSG1) with end-to-end packet loss probability  $p_1$  is sent  $(i - 1) \geq 0$  times unsuccessfully and  $i^{\text{th}}$  time successfully. MSG2 with end-to-end packet loss probability  $p_2$  is sent  $(j - 1) \geq 0$  times unsuccessfully and  $j^{\text{th}}$  time successfully and MSG3 with end-to-end packet loss probability  $p_3$  is sent  $(k - 1) \geq 0$  times unsuccessfully and  $k^{\text{th}}$  time successfully and on each retransmission doubling the RTO, handover latency for control messages as explained by [5] is

$$Latency_{handover} = 1.5RTT + \sum_{a=0}^{i-1} 2^a RTO + \sum_{b=0}^{j-1} 2^b RTO + \sum_{c=0}^{k-1} 2^c RTO$$

Or it may be written as

$$Latency_{handover} = 1.5RTT + RTO(2^i + 2^j + 2^k - 3) \quad (2)$$

Total handover delay will be:

$$T_{handover} = Latency_{handover} + T_{L_2} + T_\alpha \quad (3)$$

Where  $T_{L_2}$  is the time required for layer2 handover,  $T_\alpha$  is the time required for the acquisition of new IP address in the new network.

### Throughput degradation time:

It is the sum of total handover delay and time to reach steady state for TCP. From eq (1) and (3) as defined in [5]

$$T_{Thput Deg} = T_s + T_{handover} \quad (4)$$

To compare the performance of different approaches, we consider the following values for different parameters as defined in [6]:  $T_{L_2} = 10$  ms  $T_\alpha = 20$  ms.  $T_{L_2}$  and  $T_\alpha$  are defined in (3). End-to-end packet transportation delay = 100 ms, then  $RTT = 2 \times 100 = 200$  ms. RTO can be taken as  $RTO = 1.5 \times RTT$  i.e.  $RTO = 300$  ms. We plotted the graph for handover latency by using different number of retransmissions of handover control messages. In Fig.1 a comparison is made for schemes having three control messages (pTCP, TCP-Migrate, HIP) and two control messages (VA-TCP).

Fig.1. Handover Latency comparison for schemes having two and three control messages

The results show that greater the number of control messages a scheme has, greater will be the handover latency and vice versa. Similarly in Fig.2 a comparison is made for a single technique (pTCP) by doubling the RTT and RTO values and

found that greater values of RTT and RTO leads to longer handover delay.

Fig.2. Handover Latency comparison with respect to RTT and RTO

Throughput degradation occurs when there is no provision for parallel TCP connections i.e. for handover initiation connection is stopped or freezed and whenever data is sent on new interface TCP will start from slow start and will take time  $T_s$  as defined in (1) to reach at steady state thus resulting in throughput degradation. Whereas in schemes like pTCP, EMF data can be transmitted over multiple interfaces enjoying the capability of bandwidth aggregation, thus there is no throughput degradation.

## VI. CONCLUSION

In this paper we have surveyed various mobility management solutions for TCP and evaluated them under common parameters. Each technique has strengths and weaknesses. A tabular comparison is made highlighting these strengths and weaknesses. Finally an analysis of some approaches is done on the basis of handover delay and throughput degradation and it is found that handover latency depends upon the number of control messages an approach uses for handover initiation, the RTT and RTO values and the link conditions. Similarly throughput degradation occurs when there are no options for bandwidth aggregation. Solutions that can make use of parallel TCP connections between communicating nodes, like pTCP, EMF, Tsukamoto's TCP, should have lower handover latency and there should be minimum throughput degradation time for such schemes. In our opinion a solution for mobility management will be comprehensive if it supports multi-homing with bandwidth aggregation option and is application transparent. It may take low layer support for handover and should provide willful handover with simultaneous movement of MN and CN having low handover latency and no security issues. Also solution must not depend upon network infrastructure (proxies, gateways, MSR).

# Peer-to-Peer Mobile Applications Using JXTA/JXME

Tahmina Tahsin, Lazeeb Faiz Choudhury, Md. Lutfur Rahman

Department of Computer Science and Engineering, University of Dhaka, Dhaka – 1000, Bangladesh

**Abstract** — With the advancement in mobile wireless communication technology and the increasing number of mobile users, Peer-to-Peer (P2P) computing, in both academic research and industrial development, has found a new dimension of communication, collaboration and resource sharing. In the recent years P2P have evolved rapidly in internet especially for file-sharing. The major issue of this popularity is that no longer the networks are constrained on unreliable central servers; sharing and connectivity is the main focus. The popularity of Peer-to-Peer file sharing applications such as Gnutella, KaZaA, or Napster has created an outbreak in recent internet history. But P2P File Sharing applications have not yet been widely adopted in mobile devices. In this paper, possibilities of P2P applications in mobile devices are presented. To illustrate the possibilities two demo applications are presented here. One is a Message Passing application and another is a File Sharing application. The open source JXTA/JXME framework is used here.

**Index Terms** — P2P, mobile applications, JXTA, JXME, file sharing, JSR75 API.

## I. INTRODUCTION

P2P networks are typically used for connecting nodes via largely ad-hoc connections. Such networks are useful for many purposes. Sharing content files which contains audio, video, data or anything in digital format is very common, and real time data, such as telephony traffic, is also passed using P2P technology [1]. In the same manner that the Internet provides domain name lookup (DNS), World Wide Web, email, and other services by spreading responsibility among millions of servers, P2P has the capacity to power a whole new set of robust applications by leveraging resources spread across all corners of the Internet [2].

Mobile phones are now-a-days evolved into personal digital assistants. People have been very dependent on the information available on the Internet and with the rapid evolution of mobile devices during the last years. Everywhere people go today, they also bring their mobile phones. Because of this the demand for new applications and services are growing. To meet the demand, Sun Microsystems Inc. introduced J2ME which is a highly optimized Java runtime environment intended for small wireless handheld devices with little CPU, memory and screen resolution.

On the other hand, Project JXTA is an open source project that defines a set of open, generalized, P2P protocols, defined as XML messages, which allows any connected device on the network – from mobile phones and

wireless PDAs, to PCs and servers – to communicate and collaborate in a P2P manner. Because of the explosion of the mobile devices, Project JXTA designed JXTA for J2ME, also known as JXME [3].

Almost all of the mobile phones today use GPRS which provides data rates from 56 up to 114 kbit/s [4]. The most recent mobile phones also support EDGE and 3G data. With EDGE/GPRS the mobile phone is always connected to a network, and ready to receive and send data. For the nature of mobility, these mobile devices can be connected or disconnected at any time from any network and may join in another network. P2P is well suited in these environments. Information is stored on several peers, so it does not matter if some peers get disconnected. With P2P we are able to develop instant messaging applications for mobile phones which might cost the price of using a P2P IM application instead of sending SMS (it depends on the charge applied by carriers for transferring data and SMS). The same idea goes with MMS, which is relatively expensive today, and it might be cheaper to have a P2P application that does the same thing [3].

With the advancement of technology mobile devices are in a rapid growth and these mobile devices are capable of communicating with other mobile devices. So in our research we wanted to show some methods to make these kinds of communications more efficient and more cost effective. And we were motivated by the limitation that a user has to depend on only to the services provided by mobile phone's service providers. In this research, the implementation part is focused mainly on the GPRS/EDGE communication channel.

## II. JXTA/JXME PLATFORM

### A. Background

The current applications of P2P are incompatible with one another. They use their own protocols and form their own community while operating and are incapable of communicating with other applications. So these applications cannot leverage their services together. To evolve P2P into a mature solution platform, developers need to refocus their efforts from programming P2P network fundamentals to creating P2P applications on a solid, well-defined base. To do this, P2P developers need a common language to allow peers to communicate and perform the fundamentals of P2P networking [5].

Realizing this need for a common P2P language, Sun Microsystems Inc. formed Project JXTA, a small development team under the guidance of Bill Joy and Mike Clary, to design a solution to serve all P2P applications. The name “JXTA” is not an acronym. It is short hand for juxtapose, as in side by side. It is a recognition that P2P is juxtaposed to client-server or Web-based computing, which is today’s traditional distributed computing model [6]. At its core, JXTA is simply a set of protocol specifications. Anyone who wants to produce a new P2P application is spared the difficulty of properly designing protocols to handle the core functions of P2P communication. The JXTA Protocol Specification states that JXTA does not make any assumption about communicating devices. In addition to operating systems, programming language and computing system’s independency, JXTA is not dependent on network transport mechanism as well. JXTA assumes that peers and their resources may appear and disappear from the network spontaneously and peer’s location can be changed radically or be masked by Network Address Translation (NAT) or firewall equipment [7]. Apart from the specifications, JXTA makes some recommendations also. JXTA recommends that peers cache some information to reduce network traffic and provide message routing to peers that are not directly connected to the network.

### *B. Justification of Using JXTA*

The vision of Project JXTA is a world where each peer, independent of software and hardware platform, has the benefit of being connected to millions of other peers. Project JXTA was initiated to standardize a common set of protocols for building P2P applications and was designed to allow a wide range of devices to communicate in a decentralized manner.

Project JXTA has a set of objectives to address the shortcomings in the already existing, or under development, P2P systems [8]:

- Interoperability
- Platform independence
- Ubiquity
- Security and monitoring

**Interoperability:** P2P systems of today are designed to deliver a particular service, such as Napster provides music file sharing, Gnutella provides generic file sharing and AIM provides instant messaging. But as they use their own protocols to develop applications, they are incompatible with one another. Project JXTA aims to bring to the P2P world what HTTP and the browser brought to the Internet [7, 9].

**Platform Independence:** P2P applications today are meant for a particular operating system. Software vendors are compelled to generate different version of the same application for different operating systems or make some kind of bridge between the platforms. JXTA technology is designed to be embraced by all developers, independent of

preferred programming languages, development environment, or deployment platform [3].

**Ubiquity:** The Project JXTA protocols are designed to be implemented on any device with a digital heartbeat, which include sensors, consumer electronics, PDAs, appliances, network routers, desktop computers, data-centre servers and storage systems [3, 8].

**Security and monitoring:** For commercial and enterprise deployment, JXTA provides proper security and monitoring services. JXTA peers operate in a role-based trust model, in which an individual peer acts under the authority granted to it by another trusted peer to perform a particular task [8].

### *C. JXTA Components*

Several JXTA components are mentioned below:

- Peers
- Peer Groups
- Virtual Network Overlay
- Uniform Peer Addressing
- Message Relaying
- Messages
- Advertisements
- Universal Resource Binding and Rendezvous
- Pipes

### *D. JXTA Protocols*

JXTA uses several protocols for communication purpose. All of these are asynchronous and are based on query/response model. Using these protocols peers can discover one another or can discover network resources.

Peers do not require to implement all the protocols, they just implement what they need [6].

Six protocols of JXTA are mentioned below:

- The Peer Endpoint Protocol
- The Rendezvous Protocol
- The Peer Resolver Protocol
- The Peer Discovery Protocol
- The Peer Information Protocol
- The Pipe Binding Protocol

### *E. JXTA for J2ME*

Because of the rapid explosion of wireless devices, Project JXTA designed its stripped down version named JXME which lets MIDP compliant devices participate in Peer-to-peer activities with JXTA peers running on larger platforms. Two important ideas in understanding JXTA/JXME are:

- The JXTA Relay
- The JXME API

**The JXTA Relay:** As mobile devices are limited in processing power, most of these devices cannot handle most of the requirements of a regular JXTA peer. As for example these devices cannot parse large XML messages, so some extra component called JXTA Relay is needed to act on

behalf of these low profile devices. JXME uses the JXTA relay as a support to help these devices to become a peer [10].

JXTA relay acts as a junction between JXTA network and peers. The JXTA relay:

- Receives commands from a J2ME client, performs what is necessary on the client's behalf
- Represents a JXME client to the JXTA network
- Provides interoperability with JXTA protocols
- Filters JXTA traffic
- Acts as a proxy and trims the advertisements

Fig. 1. JXTA Relay

Different JXME peers connected to different JXTA relays can still discover each other and communicate. They are not required to establish and maintain a static relationship with one specific JXTA relay [3]. It is worthwhile to mention that a JXTA relay is not just meant to serve J2ME clients. A relay can serve any client that can communicate according to the specified protocols [10].

**The JXME API:** There are just three classes in the JXME API [3]:

- Message class: Include methods to create and manipulate JXTA messages
- Element class: Include methods to construct and manipulate the basic components of JXTA messages
- PeerNetwork class: Include operations that can be invoked on the JXTA network

### III. IMPLEMENTATION OF MESSAGE PASSING AND FILE SHARING APPLICATIONS

#### A. Components of the Application

The message passing and file sharing application has the following components.

- Graphical User Interface
- The Online Presence Service
- The Message Passing service
- The File Sharing service
- The JXTA Relay Server

To build the file sharing service, JSR 75, an extra API is used. JSR 75 is used to take advantage of features commonly found on PDAs in the J2ME space. Here the

FileConnection Optional Package (FC) API gives J2ME devices access to file systems residing on mobile devices.

#### B. Setting up the Environment

At first we need to install Java 2 runtime environment, and the Java2 software development kit. Then we install the Java 2 Micro Edition Wireless Toolkit. In our research, we worked on Netbeans editor. In this research stable 2.1.3 version of JXME was used. To set up a personal computer as a JXTA Relay, the first thing that must be done is to install the JXTA Shell. The JXTA shell can be downloaded from JXTA's homepages. After the shell is configured we log onto the shell and the JXTA relay we just created is active and ready for use.

#### C. Explanation of Functions

Some important built-in functions are used when developing the applications. Several useful methods in the PeerNetwork class are mentioned below [10]:

- createInstance() is a factory method that returns an instance of PeerNetwork with specified peer name.
- connect() method connects to a relay at a specified HTTP URL.
- create() method creates peers, pipes, groups on the JXTA network through the relay proxy.
- poll() method polls the relay for messages addressed to this mobile peer.
- listen() and close() methods open and closes the pipes respectively.
- send() method sends a message to a specified pipe.

A typical application will perform the following actions in response to calls to its MIDlet methods:

- startApp() is called by the application manager when the MIDlet is started and contains statements that are executed each time the application begins execution.
- The pauseApp() method is called before the application manager temporarily stops the MIDlet.
- destroyApp() method is called prior to the termination of the MIDlet by the application manager.
- commandAction() method is listening when the user makes a choice.
- run() method is started when a peer is created. This is an essential method when implementing the Runnable interface.

#### D. Message Passing

Target of this application is to provide presence service that is to show who are online at a certain period and to provide P2P message passing. A peer sends an "alive message" at a regular interval. When a peer does not get alive message from a particular peer for about 10 seconds, it will consider the peer as dead and remove all its informations. After a while when the peer again receives

alive message from that particular peer, it again adds all relevant informations of that peer. A peer can send personal message to another peer whenever it wishes. Steps of this application are below:

- Connect to server
- Create propagate pipe
- Create own unicast pipe
- Listen to both, poll server
- Send alive and personal messages

Screen shot of this application is show in Figure 2.

#### E. File Sharing

Target of this application is to provide presence service like message passing application and to provide file sharing upon demand of a peer. Two screen shots are shown in Figure 3 and 4. At first a peer should go to online. While online, a user can search for a file finding other peers connected to the JXTA relay. Next few steps are below:

- The client peer sends a query message with a file name to the network.
- All peers on the networks receive the message and search its local file system to see whether it contains the file.
- If it contains, it sends a positive reply to the client; otherwise negative reply is sent.
- After getting the reply, the client will request the peer who positively replied first to send the file.
- That peer will send the requested file to the client peer directly.

#### F. Test Results

##### Message Passing

All the network connections and peer creation were completed successfully. “Alive” and “p2p” messages were sent and received without any problem.

##### File Sharing

Network connections, peer creation all were done without any problem. File Connection Package of JSR75 API worked flawlessly. But sometimes the positive/negative reply of the query message is lost in the network for some unknown reason. This may happen because JXTA/JXME is still a developing project. As the reply of the query is lost, all consecutive messages that were to be propagated after the reply were not generated all the times.

Fig. 2. Chat Screen

Fig. 3. Shared Files

Fig. 4. Search Screen

#### G. Future Developments

The P2P applications developed during this research were developed to show that it is possible to develop P2P applications for mobile devices. The developed applications are very primitive and can easily be improved to have better value to a potential user. P2P Mobile Applications can be developed for transferring not only messages and files but also voice data. So that, for example, if a user of a mobile phone is out of service and needs to make an emergency phone call, a P2P software can search for other mobile phones in the vicinity using Bluetooth or WiFi technology and establish a P2P connection to a nearby device which has an active network coverage. A P2P application like Gnutella or Napster for mobile can also be developed which may take advantage of media sharing via the internet or even Bluetooth or Wifi. The possibilities of P2P applications are endless and with mobile phones increasing in power and memory every day, the future of mobile is perhaps in P2P Mobile Applications.

#### IV. CONCLUSION

As the number of wireless mobile devices used in everyday life increases exponentially, it is essential to explore the feasibility of various mobile applications and their limitations. During this research, two P2P applications for mobile have been partially developed using JXME to show that it is possible to develop useful P2P applications for mobile devices. The first application that was developed, a P2P Message Passing Software for mobile devices, is a practical implementation of chatting software independent of any client-server architecture. This message passing software demonstrates the message passing capability of JXTA and establishes a building block for the File Sharing Software developed later. This application can be practically used today as a replacement or complement to SMS. The second application is a P2P File Sharing Application for mobile devices. This application shows the potential of transferring large files between mobiles using P2P. The aim of this application was to see if it is possible to develop a P2P application for mobile devices capable of searching and transferring large files without going through a central server. With the power and storage capacity of mobile devices increasing exponentially, this software may hold the future for mobile computing. The research demonstrates that with further development and research work, various P2P applications developed using JXTA might become practical applications for everyday use.

#### ACKNOWLEDGEMENT

We would like to thank the JXTA/JXME community to provide us with useful information and for answering our query threads several times. Without their support it would be impossible for us to work in such a new arena. We would also like to thank all our family members, teachers and batch mates for their supports and encouragements.

# Connecting Telephone Exchange Centers over Metro Ethernet Networks by using Diffserv-MPLS

Ghasem Mirjalily, Parisa Bastani, and S.M.T. Almodarresi

Faculty of Electrical and Computer Engineering, Yazd University, Yazd, Iran

**Abstract** — Recent large deployment of high-speed metro Ethernet networks creates opportunity to connect legacy telephone exchange centers and cellular telephone base stations to the core telephony network. The success of data and legacy voice services convergence shall depend on whether it can provide the customer with the required QoS or not. Packet-base telephony service requires stringent bounds on end-to-end packet delay, jitter, and loss. New protocols such as MPLS and Diffserv are realized due to the major advantages associated with them such as QoS. This paper studies the performance of connecting telephone exchange centers over a metro Ethernet network using MPLS and DiffServ QoS model. We will implement some simulations to evaluate the performance in terms of delay, jitter and loss.

**Index Terms** — Data communication, Metropolitan area networks, Queuing analysis, Telephone exchanges.

## I. INTRODUCTION

Given the emerging deployment of metro Ethernets [1], a major aspect of interest is to employ these networks to connect legacy telephone centers and GSM base stations to the core telephony network. This protects investments in existing infrastructure and creates new revenues for network providers. However, to implement this convergence, these networks have to be configured in a way that customary QoS requirements for telephony, can be met. This is a crucial problem given that the data cross traffic in these networks is bursty. This burstiness can cause excessive queuing delay and frame losses due to buffer overflow.

In a telephone exchange or Base Station, the analog voice signal arriving from a user is converted to a digital signal. Then multiple calls are aggregated using Time division multiplexing (TDM) and transmitted over a single line with sufficient capacity. In Europe and Middle East, usually 32 voice channels are multiplexed into a single carrier, named the E1 standard with a bit rate equal to 2.048 Mbps [2].

During the past years, there is considerable interest in technologies, systems, and architectures supporting voice over packet (VoP) applications. Two factors have held back the deployment of VoP at the technical level on a broad scale: quality of service (QoS) considerations and robust signaling. Sager, Baumann and Fiedler [2]-[3], introduced the QoS problem of carrying TDM telephony

traffic over native Metropolitan Gigabit Ethernets. They showed by simulation and analytic evaluation that QoS requirements defined by the Metro Ethernet Forum cannot be met even when data traffic utilization is as low as 1%. They didn't use any priority or QoS mechanism in your work.

Salah [4], considered the deploying of VoIP in a small enterprise network. He studied the QoS requirements and utilized both analysis and simulation tools to determine the number of VoIP calls that can be supported for a typical native Ethernet network. Furthermore, he discussed some design and engineering issues including QoS requirements. He didn't consider QoS mechanisms in his work.

Wright, in his paper [5], compared the advantages of VoMPLS with VoATM, VoIP, and VoFR, from the viewpoints of bandwidth utilization, implementation issues, and the region of the network (access/backbone) in which implementation takes place. He concluded that VoMPLSoPPP is more efficient than VoMPLSoEthernet, and VoIP is highly inefficient.

In [6], authors proposed two new AF service models for overlay networks to accommodate emerging applications such as VoIP and real-time video streaming over the DiffServ/MPLS networks. In both service models, incoming calls are first serviced with the EF-class up to a certain threshold and after that calls would be served with AF-class. In [7], the issues of carrying voice in MPLS domain are studied and its performance in terms of delay and jitter under varying load conditions is analyzed. As a result, authors proposed Diffserv model as a solution to provide required QoS. Nair, in his thesis [8], proposed some solutions to QoS for Ethernet in the metro area. This involves traffic engineering with load balancing, uniform resource utilization and reliability.

In this paper, we review the problem whether it is reasonable to expect that TDM E1 telephony traffic can be run on Metro Ethernet by using MPLS and Diffserv mechanisms? We conduct a simulation study to investigate whether the minimum QoS requirements (in terms of loss, jitter and delay) defined by the Metro Ethernet Forum can be met when an integrated environment of MPLS and Diffserv is provided. As a simulation environment, we use OPNET modeler [9], which is widely used in both industry and academia.

This paper is organized as follows: Section II gives a brief overview of the preliminary concepts: QoS requirements, Metro Ethernet and MPLS. In Section III, using MPLS to support Diffserv is described and Simulation results are presented in Section IV.

## II. PRELIMINARY CONCEPTS

In this section, we introduce some preliminaries in brief, including: QoS, Metro Ethernet and Multi-Protocol Label Switching (MPLS) concepts. QoS is the quality a user or customer can expect from a given service. When specifying the QoS, a number of factors are taken into account:

- Latency (Delay) - the time from a packet is sent until it is received at another point.
- Jitter – timing variations from an ideal position in time, caused by packets arriving either out of order or at an inconsistent rate.
- Packet Loss - the percentage of packets lost in the transmission.

For telephony service, the first two (delay and Jitter) are very important factors. Quantifying these parameters allows us to find out how efficiently the traffic in different networks is being managed and whether the network is suitable for the data we wish to transmit or not. Different kinds of applications have different requirements for the parameters listed above. Table I summarizes QoS requirements for some common application types.

On the other hand, Ethernet technology has so far been widely accepted in enterprise deployments, and millions of Ethernet ports have already been deployed. It is said that today 90% of data traffic is Ethernet-encapsulated.

Among the attributes that have underpinned this phenomenal success are plug-and-play operation, easy troubleshooting, simple operation, and inexpensive interfaces based on economies of scale and backward compatibility. As data services become predominant, carriers are waking up to the possibility of deriving the same operational benefits by replacing their (FR/ATM/TDM) metro network infrastructures with Ethernet infrastructures. However, metro networks have very different requirements from the early LANs. The major challenge for deploying Ethernet in metro networks and wide area networks is to guarantee the quality of service (QoS) using Diffserv mechanisms [10]. This can be met either by Ethernet evolution or by MPLS encapsulation. The spread of MPLS into metro networks is driven by familiar business goals: cost reduction and revenue growth. MPLS promises to cut metro-area bandwidth costs by consolidating diverse access traffic. It also promises to boost service provider revenue by supporting more robust, scalable Ethernet services [11].

TABLE I  
QOS REQUIREMENTS FOR SOME REAL-TIME APPLICATION

Application Type	QoS requirements		
	Delay	Jitter	Packet Loss
Streaming Media	Sensitive	Sensitive	Sensitive
Video-conference	Critical	Critical	Sensitive
Pcketized Voice	Critical	Critical	Sensitive

The MPLS protocol resides between the middle of the second layer and the third layer, and it inserts a shim header between these layers. The shim header has two fields, label and exp. Labels are applied in MPLS to create virtual lines called LSPs (label-switched paths). An LSP is set up on an appropriate route that can accommodate the required bandwidth.

The IETF has also defined a way to carry L1 and L2 traffic over an MPLS network. This includes carrying TDM services over MPLS. With this type of encapsulation, Pseudowires are constructed by building a unidirectional MPLS virtual connection (VC) LSPs between the two Provider Edge endpoints. The VC-LSPs are identified using MPLS labels that are statically assigned or assigned using the Label Distribution Protocol (LDP).

## III. MPLS SUPPORTING DIFFSERV

The exp field is utilized by MPLS to support Diffserv classes characterized by different per-hop-behaviors (PHBs) [11]. The exp value of each packet is mapped to a PHB, which is implemented at each MPLS router. The Diffserv architecture defines three classes: EF (expedited forwarding), AF (assured forwarding), and BE (best effort). The EF PHB provides low packet loss, low latency, low jitter, and the maximum guaranteed bandwidth. The EF PHB is usually implemented by applying priority queuing in accordance with the order EF > AF > BE at the output queues of the routers. The EF inflow rate at the edge router must be lower than the EF maximum guaranteed bandwidth, which is determined by the contract and is in the range of the LSP required bandwidth.

The AF PHB provides a minimum bandwidth guarantee, as well as efficient utilization of excess bandwidth. The AF minimum guaranteed bandwidth of each LSP is the balance of the LSP required bandwidth that is not consumed by EF traffic. To use this excess bandwidth effectively, AF packets are allowed to inflow at a higher rate than the AF minimum guaranteed bandwidth, as long as they are labeled with an out-of-profile flag specifying a high drop preference at the edge router.

As part of the Diffserv mechanism, each MPLS router must implement some queuing discipline that governs how packets are buffered while waiting to be transmitted. Various queuing disciplines can be used to control which packets get transmitted (bandwidth allocation) and which packets get dropped (buffer space). The queuing discipline also affects the latency experienced by a packet, by determining how long a packet waits to be transmitted. Examples of the common queuing disciplines are first-in first-out (FIFO) queuing, weighted fair queuing (WFQ) and priority queuing (PQ). The idea of FIFO queuing is that the first packet that arrives at a node is the first packet to be transmitted. Given that the amount of buffer space at each node is finite, if a packet arrives and the queue (buffer space) is full, then the router discards (drops) that packet. In PQ queuing, the routers implement multiple FIFO queues, one for each priority class. Within each priority, packets are still managed in a FIFO manner. This queuing discipline allows high priority packets to cut to the front of the line [12].

In the next section, we will set up a network that carries two types of data: Packetized E1 traffic and variable rate data cross traffic. We will study how the choice of the queuing discipline in the nodes can affect the performance of the E1 traffic.

#### IV. MODELING A TYPICAL NETWORK TOPOLOGY

A network model based on a single bottleneck link was developed (Fig. 1).

This model has been simulated using OPNET package. Using this model, both MPLS and Diffserv are implemented together in the same network, providing insight on the performance of the two protocols in terms of delay, jitter and loss.

All links and ports are Ethernet-based. Center\_1 is an E1 traffic generator simulating a telephone center (or a cellular telephone base station), and Center\_2 is its corresponding destination. S1 is a variable bit rate (VBR) data generator and D1 is its corresponding destination. Sources Center\_1 and S1 are connected to the ingress node R0, passing the packets through the network to corresponding destinations, connected to the egress node R2.

Here, E1 traffic is simulated with EF flow and data traffic with BE flow. The two intermediate links between the ingress and egress nodes are assigned as a Diffserv-MPLS domain with a bandwidth of 10Mbps and a length of 10 Km, while the access links to sources and destinations are assigned a bandwidth of 10Mbps and a length of 1 Km. The explicit route of MPLS domain is R0-R1-R2. The MPLS has two LSPs; one carries the E1 traffic, other carries data traffic.

Fig. 1. Modeled Network

In a telephone exchange or Base Station, the analog voice signal arriving from a user is converted to a digital signal with a sample rate of 8 kHz according to Shannon's sampling theorem, resulting in a data rate of 64 Kbits/s for one telephone channel. Usually 32 voice channels are time division multiplexed into a single carrier, named the E1 standard with a bit rate equal to 2.048 Mbps. Actually, there are only 30 of the 32 channels used for voice traffic, the remaining 2 channels are used for synchronization purpose and other control data [2].

Since the delay has to be kept as small as possible, it is certainly better to take each individual E1 carrier packet and send it immediately instead of accumulating them to fill an Ethernet frame up to its maximum payload size of 1500 bytes. Because the E1 packet should also make it through Ethernet layer, a layer 2 header of 26 bytes is attached to the E1 packet of 32 bytes, giving 58 bytes for the Ethernet frame. This leads to a gross data rate of 3.712 Mbps [2]. Therefore, Center\_1 generates the E1 traffic at a constant bit rate of 3.712 Mbps and 800 Packets/Second, then, sends it to the destination node Center\_2. Fig. 2 shows the traffics generated by Center\_1 and S1.

Fig. 2. Generated Traffics by Sources

All simulations are done with traffic in only one direction to keep the simulation effort at a minimum without losing any important model characteristic. As you can see, there is bottleneck on intermediate links, because the aggregated traffic exceeds 10 Mbps. Here, E1 traffic flow between telephone centers is taken as a representation to study the delay, jitter and loss.

The Metro Ethernet Forum (MEF) is a consortium of ISPs and network equipment manufacturers that specify quality of service requirements for telephony circuit emulation over metro Ethernets. These requirements pertain to a requirement for maximum delay, jitter and frame loss rate within an observation interval. Numbers are listed in Table II. Moreover, MEF specifies an additional composite requirement that is the number of frames that violate any of the three above stated requirements. This requirement is called the frame error rate (FER), and is defined as [3]:

$$FER = \frac{\text{number of errored frames}}{\text{total frames sent}}$$

Where an errored frame is a frame delayed more than 25 ms or exceeded the jitter limit of 10 ms or dropped by any network node. MEF specifies that this frame error rate is less than  $8.75 \times 10^{-7}$ .

#### A. QoS Analysis

The total delay in a network topology like in Fig. 1, consists of propagation, transmission and queuing delays. Signal propagation delays over links (due to distance) are an important cause of communication delays. The speed of propagation in optical fibers is  $0.68c$ , where  $c$  is the speed of light in vacuum (300000 Km/s). For the bottleneck links of the network simulation topology in Fig. 1, the propagation delay is  $49 \mu s$  which corresponds to a distance of 10 km for the optical link. For access links, the propagation delays are  $4.9 \mu s$  for 1 km optical links that are very small compared to the bottleneck link's propagation delays. All propagation delays together from the source nodes to the sink nodes are  $107.8 \mu s$  for both types of traffic.

Transmission delay is the second form of delay incurred by each packet as it is sent over a link. An E1 frame consists of 464 bits that are to be transmitted over the 10 Mbps links. The transmission delay at each node is therefore  $46.4 \mu s$ . Any frame sent from source to sink node in the network is processed 4 times (Center\_1, R0, R1 and R2), introducing total  $185.6 \mu s$  of transmission delay.

Queuing delays occurs when data is made to wait for resources to become available, typically a communications link or a processor.

TABLE II  
METRO ETHERNET FORUM'S QoS REQUIREMENTS [3]

Metric	QoS requirement
Jitter	Max. 10ms
Delay	Max. 25 ms
Loss rate	Max. $8.75 \times 10^{-7}$
Frame error rate	Max. $8.75 \times 10^{-7}$

This type of delay can in some cases account for the majority of a frame's end-to-end delay from its source to its destination node. Queuing delays is the only delay that depends on the variable workload traffic. When no data traffic is sent, the total end-to-end delay of an E1 frame is at its minimum of  $420 \mu s$  as shown by simulation results (see Table III and IV). Subtracting the propagation delay ( $107.8 \mu s$ ) and the transmission delay ( $185.6 \mu s$ ) from it, the minimum queuing delay in the network results to be  $126.6 \mu s$ , which accounts for the processing delays of all nodes of the given network. In the simulation setup of this work, E1 and data traffic is sent independently over a 10 Mbps link to the bottleneck entry node R0. As long as the incoming traffic at the R0 is less than the output link's capacity (which is also 10 Mbps), no relevant queues build up in this node and the delay of the E1 traffic is constant at its minimum value of approx.  $420 \mu s$ . When the incoming traffic at the R0 is greater than the output link's capacity, the queue grows at the rate of the output link's exceeding capacity. With growing queue size, also the delay increases.

In networks, packets are sometimes lost or damaged due to buffer overflows or transmission errors. In the simulation setup of this work, losses mainly originate from buffer overflows in the bottleneck entry node R0 (Fig. 1). Losses due to transmission errors are negligible small and buffer overflows in other nodes do not occur.

The point of buffering in the network is to absorb data bursts and to transmit them during the (hopefully) ensuing bursts of silence. This is essential to permit the transmission of bursty data. OPNET Modeler's node queues use first-in-first-out (FIFO) queue scheduling and tail drop queue management algorithms like most of the QoS unaware equipment today.

#### B. Simulation Results

The network was studied with different conditions. At the first scenario, we assumed native Ethernet links and switches without MPLS and without any QoS mechanism. There is naturally, a large FIFO queue at each node. Therefore, packet loss is negligible, but the delay and jitter are not acceptable, as shown in Fig. 3 and Table III.

TABLE III  
QoS Metrics in Implemented Scenarios without MPLS

		FIFO Unlimited	FIFO Size 100
Delay (msec)	Min	0.42	0.42
	Max	22902	173.8
	Avg.	266.8	37.8
Jitter (msec)	Min	1042	64
	Max	8630	86
	Avg.	5340	72
Packet Loss Ratio		$7.53 \times 10^{-7}$	$62.24 \times 10^{-3}$
Frame Error Rate		1	1

In second scenario, we limited the FIFO queue size to 100 packets. As a consequence, delay and jitter are decreased, but packet loss is increased. As shown in Fig. 4 and Table III, QoS parameters are larger than the MEF's acceptable values.

In third scenario, we implemented MPLS without Diffsev. Two LSPs are set, one for E1 traffic and another for data traffic. As you can see, in MPLS without Diffserv model, packet loss is negligible, but the delay and jitter are not acceptable, as shown in Fig. 5 and Table IV.

Last scenario is implemented by using Diffserv-MPLS model with PQ queuing discipline. For PQ, the queue size of BE traffic is set to 60 and the queue size of EF traffic is set to 40 (total queue size is 100).

TABLE IV  
QoS Metrics in Some Implemented Scenarios with MPLS

		MPLS without Diffserv	MPLS with PQ
Delay (msec)	Min	0.42	0.42
	Max	20727	16.2
	Avg.	167.8	4.6
Jitter (msec)	Min	303	4.43
	Max	6740	7.96
	Avg.	4490	5.75
Packet Loss Ratio		$7.53 \times 10^{-7}$	$7.53 \times 10^{-7}$
Frame Error Rate		1	$7.53 \times 10^{-7}$

Fig. 3. Delivered E1 traffic, Delay and Jitter (large FIFO queue without MPLS)

Fig. 4. Received E1 traffic, Delay and Jitter (FIFO queue size 100 without MPLS)

Fig. 5. Received E1 traffic, Delay and Jitter (MPLS without DiffServ)

Fig. 6. Received E1 traffic, Delay and Jitter (MPLS with Priority Queue)

For MPLS with PQ model, the network performance reflected acceptable loss, delay and jitter. The delay is very small as shown in Fig. 6 and Table IV. This was expected, as the EF traffic normally arranges to pass through Diffserv domain without much delay, jitter or loss.

## V. CONCLUSION

In this paper, we studied the performance of packet-based E1 traffic transmission over a metro Ethernet network using MPLS and DiffServ QoS model. We implemented some simulations to evaluate the performance of connecting telephone exchange centers in terms of delay, jitter and loss under varying conditions. We showed that without using DiffServ-MPLS, MEF's QoS requirements are not met, but by using MPLS with PQ queuing discipline, these requirements are satisfied.

## ACKNOWLEDGEMENT

This work is supported by Iranian Telecommunication Research Center (ITRC).

# Security Enhancement of MD5 Hashed Passwords by Using the Unused Bits of TCP Header

Md. Didarul Alam Chawdhury, and A.H.M. Ashfak Habib

Chittagong University of Engineering & Technology, Chittagong – 4349, Bangladesh

**Abstract** — When a password is encrypted by a hash algorithm the resultant is called hashed password. In a server client based communication system such as Yahoo Messenger, AIM, passwords of clients are hashed by MD5 and passed to the server for authentication [1]. This type of transmission is always a subject of interception by the hackers. These hashed passwords are passed through the internet as a data packet. TCP header is a most common part of the data packet. In a TCP header there are six reserved bits which remains always unused [2]. In this paper we propose a new approach to enhance the security of hashed passwords by using the six reserved bits of a TCP header. Here we encrypt the hashed password by a random key using simple mathematical function. The information needed to decrypt the encrypted hashed password is carried by the six bits of TCP header.

## I. INTRODUCTION

Communication is the most important aspect of this modern age. Computer network i.e. internet is one of the most important part of communication of this modern civilization. Since valuable information is passed through the internet, the question of security arises. In a server client based communication, passwords are top secret information. Therefore passwords are first hashed and then passed through the internet. At the time of transmission the hackers always try to intercept those hashed passwords. So it is important to make the transmission of those passwords secure as much as possible.

A few techniques are developed for securing hashed passwords. Most common of them is salting. Salting means adding some bit pattern to the password and then encrypting it by message digest algorithm [1]. The encrypted password is then passed through the internet. Another technique is double hashing, where the password is hashed twice. Usually data passes through the network as a packet. A data packet consists of a number of bits. There are some bits which always remain unused in that packet. In fact in a TCP header 54 bits remain unused on an average case [2]. Moreover there are six reserved bits in TCP header which are never used. In this paper we tried to improve the security of the hashed passwords by using the unused six bits of TCP header.

## II. SERVER CLIENT SYSTEM

Among various types of communication systems, server & client based systems are one of the most important and widely used communication systems. Fig. 1 illustrates a server client based communication system. Server is a computer which is used to provide a particular service to the clients and clients are a group of computer that receives the service provided by the server [3]. To determine the eligible users the server applies an authentication scheme. Most typical one is user name and password verification.

Fig. 1. Server Client Communication System.

Before transmitting through the media the passwords are encrypted. The most commonly used encryption algorithms are hash (message digest) algorithms. The passwords in the server database are stored as hashed password. When a client is challenged for authentication then a login page appears at the client end. The client enters his/her user name and password. The user name is passed as plain text but the password is encrypted by a message digest algorithm. The resultant cipher text i.e. hashed password is passed to the server and the server verifies them. The most widely used hash algorithm is Message Digest 5 (MD5). In this paper we only concentrate on MD5 hash algorithm.

### III. MESSAGE DIGEST 5 (MD5)

The MD5 algorithm is an extension of the MD4 message-digest algorithm. It is an irreversible encryption algorithm. That is, from an encrypted message it is not possible to recover the original message. The algorithm takes a message of arbitrary length as input and produces a 128-bit "fingerprint" or "message digest" of the input as output. It is conjectured that it is computationally infeasible to produce two messages having the same message digest, or to produce any message having a given pre-specified target message digest. The MD5 algorithm is intended for digital signature applications, where a large file must be "compressed" in a secure manner before being encrypted with a private (secret) key under a public-key cryptosystem such as RSA [4].

### IV. ATTACKS ON MD5 HASH

The hashed password can be hacked during transmission. When MD5 hash is hacked then we call it attack on MD5 hash. This hash can be hacked effectively by using two efficient techniques [1]. These are:

- a) Dictionary Attack
- b) Rainbow Table.

#### A. Dictionary Attack

A dictionary attack refers to the general technique of trying to guess some secret by running through a list of likely possibilities, often a list of words from a dictionary [5]. It contrasts to a brute force attack in which all possibilities are tried. The attack works because users often choose easy to guess passwords, even after being exhorted against doing so. Dictionary attacks either pre-compute hash values for a given dictionary file and then compare target password hashes to the pre computed tables for a match, or words in a dictionary file are hashed and compared against a target password hash for a match.

#### B. Rainbow Table

In 2003, Philippe Oechslin [6] introduced Rainbow Tables, a time-memory trade-off used for cryptanalysis of hashed passwords. From his work, several applications have been developed that create rainbow tables.

The entry in a rainbow table is called chain. Chain is pre-computed to hack a password. Rainbow tables use a successive reduction function for every point in the chain. They start with a reduction function 1 and end with a reduction size of  $t-1$  (one less than chain length). The password is first hashed and then the reduction function is applied to it. Only the first and the intermediate hash (at the length of the chain) are stored in the table. To hack a hash, a chain from the hash is generated. For each

password that in the chain, hackers check to see if it is at the end of the chain. When they hit a match at the end of the chain, then it is known that the hash was part of this chain. Thus the complete chain again generated and the password is hacked.

### V. HASHED PASSWORD ENCRYPTION

We name the new approach of encryption which enhances the security of MD5 hashed password as Hashed Password Encryption (HPE). There are three steps in this encryption process which are executed at the client side. The first step is the generation of a random key. By using the key we determine a value from a spiral arrangement of number sequence. Second step is the encryption of the MD5 hashed password. Encryption of the key is the third and final step of this encryption process.

Decryption takes place at the server side and it consists of two steps. First step of decryption is to recover the original key and the final step is to decrypt the encrypted hashed password.

The encryption and decryption processes are explained in details with the help of an example as follow:

Consider a server client based communication system where MD5 is used to encrypt the client password. Suppose the original password of a client is "abc" and the corresponding MD5 hashed password is  
900150983cd24fb0d6963f7d28e17f72

#### A. Encryption Process (Client Side)

At first a random key is generated. For choosing a key the following constraints are followed:

- 1) Key must be a prime number.
- 2) Key length will be 3, 4 or 5. That is the number of digits in the key is either 3 or 4 or 5.
- 3) In case of 3-digit-key the last digit will be greater than or equal to the preceding digits and no digit can be zero. For example 233 can be a key but 253 cannot be a key.
- 4) In case of 4-digit-key the value of the last two-digit-number will be greater than or equal to each of the preceding two digits. Moreover none of the first two digits can be zero. For example 1049 or 2301 cannot be a key but 6871 can be a key.
- 5) In case of 5-digit-key the value of last three-digit-number will be greater than or equal to each of the preceding two digits. In the first two digits no digit can be zero. For example 10049 or 14001 cannot be a key but 14983 can be a key.

The range of the key space of our HPE cryptosystem is 15000. In this range we get over 1300 keys.

We use a spiral arrangement of number sequence. This arrangement can be considered as a number grid. Suppose

the random key generated is 227. The grid for the key is shown in Table I.

TABLE I  
SPIRAL ARRANGEMENT OF NUMBERS

31	30	29	28	27	26	49
32	13	12	11	10	25	48
33	14	3	2	9	24	47
34	15	4	1	8	23	46
35	16	5	6	7	22	45
36	17	18	19	20	21	44
37	38	39	40	41	42	43

The first digit of the key indicates row and the second digit indicates the column. The rest of the digits indicate the size of the grid. The above grid is of size 7.

The value that will be used for encryption is found from the grid. For the key 227 the value is 17.

#### 1. Encryption of the Hashed Password

Now we encrypt the hashed password by using a simple arithmetic addition and mod operation. The encryption is stream ciphering. That is we encrypt the hashed password character by character. The function can be shown as follows:  $C = (A + V) \bmod 256$

Where A is the ASCII value of each character in the hashed password, V is the value found from the key. For our example it is 17, C is the ASCII value of the character that will replace the character in the previously encrypted hashed password.

In our example the hashed password is 900150983cd24fb0d6963f7d28e17f72. For the first character '9' in the hashed password the encryption can be shown as follows:

$$C = (57 + 17) \bmod 256$$

$$C = 74$$

Since the ASCII value of J is 74, '9' is replaced by 'J'. Thus the encrypted hashed password obtained is JAABFAJIDtuCEwsAuGJGDwHuCIvBHwHC. This newly encrypted hashed password is sent to the server.

#### 2. Encryption of the key

We have the key 227. In this step this key is encrypted. First we calculate the sum of ASCII value of all characters in the original hashed password. Then we use the following function to encrypt the key:

$$Q = (P * K) \bmod 61$$

Where, P is the sum of ASCII value of all characters in the original hashed password, K is the key, Q is the encrypted key. In our example the encryption is as follow:

$$Q = (2107 * 227) \bmod 61$$

$$Q = 49$$

The value 49 is passed through the six reserved bits of TCP header.

#### B. Decryption (Server Side)

The newly encrypted password is sent to the server through the data field of the TCP packet. Moreover the value of Q is passed through the reserved six bits of the header.

##### 1. Decryption of the key

Server has original hashed password against the user name in its database. It calculates the sum of ASCII value of all characters in the original hashed password. From the six reserved bits in TCP header of the packet received from the client the server gets the value  $Q = 49$ . After this the server has to do the followings

- 1) Calculates  $M = (P * S) \bmod 61$  for all keys in a range. Where P is the sum of ASCII value of all characters in the original hashed password, S is the possible key.
- 2) If  $M = Q$  then the value of S is kept in a list.

On an average case 20 possible keys are found. In our example the possible keys are: 227, 349, 1447, etc.

##### 2. Decryption of the Encrypted Hashed Password

The server has the encrypted hashed password JAABFAJIDtuCEwsAuGJGDwHuCIvBHwHC. For all possible keys the server does the following:

- 1) Determine the value that is used in encryption from the spiral arrangement of numbers. For the first possible key 227 the value  $H = 17$  is found.
- 2) Determine  $T = H \bmod 256$ . In our example  $T = 17$ .
- 3) Determine  $A = C - 17$ . If A is less than zero then the following operation is done:  $A = A + 256$ .

A is the ASCII value of the corresponding characters in the original hashed password. For the example J is the first character of the encrypted hashed password. For J we get  $A = 74 - 17 = 57 = '9'$

Thus the original password is recovered. Then the server finds match with the password in its database. If a match is found the server stops and the client is authenticated. If no match is found it is considered that the client supplied wrong password.

## VI. PERFORMANCE ANALYSIS

We evaluated our approach by calculating the new computation information for the two hacking techniques illustrated in this paper.

#### A. Computation Information for Dictionary Attack without Using HPE

Computation information for the dictionary attack [1], when HPE algorithm is not used, is as follows:

Character set = [abcdefghijklmnopqrstuvwxyz]  
 Password length = 7  
 Words = 23109  
 Dictionary = English  
 Algorithm = MD5  
 Record Format = \$hash\$password , ordered by \$hash  
 File Size = 231MB  
 Average lookup time =  $2.9 * 10^{11}$  floating seconds

#### B. Computation Information for Dictionary Attack Using HPE

Computation information for dictionary attack taking HPE algorithm into account is as follows:

Character set = [abcdefghijklmnopqrstuvwxyz]  
 Password length = 7  
 Words = 23109  
 Dictionary = English  
 Algorithm = MD5  
 Record Format = \$hash\$password , ordered by \$hash  
 File Size = 947469 bytes  
 Average lookup time = 1134440021.7656 floating seconds

#### C. Pre-computation estimates for Rainbow Table without Using HPE

The following data are the pre-computation estimates for Rainbow Table without using HPE and are calculated by using MATLAB [1].

[key space] 8,031,810,176  
 [chain length] 2100  
 [chain count per table] 8000000  
 [precomputation time(days)] 0.83844

#### D. Pre-computation estimates for Rainbow Table Using HPE

The following data are the pre-computation estimates for Rainbow Table when HPE algorithm is used.

[key space] 8,031,810,176  
 [chain length] 2100  
 [chain count per table] 2048000000  
 [precomputation time(days)] 214

## VII. CONCLUSION

In this paper we proposed a new cryptosystem for further encrypting the MD5 hashed password before transmitting it through the internet. We showed the performance analysis of our cryptosystem. From the performance analysis the benefit of our proposed HPE cryptosystem is clear. If a server client based communication system uses HPE in authenticating users then the possibility of interception of the password will be reduced to a considerable extent. It will be infeasible for the hackers to pre-compute the hash for dictionary and rainbow table when HPE is implemented in the system. Moreover HPE makes a good use of six reserved bits in TCP header which implies an efficient utilization of network resources. Thus the transmission overhead due to transmitting unused bits is reduced.

**Abstract** --- This paper presents an optical wavelength division multiplexed (WDM) cross-connect (OXC) topology, which is the modified form of the existing topologies. The analytical approach for the proposed topology is derived to explore the effect of crosstalk induced in multichannel WDM network due to OXC. The factors that affect the magnitude of crosstalk in the OXC are investigated and identified. The bit error rate (BER) performance of a WDM optical system is evaluated at a bit rate of 10 Gb/s on account of OXC-induced crosstalk and different noises. Power penalty is evaluated at BER of  $10^{-9}$  shows that there is a significant impact of crosstalk on the number of wavelengths and input fibers. The results obtained from the present study demonstrate that the crosstalk performance of the proposed topology can be improved significantly than the existing topologies.

**Index Terms** -- optical cross connect, optical crosstalk, optical filter, optical switches, Wavelength division multiplexing.

## I. INTRODUCTION

The advent of wavelength division multiplexing (WDM) technique provides a dynamic increase in the information carrying capacity of a fiber [1]. WDM corresponds to the scheme in which multiple optical carriers at different wavelengths are modulated by using independent electrical bit streams and are then transmitted through the fiber. WDM networks are very attractive due to high capacity, network security, flexibility and possibility of upgrading the existing optical fiber networks to WDM networks [2]. The optical cross-connect (OXC) is an essential WDM network element which offers a dynamic wavelength routing scheme that can reconfigure the network while maintaining its non blocking (transparent) nature to WDM networks [3].

In practical systems while propagating through the switching element that are the part of OXC many signals and wavelength channels could influence each other and cause significant crosstalk [4]. Crosstalk is one of the major limiting factors that may degrade WDM network performance. The crosstalk sources are related to the different individual components of the OXC's. Up to now several OXC topologies [4] were utilized to evaluate the bit error rate (BER) performance of WDM optical fiber transmission system including the effect of OXC-induced crosstalk [5,6]. Since the performance of WDM networks is

limited by the OXC-induced crosstalk [8-10], it is desirable to develop a suitable OXC topology, so that, it contributes minimum crosstalk due to OXC. It is also desirable to investigate the BER performance of a WDM transmission system including the effect of crosstalk induced by the OXC components of the proposed topology.

In this work we have proposed an OXC topology with modification of the existing topologies. Afterwards the analytical equation for the proposed topology is derived by identifying and quantifying different crosstalk sources. The BER performance for a particular WDM system is evaluated at 10 Gb/s on account of OXC-induced crosstalk and different noises. Finally, with a specific BER, the amount of power penalty as a function of the component parameters of the OXC is evaluated and compared with the existing topologies.

## II. OXC TOPOLOGY

Several topologies exist for all optical WDM cross connects [4,7]. The most suitable topology for an application depends in general on the required functionality and on the cost, capacity and flexibility constraints. In this paper, we have analyzed the performance of OXC by placing filter before and after the switching matrix and selecting of the wavelength channels. The schematic diagram of the proposed OXC topology is shown in fig. 1. This topology is the combination of the first and third topology as defined in Ref. [4]. In the proposed topology, the switching matrix of topology 1 is used but the wavelength channels are selected by the filters (with a fixed centre frequency), before and after being routed to the desired output fiber.

The block diagram of a WDM transmission link with proposed OXC is shown in fig.1. The switching matrix in the OXC shown in fig.1 is based on an array of gates which are implemented by gain-clamped semiconductor optical amplifier (GC-SOA) [11] to route the different wavelength channels. Splitters and combiners are placed in front of and behind the switch matrix and filters are used to select the wavelength channels. The wavelength channel to be transmitted is multiplexed by a WDM MUX and fed to an

## OXC

Fig. 1: Block Diagram of a WDM optical system with a new OXC topology.

incoming fiber. At the input of cross-connect, the incoming signals are splitted by a first array of power splitters followed by a array of filters and a second array of power splitters. At the input of GC-SOA gates, all channels are present. The gate selects the wavelength that carries the desired channel. The OXC enables any wavelength channel from any input fiber to be cross-connected to any output fiber, on condition that no two channels in the output fiber have the same wavelength. In fig.1, each fiber carries wavelength channels  $\lambda_1, \lambda_2 \dots \lambda_M$ . Given that the  $N$  input fibers are routed to the desired  $N$  output fibers, each carrying  $M$  wavelength channels, so there are a total of  $N \times M$  wavelength channels. The  $N \times M$  wavelength channels passed through first array of power splitters. There are  $N$  power splitters for all the  $N$  input fibers. All the different wavelength channels appear at the output of the power splitter at lesser power due to power splitting which are fed to  $N$  different filters. Wavelengths  $\lambda_1, \lambda_2 \dots \lambda_M$ , from the output of filters are then fed to another array of  $M$  power splitters, one for each wavelength. So there is a total of  $N \times M$  power splitters at the second array. The output of the second array of power splitters are fed to  $N \times M$  gates, which allows only specific wavelength to pass through. The outputs of the gates are combined by  $N \times M$  combiner at the first array of combiner. Outputs of  $N \times M$  combiners are fed to  $N \times M$  filters. Then,  $N$  times  $M$  outputs with a different central wavelength, are combined into the  $N$  output fibers by the second array of  $N$  combiners. Finally, the desired

wavelength channel of an outgoing fiber is demultiplexed by a WDM DMUX and is received by a direct detection receiver.

### III. CROSSTALK AND BER MODEL

The analytical equation illustrated in this paragraph which describes the output power of the proposed topology in function of the input powers and OXC component parameters. The crosstalk is calculated for a certain wavelength channel, this channel will be called the channel under study. The absolute power levels are only relevant in front of the GC-SOA. Therefore, the power levels at the input of the gate are taken as reference, gains and losses are not relevant since they are assumed uniform for all possible routing ways.

To drive the equations for the proposed topology, the signal power is defined by  $P_i^j$ , where  $i$  designates the wavelength channels and  $j$  the number of the fibers. The fiber which contains the channel under study is indicated by  $j_0$ , and the wavelength under study is  $i_0$ .  $P_{i_0}^{j_0}$  is the input power of a channel,  $P_{i_0}^{out}$  is defined as the output power of wavelength channel  $i_0$  with crosstalk contributions added with all wavelength channels carrying bit 1.  $P_i^{j_0}$  is the signal power at fiber  $j_0$  with another wavelength  $i$ .  $P_{i_0}^j$  is the signal power at another fiber  $j$  that carries the wavelength under consideration,  $i_0$ . We assume that all wavelength channels including  $P_{i_0}^{j_0}$  carry bit 1.  $P_{i_0}^{out}$  at any output fiber

may be just  $1/N$  of the output power, due to division of power before entering the GC-SOA. However, it is also assumed that the GC-SOA is set with gain of  $N$  times to compensate for the division of output optical power.  $N$  is the number of input fibers into OXC,  $M$  is the number of wavelengths per input fiber. Due to the gate's imperfection in gain clamping, it adds crosstalk. The crosstalk power at wavelength  $i$  is then given by [4]

$$P_{cros,i} = X_{gate} P_{in,i} \sum_{k=1}^M P_{in,k} \quad (1)$$

with  $X_{gate}$  is the crosstalk parameter of the GC-SOA,  $P_{in,k}$  is the power at wavelength  $k$  and  $M$  the number of wavelength channels at the input of the gate. The sum is made over all  $M$  wavelength channels.  $T_F$  is derived from the filter suppression of wavelength channel,  $T_F^{-1}$ . This means that  $T_F$  is the transmission of the filter seen by that channel ( $< 1$ ). The ON-OFF ratio of the gate is given by  $R_{gate}^{-1}$ , so that  $R_{gate}$  is the transmission of a gate or gate extinction ratio in the off-state ( $< 1$ ). Extinction ratio is defined as,  $R_{gate} = P_{off}/P_{on}$  where  $P_{on}$  is the input power and  $P_{off}$  is the off state power through each gate. The expression for output power with crosstalk of wavelength channel  $i_0$  can be given by

$$\begin{aligned} P_{i_0 1}^{out} = & P_{i_0}^{j_0} + P_{i_0}^{j_0} \{ X_{gate} ((M-1)T_F P_i^{j_0} + P_{i_0}^{j_0}) \} \\ & + P_{i_0}^j \left\{ \begin{aligned} & (N-1)R_{gate} [1 + X_{gate} T_F M P_i^j] \\ & (M-1)^2 T_F^2 [1 + X_{gate} T_F M P_i^j] \\ & + (M-1)^2 (N-1) T_F^2 R_{gate} \end{aligned} \right\} \\ & - 2\sqrt{P_{i_0}^{j_0}} \sqrt{P_{i_0}^j} \left\{ \begin{aligned} & (N-1)\sqrt{R_{gate}} + (M-1)^2 T_F + (M-1)^2 (N-1) T_F \sqrt{R_{gate}} \\ & (N-1)(M-1)^2 T_F \sqrt{R_{gate}} \\ & + (N-1)^2 (M-1)^2 T_F R_{gate} \\ & + (N-1)(M-1)^4 T_F^2 \sqrt{R_{gate}} \end{aligned} \right\} \\ & - 2P_{i_0}^j \left\{ R_{gate} \sum_{t=1}^{N-2} t + T_F^2 \sum_{t=1}^{(M-1)^2-1} t + T_F^2 R_{gate} \sum_{t=1}^{(M-1)^2(N-1)-1} t \right\} \quad (2) \end{aligned}$$

for the proposed topology under the assumption that all channels carry bit 1. The above equation has six contributions. The first three terms are the non interfering contributions and the last three terms are the contributions due to the interference of different channels (beat terms). In this topology the crosstalk due to the non-perfect gain clamping of the gate is same as the topology 3 [4]. The analytical equations for the proposed topology differ from the topology 1 and 3 due to the filters placed both sides of the switching matrix. It is expected that the crosstalk performance of the proposed topology may improve because

the desired wavelength channels are selected by the filters (with a fixed centre frequency) before and after the channels are routed to the output fiber.  $P_{i_0}^{out(ref)}$  is the output power of wavelength channel  $i_0$  when the OXC carries only this wavelength channel, such as when there is no crosstalk.  $P_{i_0}^{out(ref)}$  is given by [4]

$$P_{i_0}^{out(ref)} = P_{i_0}^{j_0} + X_{gate} (P_{i_0}^{j_0})^2 \quad (3)$$

Since wavelength channel  $i_0$  may carry bit 1 or bit 0 at any instant of time, equation (3) has to be modified. If wavelength channel  $i_0$  carries bit 0, then equation (2) reduces to equation (4).

$$\begin{aligned} P_{i_0 0}^{out} = & P_{i_0}^j \left\{ \begin{aligned} & (N-1)R_{gate} [1 + X_{gate} T_F M P_i^j] \\ & (M-1)^2 T_F^2 [1 + X_{gate} T_F M P_i^j] \\ & + (M-1)^2 (N-1) T_F^2 R_{gate} \end{aligned} \right\} \\ & - 2P_{i_0}^j \left\{ \begin{aligned} & (N-1)(M-1)^2 T_F \sqrt{R_{gate}} \\ & + (N-1)^2 (M-1)^2 T_F R_{gate} \\ & + (N-1)(M-1)^4 T_F^2 \sqrt{R_{gate}} \end{aligned} \right\} \\ & - 2P_{i_0}^j \left\{ R_{gate} \sum_{t=1}^{N-2} t + T_F^2 \sum_{t=1}^{(M-1)^2-1} t + T_F^2 R_{gate} \sum_{t=1}^{(M-1)^2(N-1)-1} t \right\} \quad (4) \end{aligned}$$

$P_{i_0}^{out(ref)}$  when wavelength channel  $i_0$  carries bit 0 can be written as,  $P_{i_0}^{out(ref)} = 0$ .

Following the analytical equations for the OXC topology presented here, the crosstalk contribution from different crosstalk sources are quantified and total crosstalk is calculated. The expression for relative crosstalk for a channel under study can be given by [4]

$$Crosstalk = \frac{P_{i_0}^{out(ref)} - P_{i_0 1}^{out}}{P_{i_0}^{out(ref)}} \quad (5)$$

To evaluate the BER of a WDM system, the crosstalk model presented for the proposed OXC topology is used to derive BER model. The mathematical formulation for BER of the proposed topology in case of IM-DD system can be given by [12].

$$BER_{worstcase} = \frac{1}{8} \left[ \begin{aligned} & \operatorname{erfc} \left( \frac{1}{\sqrt{2}} \frac{i_1 + i_{CT0} - i_D}{\sigma_{1,0}} \right) + \operatorname{erfc} \left( \frac{1}{\sqrt{2}} \frac{i_D - i_0 - i_{CT0}}{\sigma_{0,0}} \right) \\ & + \operatorname{erfc} \left( \frac{1}{\sqrt{2}} \frac{i_1 + i_{CT1} - i_D}{\sigma_{1,1}} \right) + \operatorname{erfc} \left( \frac{1}{\sqrt{2}} \frac{i_D - i_0 - i_{CT1}}{\sigma_{0,1}} \right) \end{aligned} \right] \quad (6)$$

where,  $i_D$  is the threshold current. In equation (6), it is assumed that when a bit 1 is interfered by a crosstalk bit 1, bit 0 is interfered by crosstalk bit 0, bit 1 is interfered by crosstalk bit 0 and bit 0 is interfered by crosstalk bit 1 as reported so far [8]. The variance of the interference is

given in equations (7) to (10)

$$\sigma_{1_0}^2 = \sigma_{th}^2 + 2qR_d(P_s + P_{sp} + P_{CT0})B + \sigma_{s-sp}^2 + \sigma_{sp-sp}^2 + \sigma_{CT0-sp}^2 + \sigma_{s-CT0}^2 \quad (7)$$

$$\sigma_{1_1}^2 = \sigma_{th}^2 + 2qR_d(P_s + P_{sp} + P_{CT1})B + \sigma_{s-sp}^2 + \sigma_{sp-sp}^2 + \sigma_{CT1-sp}^2 + \sigma_{s-CT1}^2 \quad (8)$$

$$\sigma_{0_1}^2 = \sigma_{th}^2 + 2qR_d(P_{sp} + P_{CT1})B + \sigma_{CT1-sp}^2 + \sigma_{sp-sp}^2 \quad (9)$$

$$\sigma_{0_0}^2 = \sigma_{th}^2 + 2qR_d(P_{sp} + P_{CT0})B + \sigma_{CT0-sp}^2 + \sigma_{sp-sp}^2 \quad (10)$$

where  $\sigma_{1_0}^2$  is the noise variance when signal bit 1 is interfered by crosstalk due to bit 0 and  $\sigma_{0_0}^2$  is the noise variance when signal bit 0 is interfered by crosstalk due to bit 0.  $\sigma_{1_1}^2$  is the noise variance when signal bit 1 is interfered by crosstalk due to bit 1 and  $\sigma_{0_1}^2$  is the noise variance when signal bit 0 is interfered by crosstalk due to bit 1.  $\sigma_{th}^2$  is variance of thermal noise,  $q$  is the electronic charge,  $R_d$  is the receiver responsivity,  $B$  is the bandwidth of the receiver low-pass filter,  $P_s$  is signal power.  $i_1$  is the photocurrent for a transmitted bit 1 and is given by  $i_1 = 2R_d P_s$ , The photocurrent  $i_0 = 0$  for a transmitted bit 0, with  $P_s$  assumed to be zero. The expression for amplified spontaneous emission (ASE) power,  $P_{sp}$  is given by  $P_{sp} = hf\eta_{sp}(G-1)\Delta\nu_{sp}$ , where  $h$  is the plank's constant,  $f$  is the optical frequency,  $\eta_{sp}$  is spontaneous emission factor,  $G$  is the optical amplifier gain, and  $\Delta\nu_{sp}$  is the effective bandwidth of spontaneous emission. The crosstalk power due to bit 1 is  $P_{CT1} = P_{i0_1}^{out(ref)} - P_{i0_1}^{out}$  and due to bit 0 is  $P_{CT0} = -P_{i0_0}^{out}$ . The corresponding crosstalk currents are  $i_{CT1} = R_d P_{CT1}$  and  $i_{CT0} = R_d P_{CT0}$  respectively.

#### IV. RESULTS AND DISCUSSION

Using the analytical approach presented in section III, the

Fig. 2 : Plot of BER as a function of received power for 10 Gb/s optical WDM system with proposed OXC topology

Fig. 3: Comparison of power penalty for the proposed topology and the existing topologies 1 and 3. The penalty is calculated at 10Gb/s for  $M = 4$ ,  $N = 2$ ,  $T_f = -30\text{dB}$ ,  $X_{gate} = 0.1\text{mW}^{-1}$  and  $R_{gate} = -50\text{dB}$ .

BER performance is evaluated for the proposed system at 10 Gb/s taking into account of OXC-induced crosstalk, ASE, and receiver noises. The plots of BER vs received power is shown in fig 2 with different values of input powers. It is observed from fig. 2 that the BER decreases with increasing the received power for a particular input power. However, for a particular received power, the BER is found to increase with increasing the input power. The power penalties due to crosstalk are determined for the topology 1 and 3 [4] and the proposed topology at BER of  $10^{-9}$ . The results obtained for  $M = 4$ ,  $N = 2$ ,  $T_f = -30\text{ dBm}$ , and  $R_{gate} = -50\text{ dBm}$  are shown in fig. 3. Form the plots, it is observed that the system suffers a power penalty due to OXC-induced crosstalk and the penalty increases with increasing input power for a given number of wavelengths and fibers. As seen in fig. 3 the power penalty for the topology 1 and 3 is almost the same. But, for the proposed topology the penalty is found to be lower than the topology 1 and 3. For a 2 dB penalty, the allowable input power for the topology 1 and 3 is less than -29 dBm. On the other hand, for the proposed topology it is less than -19 dBm. The increase in penalty at higher input power can be compensated if the performance of the switching matrix as well as that of filter is improved and wavelength converter is used.

The plots of penalty versus the number of wavelengths and the number of fibers for different topologies are shown in figs. 4 and 5, respectively. It is noticed from figs. 4 and 5 that there is an increase in penalty with increasing number of wavelengths as well as the number of fibers, at a given input power. The proposed topology shows lower crosstalk level and lower power penalty than the topology 1 and 3.

Fig. 4: Power penalty vs number of wavelengths in a fiber for different topologies. Data for topology 1 and 3 are taken from Ref. [4].

From the above discussion it is concluded that OXC-induced crosstalk limits the number of wavelengths, the number of input fibers as well as allowable input power per fiber in a WDM system. Considering the system impairments, the performance of the proposed topology is found to improve significantly than the existing topology 1 and 3.

## V. CONCLUSION

In this paper, crosstalk and BER performances of a WDM network are evaluated analytically for a proposed OXC topology and then compared with the existing topologies 1 and 3. Different factors that affect magnitude of crosstalk

Fig. 5 : Power penalty vs number of input fibers for different topologies. Data for topologies 1 and 3 are taken from Ref. [4].

and BER in the OXC are also investigated in details. The system performance is evaluated in terms of power penalty at BER of  $10^{-9}$  with different OXC parameters and noises. It is found that the allowable input power for the proposed topology is higher than the exiting topologies, which means that the influence of OXC-induced crosstalk is lower in the proposed topology than the existing topologies. The results obtained from the present study indicate that for an allowable power penalty more number of wavelengths or fibers can be used in the proposed OXC topology than the existing topologies 1 and 3. Therefore, system throughput ( $N$  multiplied with  $M$ ) can be increased by the proposed topology with the suffering of minimum power penalty.

# Solar Cell Efficiency Improvement Using Compound Parabolic Concentrator and an Implementation of Sun Tracking System

Eklas Hossain, Riza Muhida, Ahmad Faris Dzulkpli, and Khairul Azizi Abdul Rahman

Department of Mchatronics Engineering, International Islamic University Malaysia, Jalan Gombak,  
53100 Kuala Lumpur, Malaysia

**Abstract** — This paper presents how the efficiency of solar cell can be increased with the design of compound parabolic concentrator and the implementation of sun tracking system. Sun tracking systems is an application of the Machine Vision (MV) and collaboration with Data Acquisition (DAQ) to systems by using a webcam as a sensor and sound card as an output channel to drive a motor. The motors react as the mechanism of the camera to make sure it always focuses on the target of sun. By using a MatLab software programming environment, closes loop control is implemented to provide interaction between camera and sound card as a device to control the motor to track the sun.

**Index Terms** — Solar cell, concentrator, machine vision, close loop control, sun tracking.

## I. INTRODUCTION

Sunlight is a source of energy has been regarded as an alternative source of energy along with other alternative source such as hydrogen and natural gas. Solar energy is a vital that can make environment friendly energy more flexible, cost effective and commercially widespread. Photovoltaic source are widely used today in many applications such as battery charging, water heating system, satellite power system, and others. Although the installation cost is high but the advantage of photovoltaic source is free population.

The problem identification for the PV solar cell is the solar cell has low efficiency if the position of the solar cell in static location. It needs maximum heat sun light to produce the highest efficiency. Therefore, the compound parabolic concentrator is used to solve this problem. When the tracking system is combined with the compound parabolic, it can produce the voltage in the maximum efficiency. Compound parabolic concentrator is a significant of photovoltaic source because it is the combination of parabolic concentrator and the solar panel. The purpose of using parabolic concentrator is to get the ray reflection of light at the highest efficiency and to get the source of energy at the maximum value. The development of this system is as an alternative of power source and also to increase the source of the electricity at the highest efficiency from morning until afternoon.

Solar radiation can be converted into useful energy directly. In order to get the maximum efficiency of solar

cell, the sun has to be targeted at focal point. Since sun is changing position all the time, it should be tracked. Currently there are some researches on sun tracking systems, but almost all of them were using photosensitivity sensors as devices. The mechanism which follows the sun is not a new problem. In 1962 in Chile, Finster first attempted was completely mechanical [1]. Later Saavedra [2] presented a mechanism with automatic electronic control to orient an Eppley pyrheliometer. A recent review of the existing systems has been published by Myers et al. [3]. Roth, Georgiev, and Boudinov [4] presented a design of a system for sun-tracking. In this paper, the webcam and sound card are chosen as alternative devices to get the best performance of the tracking system with machine vision method and data acquisition (DAQ). By using the webcam as a sensor, the machine vision techniques are used to implement to make the systems efficient.

## II. DESIGN CONFIGURATION AND SELECTION

Figure 1 illustrates the design of the project starts with the base design by using CATIA programs and AUTOCAD programming. The design is used to measure and plot the dimension of the prototype of the project. It can be used as a guideline before start doing assembly process of the prototype. There are two types of DC motor that uses in this project, the 6W DC motor for pan rotation of the CPC, and 40W DC motor for tilt rotation of the base. The worm gear is combined with the 6W DC motor to make the CPC rotate and hold its position when the motor stop. The worm gear is combining with spur gear with ratio reduction 10:1. The DC motor also is combined with the gear head. The gear head is used to reduce the speed from high rotation to slow rotation with reduction ratio 50:1. Therefore, the combination of both reduction gears will produce 500:1 of the reduction speed. The slow rotation of the CPC is important because the movement of the sun is slow and it is easy to control the position of the CPC when doing the tracking process. The reduction gear for base rotation is also same as 6W DC motor.

Figure 2 illustrates the dimension of the CPC. The material that use in designing compound parabolic concentrator are aluminum beam for supporting base,

stainless steel for reflection, and camera as a sensor. The most important part in designing CPC is the focus point location of the solar cell. The focus point is the place where the location of the sunray is reflected on that point. Therefore, the calculation of the focus point of CPC is based on the standard parabolic formula.

Fig. 1. The base design and full design

Figure 3 illustrates the curve and calculation of the CPC. From the calculation shows that the focus point of the reflection is 15cm. therefore, the solar cell should be located at this position.

Fig.2. The dimension of the compound parabolic concentrator

Fig.3: The curve of the parabola and focus point

### III. FLOW OF THE SYSTEM

Figure 4 shows the system of this project uses web camera as a sensor detector of the sun. Then it will connect with computer and process by using matlab

programming. In this program the image will process by using simulink image processing tool. From the matlab programming, it will be used to determine the center position of the sun. The signal will be created from the matlab programming to create the PWM (Pulse Width Modulation) to control the speed of motor. This system uses two types of signal, sound card from motherboard and external sound card. The signal from the sound card produce negative and positive signal. The signal positive signal will generate the forward rotation and the negative signal will generate backward rotation. The output signal is applied at the H bridge circuit and amplified with Opamp. The opamp is used to amplify the signal to increase the value of the output voltage. This two sound card will control the motor at tilt rotation and pan rotation. The rotation of the motor is used to make the position of the camera center with the sun position.

Fig. 4. Schematic diagram for the sun tracking system

Figure 5 shows the controlling system for the sun tracking system uses MATLAB simulink programming and M file to control the speed of motor rotation. Basically, the MATLAB simulink is used to process the data and image processing of the sun. The process that includes in the image processing step is thresholding, median filter, image enhancement, centroid and quadrant of the image. All the steps are important because it is the way to determine the center position of the sun with camera. Part A is included the process of the image processing. It is also include the pixel adjustment of the camera. The adjustment of the pixel is very important because it can protect the camera from any damage. From the image processing, the position of the camera will be controlled by using M file coding to generate the PWM signal. The PWM signal is produced at the sound card. All the controlling motor rotation is at part B. The motor of tilt and pan rotation is controlled at this part and it will default condition when the position of the camera and sun is centered. The centroid position of the camera is displayed at the centroid display. The pulse generator is used to generate the controlling system according

whatever time we want. In this system, the system is set to do the process for every 30 second. Therefore, the process of the controlling system will be generating in every 30 second.

All the four images is the output from the image processing toolbox in the simulink programming. The original image is the image that produces form the camera. The camera is filtered with film. The purpose of using film

is to filter the sunray and to get only the picture of the sun. The enhancement of the image is used to reduce the pixel of the sun resolution. It is also to reduce the noise of the sun image. Form the enhancement process, the sun image is thresholding to get black and white of the image. The black and white is used to get the quadrant position of the centroid of the image. The centroid is the center position of the object.

Fig. 5. The whole controlling system

Fig. 6. The image processing

Fig. 7. Pulse Width Modulation (PWM)

Fig. 8. h-bridge circuit

Figure 7 illustrates the matlab command can generate PWM signal from the sound card. The PWM is very important because it is used to control the motor speed rotation. The speed of motor is depending on the duty cycle of the PWM signal. The motor will rotate at high speed rotation if the duty cycle is high. The impulse signal from the sound card is small and it is not enough to generate the motor. Therefore, the signal needs to amplify at the opamp. The opamp is used to increase the impulse of the signal. The impulse of the signal is depend on the gain of the resistor that uses in the opamp. From the figure

shows that, the signal that produce from different types of duty cycle and the output that produces when it is amplified at the opamp with gain 20. When the signal is amplified, the value of the impulse voltage is increased and it is enough to make the motor move. From the opamp, it will go to the H bridge circuit. Figure 8 shows the H bridge circuit that controls the movement of the DC motor. The H bridge circuit is used to rotate the motor move forward and backward.

#### IV. EXPERIMENTAL RESULTS

Figure 9 illustrates the result of the experimental graph that plot during the experiment test. The result of the experiment is the comparison between solar cell at CPC and non CPC. From the experiment, the result of efficiency of solar cell at the CPC is better than non CPC. The experiment shows that the power of solar cell can successfully produce when it is located at the CPC. The range of Current (I) vs Temperature ( $^{\circ}\text{C}$ ) is shown in Figure 10. It is evident that CPC system's temperature increase in much higher than non CPC. Our proposed design and system could provide better performance improvement for solar cell energy improvement.

Fig. 9. Graph Power (W) vs Time (h)

Fig. 10. Graph for the range Current (I) vs Temperature (°C)

## V. CONCLUSIONS

Camera is the sensor of the system, be an eye of the human to take care and observe the sun. As soon the sun can be tracked with the CPC, the voltage, current and power received will always be at the maximum of the efficiency. If the efficiency becomes the matter of the improvement of the solar cells, now with this project we already surpass the problems. This project should be continued and upgrade from time to time to get the higher efficiency to the maximum.

# Comparison of GARCH and Neural Network Methods in Financial Time Series Prediction

Altaf Hossain and M. Nasser

Department of Statistics, Rajshahi University, Rajshahi-6205, Bangladesh

E-mails: rasel\_stat71@yahoo.com; mnasser.ru@gmail.com

**Abstract** — Many researchers have already published huge number of papers comparing Autoregressive (AR) model, a model based on Box-Jenkins methodology, and Back Propagation Artificial Neural Network (BPANN) in financial time-series forecasting. Among them, some compared SVMs and BPs taking AR as a benchmark in forecasting the six major Asian stock markets. They showed that both the SVMs and BPs outperform the traditional models, ARs. They did prediction of transformed data, but not level data. They did not take account of GARCH model, specially developed to model financial time series. Generalized Autoregressive Conditional Heteroskedastic (GARCH) model is needed to capture high volatility for better forecasts. This article applies GARCH model instead AR or ARMA model to compare with standard BP in forecasting of the four international including two Asian stock markets indices. Our fitted GARCH models give better forecasts than the fitted standard BP models in forecasting of the four international markets indices except one market.

**Index Terms** — Autoregressive Moving Average (ARMA); Generalized Autoregressive Conditional Heteroskedastic (GARCH) and Back Propagation Artificial Neural Network (BPANN).

## I. INTRODUCTION

A time series  $\{Y_t\}$  is a discrete time, continuous state, process where  $t: t=1, 2, \dots, T$  are certain discrete points. Usually time is taken at equal spaced intervals and the time increment may be from everything from seconds to years. The study of time series is concerned with time correlation structures. It has diverse applications ranging from oceanography to finance. In the business and economic environment, it is very important to predict various kinds of financial variables accurately in order to develop proper strategies and avoid the risk of potentially large losses. There are some classical methods that have been developed in predicting financial time series. Among them, there is a powerful method, available in the literature for univariate time series forecasting, known as Box-Jenkins [2] ARMA (Autoregressive Moving Average) approach on stationary time-series. In conventional econometric models, the variance of the disturbance is assumed to be constant. But many economic and financial time series such as exchange rates, indices, market returns, inflation rate etc exhibit periods of unusual large volatility, followed by periods of relative

tranquility (i.e., time series exhibits clustering of large and small disturbances). Such circumstances suggest a form of heteroskedasticity in which the variance of the disturbance depends on the size of preceding disturbance and hence the conditional variance is non-constant over the sample period. Engle [5] showed that it is possible to model the mean and the variance of a series simultaneously by a model named Autoregressive Conditional Heteroskedastic (ARCH); whereas Box-Jenkins [2] modeled only the mean series. ARCH model allows the conditional variance to be an AR process. In latter, Bollerslev [1] extended Engle's original work by developing a technique that allows the conditional variance to be an ARMA process and that extended process is known as the GARCH process.

The classical methods are based on some specific assumptions, such as linearity; or on error distributions, such as normality. In this circumstance, ANNs were developed to meet the increasing demand that can predict, detect, classify and summarize the structure of variables and define the relationships between them – without relying too much on such assumptions. Not all relationships in economics and finance are direct. But the hidden layer of an ANN can capture all non-direct relationships between input and output variables. ANNs have been successfully applied in different areas, including marketing, retail, banking and finance, insurance telecommunications and operations management (Smith and Gupta [11]). The reason for its popularity among econometricians can be attributed to the ability to approximate any nonlinear relationship with a reasonable degree of accuracy. A number of research articles used Artificial Intelligence (AI) methods to forecast the price behavior of the financial commodities and compare the results with the traditional statistical methodologies. Refenes et al. [10], for example, modeled stock returns with ANNs in the framework of Arbitrage Pricing Theory (APT) and compared their study with regression models. Steiner and Wittkemper [12] investigated the performance of several ANN models that forecast the return of a single stock. Kamruzzaman and Sarker [7] modeled and forecasted currency of exchange rates using three ANNs and a comparison was made with traditional ARIMA model. In most of studies like the above, they showed that even the simple neural learning

procedures, such as BP algorithms easily outperform the best practice of traditional statistical models. They reported that the relationship between the return of a stock and factors of the capital market is usually non-linear and may contain dependencies in time. Chen and Wu [3] compared SVMs and BPs taking AR as a benchmark in forecasting the six major Asian stock markets. They showed that both the SVMs and BPs outperform the traditional models, ARs. They did prediction of transformed data, but not level data.

Although the superiority of the AI models has been shown comparing with traditional statistical methods like ARs in financial markets, as far we know, no research has been carried out comparison between the recently developed statistical method, GARCH and AI methods. So far the GARCH model has been developing theoretically. Few applied works regarding GARCH, especially, in forecasting financial time series are available in the literature.

The data source and nature are introduced in Section II. The methodology including two prediction methods in this paper is discussed in Section III. The results and discussion are presented in Section IV. Finally, our conclusion is in Section V.

## II. DATA SOURCE AND NATURE

For analysis we have used the monthly data of the four international stock market indices including two Asian markets, collected from the *Financial Forecast Center Home Page*. The names of the stock markets are Japan (Nikkei 225 from January, 1984 to January, 2006), Hong Kong (Hang Seng from December, 1986 to January, 2006), U.K. (FTSE 100 from April, 1984 to January, 2006), and Germany (DAX from November, 1990 to January, 2006).

## III. METHODOLOGY

A time-series is a dynamic consequence of events over time. It can be interpreted as a stochastic process. A time series of successive observations is regarded as a sample realization from an infinite population which has been generated by a process. A single equation ARMA model states how any value in a single time series is linearly related to its past values. In theory, if the “correct” model is chosen, the ARMA forecasts are “best”. See Box & Jenkins [2] and Pankratz [9]. Standard ARMA analysis rests on the simplifying assumption that the mean and unconditional variance of time series is independent of time, i.e., the series is stationary. The plot of ACF (Autocorrelation Function) and PACF as well some conventional tests like ADF (Augmented Dickey Fuller) test are used to decide whether a data series is stationary

or not. For non stationary time series, the data is transformed to be stationary; see Pankratz [9] for details. In the article, the most recent developed model, GARCH, has been used to overcome high volatility problem in forecasting financial time series. In the GARCH process, we additionally model the volatility (i.e., the variance of the disturbance) and most of the tests like stationarity are similar to that of the ARMA process.

### A. The ARCH and GARCH Modeling

Engle [5] showed that the serial correlation in squared returns, or conditional heteroskedasticity, can be modeled using an autoregressive conditional heteroskedasticity (ARCH) model of the form

$$y_t = E_{t-1}[y_t] + \epsilon_t \quad (2)$$

$$\epsilon_t = z_t \sigma_t \quad (3)$$

$$\sigma_t^2 = a_0 + a_1 \epsilon_{t-1}^2 + a_2 \epsilon_{t-2}^2 + \dots + a_q \epsilon_{t-q}^2 \quad (4)$$

where  $E_{t-1}[\cdot]$  represents expectation conditional on information available at time  $t-1$  and  $z_t$  is a sequence of iid random variables with mean zero and unit variance. In the ARCH model  $z_t$  is assumed to be iid standard normal. The restrictions  $a_0 > 0$  and  $a_i \geq 0$  ( $i = 1, \dots, q$ ) are required for  $\sigma_t^2 > 0$ . The representation (2) - (4) is convenient for deriving properties of the model as well as for specifying the likelihood function for estimation.

An important extension of the ARCH model proposed by Bollerslev [1] replaces the AR (p) representation in (4) with an ARMA (p,q) formulation

$$\sigma_t^2 = a_0 + \sum_{j=1}^p b_j \sigma_{t-j}^2 + \sum_{i=1}^q a_i \epsilon_{t-i}^2, \quad (5)$$

where the coefficients  $a_i$  ( $i = 0, \dots, q$ ) and  $b_j$  ( $j = 1, \dots, p$ ) are all assumed to be positive to ensure that the conditional variance  $\sigma_t^2$  is always positive. The model in (5) together with (2)-(3) is known as the generalized ARCH or GARCH (p,q) model. When  $p=0$ , the GARCH model reduces to the ARCH model.

The GARCH model reduces the number of estimated parameters from infinitely many to only just a few. GARCH has gained fast acceptance and popularity in the financial world. This can be explained by various arguments: the GARCH process has a close relation to ARMA processes. This suggests that the theory behind the GARCH process might be closely related to the theory of ARMA processes, which is well studied and widely known. That is, there is no logical difference between ARMA and GARCH modeling. In the GARCH modeling, we model and forecast the mean series additionally with the conditional variance; as a result, GARCH is more able than ARMA to capture the unusual volatility. For testing ARCH/GARCH effects, assessing the fit, diagnostic checks for model adequacy and estimation see Enders [4].

### B. Parsimonious Property of GARCH over ARCH

A high-order ARCH model may have a more parsimonious GARCH representation that is much easier to identify and estimate. Usually a GARCH (1,1) model with only three parameters in the conditional variance equation is adequate to obtain a good model fit for financial time series. Indeed, Hansen and Lunde [6], provided compelling evidence that it is difficult to find a volatility model that outperforms the simple GARCH (1,1).

### C. ANNs for Time Series Forecasting

An ANN is a biologically inspired form of distributed computation. It simulates the functions of the nervous system by a composition of interconnected simple elements (artificial neurons) operating in parallel, as shown in Figure 1. An element is a simple structure that performs three basic functions: input, processing and output. ANNs can be organized into several different connection topologies and learning algorithms (Lippmann [8]). In case of time-series, the series at different lags act as inputs of ANNs. The number of inputs to the network is constrained by the problem type, whereas the number of neurons in the output layer is constrained by the number of outputs required by the problem type. However, the number of hidden layers and the size of the layers are decided by the designer.

Figure 1 A neural network with one hidden layer

BP trains multilayer feedforward networks with differentiable transfer functions to perform the function approximation, pattern association and pattern classification. It is the process by which the derivatives of network error, with respect to network weights and biases, are computed to perform computation backwards through the network. Computations are derived by the chain rule of calculus.

There are several different BP training algorithms with a variety of different computation and storage requirements. Kamruzzaman and Sarker [7] used three algorithms, Standard Backpropagation (SBP), Scaled Conjugate Gradient (SCG) and Backpropagation with Bayesian

Regularization (BPR), in training the ANN. It was found that SCG based model performs best when measured on the two most commonly used metrics and showed competitive results when compared with BPR based model on other three metrics. Chen and Wu [3] used only the SBP and mentioned, "No single algorithm is best suited to all the problems." So we consider SBP for training the ANN models in our paper. All the algorithms use the gradient of the performance function to determine how to adjust the weights to minimize the performance. For example, the performance function of the feed forward networks is the Mean Square Error (MSE). The training process requires a set of examples of the proper network inputs and target outputs. During the training, the weights and biases of the network are iteratively adjusted to minimize the network performance function.

### D. Performance Criteria

Although the MSE is a perfectly acceptable measure of performance, in practice the ultimate goal of any testing strategy is to confirm that the results of models are robust and capable of measuring the profitability of a system. It is important, therefore, to design a test from the outset. According to Tay and Cao [13] and Thomason [14], [15], the prediction performance is evaluated using the following statistics: MSE, Normalized Mean Squared Error (NMSE), Mean Absolute Error (MAE), Directional Symmetry (DS) and Weighted Directional Symmetry (WDS). These criteria are defined in the Table 1. See Chen and Wu [3] for more details.

## IV. RESULTS AND DISCUSSION

### A. Explorative Data Analysis (EDA)

We examined the four international stock market indices. The time periods used and the indices' statistical data are listed in Table 2, and the monthly closing prices used as the data sets are plotted in Figure 2. The time periods cover many important economic events, which we believe are sufficient for the training models.

### B. Preprocessing and Design of The Models

We transform the original closing price into white noise series differencing two times at lag one for each series except the market NK, where we take one time difference. White noise series is the first requirement for a data series to which we can apply the classical statistical techniques as well as the AI models for better fitting. According to Thomason [14], [15] and Tay and Cao [13], this transformation has many advantages. The most important is that the distribution of the transformed data becomes more symmetrical so that it follows a normal distribution

more closely. This also improves the predictive power of neural network.

TABLE 1  
PERFORMANCE METRICS AND THEIR  
CALCULATION

METRICS	CALCULATION
MSE	$MSE = \frac{1}{n} \sum_{i=1}^n (a_i - p_i)^2$
NMSE	$NMSE = \frac{1}{\delta^2 n} \sum_{i=1}^n (a_i - p_i)^2$ $\delta^2 = \frac{1}{n-1} \sum_{i=1}^n (a_i - \bar{a})^2$
MAE	$MAE = \frac{1}{n} \sum_{i=1}^n  a_i - p_i $
DS	$DS = \frac{100}{n} \sum_{i=1}^n d_i$ $d_i = \begin{cases} 1 & (a_i - a_{i-1})(p_i - p_{i-1}) \geq 0 \\ 0 & \text{otherwise} \end{cases}$
WDS	$WDS = \frac{\sum_{i=1}^n d_i  a_i - p_i }{\sum_{i=1}^n d'_i  a_i - p_i }$ $d_i = \begin{cases} 0 & (a_i - a_{i-1})(p_i - p_{i-1}) \geq 0 \\ 1 & \text{otherwise} \end{cases}$ $d'_i = \begin{cases} 1 & (a_i - a_{i-1})(p_i - p_{i-1}) \geq 0 \\ 0 & \text{otherwise} \end{cases}$

TABLE 2  
DESCRIPTION OF DATA SETS

INDEX	TIME PERIOD	N	HIGH	LOW	MEAN	SD
Nikkei 225 (NK)	1984.01-2006.01	265	38920	7837	18020	6643.7
Hang Seng (HS)	1986.12-2006.01	230	17410	2138	8977	4411.6
FTSE 100 (FT)	1984.04-2006.01	262	6930	1009	3559	1612.3
DAX (DX)	1990.11-2006.01	183	7645	1398	3637	1690.4
Here N indicates the number of realizations for each market						

The modification is known, so we can reverse it to compare the forecasts with the original series. Each of the

four data sets is partitioned into three subsets according to the time sequence in the ratio 95: 2.5: 2.5. The first part is used for training; the second is a validating set and the last is used for testing. In Standard BP models, we use one hidden layer of different units for each market. We select the number of inputs for the ANNs, and units for the hidden layer of that ANNs which give minimum MSE on the validation sets. The used activate functions are sigmoid in the hidden layer and linear in the output layer.

Figure 2 Indices of the four International stock markets

### C. Comparison and Discussion

For each market, we also design different ordered ARMA models as to show the necessity of GARCH model. The ACF of squared residuals for each fitted ARMA indicates the presence of GARCH effects. The forecasting results of the ARMA, GARCH and BP for the test set are collated in Table 3. In general, GARCH and BP models outperform the ARMA model in the deviation performance criteria. However, in the either direction and weighted direction performance criteria, the ARMA model shows better results than BP model for the four markets, possibly because BPs are trained in terms deviation performance. With regard to the direction criteria, the time-series model has an intrinsic merit because it emphasizes the trend of the series. Therefore, the BP model, even GARCH model cannot outperform ARMA in the direction criteria in the four international markets under study. Figure 3 shows the fitted lines of the GARCH, BP models and real value line where the fitted line of the GARCH model seems closer to the real value line than the BP model for different markets except the market FT for the period 1991-1998.

TABLE 3  
COMPARISON OF THE RESULTS OF NN AND  
GARCH MODELS ON THE TEST SET

		SQRT MSE	MAE	NMSE	DS	WDS
N K	ARMA (3,4)	3172.5	2706.4	3.12	57.1	0.66
	GARCH (1,1)	824.82	686.75	0.21	85.7	0.00
	BP (2,12)	900.91	765.64	0.25	71.4	0.42
H S	ARMA (3,4)	545.12	459.55	1.30	16.6	2.07
	GARCH (1,1)	656.85	525.59	1.88	0.00	-----
	BP (4,8)	778.94	684.11	2.65	33.3	1.18
F T	ARMA (4,3)	521.08	497.87	7.33	71.4	0.12
	GARCH (1,1)	196.91	170.64	1.04	42.8	1.23
	BP (7,4)	236.81	220.12	1.51	28.5	5.87
D X	ARMA (7,0)	961.35	921.55	9.23	60.0	0.38
	GARCH (1,1)	234.99	229.32	0.55	40.0	0.66
	BP (4,5)	191.05	156.14	0.36	60.0	0.79

The first order of BP ( , , ) indicates the number of inputs and the second order indicates the number of units used in the hidden layer.

Table 4 gives the comparison of the result of the GARCH and BP models. In the NK, HS and FT data sets, the GARCH models perform better than the BP models. On the other hand, the BP method performs only a little better than GARCH in only one market, DX. If we consider the ARMA models to compare with GARCH and BP models, both seem to perform better for three markets in terms of the deviation measurements. Only in the market HS, the ARMA performs better than both. For the other one directional criteria (DS), BPs work better than GARCHs in the NK and FT indices. The performance of GARCHs is not always better than the BPs in these performance criteria. Table 4 summarizes the two models. Generally speaking, based on the five performance criteria, GARCHs fit the NK, HS and FT indices well, whereas BP fits only DX indices.

Figure 3 The values of indices fitted by GARCH and NN models and their real values

TABLE 4  
COMPARISON OF NN AND GARCH ON THE  
TEST SET

	SQRT MSE	MAE	NMSE	DS	WDS	SUMMARY
NK	+	+	+	-	+	+
HS	+	+	+	+	-	+
FT	+	+	+	-	+	+
DX	-	-	-	+	+	-

GARCH, '+' represents GARCHs that perform well and '-' represents NNs that perform well.

## V. CONCLUSION

In this article, we examine the feasibility of applying two models (GARCH and standard BP) to financial time-series forecasting for the four international stock markets including two Asian markets. Our experiments demonstrate that both models perform better than the ARMA model in the deviation measurement criteria. Previous research claims that the NN method is superior to the classical statistical method, ARMA or AR. If we consider the classical statistical method GARCH (just extended version of ARMA process), it is superior to the NN method except in the only one market DX of indices. The statistical methods, ARMA and GARCH, require large number of sample size for better forecasting and these drastically reduce the original sample size when the

high order model is fitted. From Figure 2, it is evident that DX data set is less volatile. Perhaps, due to this reason in this case standard BPANN (wins in three metrics out of five) slightly outperforms GARCH. Again if we look at the validation (short-time) errors, the ANNs perform better than the GARCHs – which indicates the generalization power of NN method is not as good as that of GARCH. If we investigate ANN with other training methods and compare with GARCH, what would be happened – it is the matter of study. ANN as well GARCH has several improved versions. The GARCH models are more parsimonious than the NN models since the GARCH models take smaller number of parameters for better forecasting. The GARCH models are also more interpretable than that of NN because the ANN structures contain hidden layers which are not interpretable. In general, the GARCH and the BP models perform well in the prediction of indices behavior in terms of the deviation criteria. Our experiments also show that both the statistical and the AI techniques can assist the stock market trading and the development of the financial decision support systems. But if we consider predictability along with interpretability and parsimonious property, then we recommend the GARCH models in financial time series prediction.

Our future study is to apply more complex GARCH methods and ANN with other training methods to the forecasting of Bangladesh stock markets and compare it with also the SVM methods. In our current GARCH models, we only select the return of index price information as input variables. But we want to enhance the performance of prediction GARCH models by including other efficient input variables (such as some macroeconomic variables).

#### ACKNOWLEDGEMENT

First I wish to my thanks and gratitude to my elder brother Faisal Zaman for his cordial guidance. I acknowledge the valuable suggestion of reviewer. I am also grateful to the core team of R language; using their packages our output is found.

# Neural Network and Genetic Algorithm Approaches for Forecasting Bangladeshi Monsoon Rainfall

Shipra Banik, Farah Habib Chanchary, Khodadad Khan, Rifat Ara Rouf and Mohammed Anwer

School of Engineering and Computer Science, Independent University, Bangladesh, Dhaka, Bangladesh  
email: [banik@secs.iub.edu.bd](mailto:banik@secs.iub.edu.bd), [farah@secs.iub.edu.bd](mailto:farah@secs.iub.edu.bd), [khan@secs.iub.edu.bd](mailto:khan@secs.iub.edu.bd),  
[rifatar@secs.iub.edu.bd](mailto:rifatara@secs.iub.edu.bd), [manwer@secs.iub.edu.bd](mailto:manwer@secs.iub.edu.bd)

**Abstract-** True information about rainfall is crucial for human activities such as the use and the management of water resources, hydroelectric power projects, warning to impend droughts or floods, urban areas sewer systems and many others. This paper investigates the development of an efficient model to forecast monthly monsoon rainfall for a number of stations, namely Barishal, Chittagong, Dhaka, Khulna, Rajshahi and Sylhet. It is believed that rainfall forecasting is difficult and also a challenging task for anyone because rainfall data are multi-dimensional and nonlinear. Therefore, to model rainfall data, the AI models, namely artificial neural network (ANN), adaptive neuro fuzzy inference system (ANFIS) and genetic algorithm (GA) have been used. Results found by the AI models are also compared to the linear regression model to show advantages of selecting these models. Findings suggest that ANFIS and GA approaches could be used more accurately than the other two selected approaches to forecast the Bangladeshi monsoon rainfall.

**Index Terms-** Atmospheric dynamics, forecasting, artificial intelligence, neural network, fuzzy inference system, genetic algorithm

## I. INTRODUCTION

The important hydrological event rainfall is the quantity of water falling in drops from vapor condensed in the atmosphere. When water droplets in clouds become too heavy to stay in the air, they fall out towards the ground. This paper proposes an appropriate model to predict monsoon rainfall in different stations of Bangladesh (see section II, for details). Making reliable prediction about rainfall is very important in many areas of human activity, indicated as follows: Rainfall mainly controls our water supplies, which are the basis for crops production. It is especially important for rainfed (or dry) land agriculture. For example, crops plant use a huge amount of water and rains, to a major extent, provide this water through the soil, for the development and growth of plants. Since Bangladesh is an agro-based country, accurate prediction of rainfall will be useful for proper plannings of cultivation. That's why those who are involved in agriculture, they will be interested to know whether the next days (or months) will be rainy/non-rainy. Although water is vital to life, yet water can be extremely destructive. Thus, rainfall forecasting can warn of happening flood or drought so that one can save their lives and properties. Rainfall forecasting is also

important for engineering applications, mainly for the design of hydroelectric power projects, because this system requires prior information about average rainfall, maximum/minimum rainfall, maximum intensity, duration etc. for a year/each month. In urban areas, rainfall also has a strong influence on traffic control, operations of sewer systems and others. Thus, we believe that precise rainfall prediction is important for practitioners who are interested to make wise policies related to this event.

True quantitative rainfall forecasting is generally difficult and also a challenging task for anyone because of our complex atmospheric processes. Thus, rainfall is treated as one of the most complex and difficult events among other hydrological events. Forecasting techniques, namely the statistical methods (ARIMA, regression, exponential smoothing etc.) and the AI methods (neural networks (artificial neural network (ANN), adaptive network based fuzzy inference system (ANFIS) etc.), fuzzy inference system (FIS), genetic algorithm (GA) and others) are proposed in literature. Note that statistical techniques have been developed for many years but have proven to be incapable to handle the non-linear series [1-2]. Hence, the AI methods have been proposed and engaged successfully in series forecasting, where the only goal is to minimize predictive error for the considered model. Thus, these methods have been applied in solving numerous forecasting problems (e.g. [3-6] and many others). We believe rainfall data are multi-dimensional, non-linear and dynamic, therefore to search for an appropriate model, the powerful techniques ANN, ANFIS and GA have been chosen. Results obtained by these models are also compared to the linear multiple regression (MR) model to show selected AI models performances. Empirical works (e.g. [7-13] and many others) have been carried out to forecast rainfall in context of various countries. Although studies have been conducted to predict rainfall for Bangladesh (e.g. [11-13] and others), to our knowledge, no comparative work is available to predict rainfall under the AI models for various Bangladeshi stations. We have considered this issue in this paper, which is planned as follows: Rainfall model and data sets description are explained in the next section. Considered techniques to predict rainfall are reviewed in the section III. Computational settings of the

TABLE I.  
NUMERICAL SUMMARY STATISTICS FOR  $R_t$

Stations	Time Periods	Mean	SD	Skewness
Barishal	Jan-53:Dec-02	285.43	176.38	0.79
Chittagong	Jan-49:Dec-02	387.81	285.10	1.06
Dhaka	Jan-53:Dec-02	274.24	154.35	0.73
Khulna	Jan-53:Dec-02	234.09	150.81	0.91
Rajshahi	Jan-64:Dec-02	210.16	147.09	0.82
Sylhet	Jan-56:Dec-02	547.55	291.42	0.38

selected techniques are given in the section IV. The relative performances of the considered methods are discussed in the section V. The final section concludes the paper with some future research plans.

## II. MODEL AND DATA SET

### A. Rainfall Model

The following functional relation is considered to predict monsoon rainfall:

$$R_t = f(\text{Intercept}, T_t, RH_t, CL_t), t=1,2,\dots,n \quad (1)$$

where  $R_t$  = rainfall (mm),  $T_t$  = temperature ( $^{\circ}\text{C}$ ),  $RH_t$  = relative humidity (%) and  $CL_t$  = cloud coverage (octas). Our target is to estimate model (1) parameters using the techniques of ANN, ANFIS, GA and MR.

### B. Data Set

For different stations of Bangladesh (see Table I), monthly  $R_t$ ,  $T_t$ ,  $RH_t$  and  $CL_t$  for monsoon periods (April to October) are used, which are extracted from <http://www.barc.gov.bd/database>. To understand behaviors of the considered variables, summary statistics are reported in Tables I-II. It can be seen that the highest mean rainfall is observed for the Sylhet region (547.55 mm) and the least mean amount for the Rajshahi region (210.16 mm). Standard deviation measures, e.g., for the Sylhet region, show that all times rainfall was not observed 547.55 mm (expected range: 256.13 to 838.97). Skewed measures indicate that rainfall patterns do not follow the normal distribution. For example, skewness 0.38 mm for the Sylhet region indicates that most of months rainfall amounts are observed below 547.55 mm. From Table II, it is observed that mean of  $T_t$  and mean of  $RH_t$  are almost same for all regions. But records of  $CL_t$

TABLE II.  
NUMERICAL SUMMARY STATISTICS FOR  $T_t$ ,  $RH_t$  AND  $CL_t$

Sta.	Mean			SD			Skewness			CC		
	$T_t$	$RH_t$	$CL_t$	$T_t$	$RH_t$	$CL_t$	$T_t$	$RH_t$	$CL_t$	$T_t$	$RH_t$	$CL_t$
Bar.	29	85	5.2	0.7	4.5	1.3	0.1	-0.9	-0.5	-0.3	0.6	0.64
Chi.	28	83	5.2	0.6	3.7	1.3	-0.1	-0.3	-0.5	-0.2	0.7	0.70

Fig. 1. An ANN architecture

show that like rainfall, Sylhet region experiences the highest mean amount (5.9 octas), can be a cause of occurring highest rain. Skewed measures (like  $R_t$ ) show that  $T_t$ ,  $RH_t$  and  $CL_t$  variables do not follow normal distribution. Correlation coefficient (CC) results indicate that there is a negative relationship exists between  $T_t$  and  $R_t$  and a positive relationship between  $RH_t$  and  $CL_t$ . We believe these findings will be useful for individuals who are interested about the events  $R_t$ ,  $T_t$ ,  $RH_t$  and  $CL_t$ .

## III. TECHNIQUES USED TO PREDICT RAINFALL

### A. ANN

Culloch and Pitts [14] introduced this system. A basic ANN structure (see Fig.1, details [5]) contains 1 input layer, number of hidden layers (with sufficient no. of neurons) and 1 output layer. Each neuron receives an input  $P_{Q \times 1}$  ( $T_t$ ,  $RH_t$  and  $CL_t$ ) and produces the net output as  $\hat{R}_t = W_{N \times Q} + b$ , where  $W_{N \times Q}$  are the weights,  $b_{N \times 1}$  is the bias,  $N$  are the number of neurons in the hidden layers and  $Q$  are the number of elements in  $P$ . The training algorithm is the standard BP, which uses the GD technique to minimize error. During training, each desired  $\hat{R}_t$  is compared with the actual  $R_t$  and calculates error at the output layer. When the training process is completed, then the network with adjusted  $W_{N \times Q}$  and  $b_{N \times 1}$  (estimated parameters) is used to test a set of data, which is different from the training set of data.

### B. ANFIS

This system is developed by Jang [3]. It is a combination of ANN and FIS, in such a way that the ANN learning algorithm is used to determine parameters of FIS. An ANFIS system (see Fig.2, details [3] or [5]) has 5 fixed layers: 1 input layer, 3 hidden layers and 1 output layer. The learning algorithm is a hybrid system, which uses two types of error estimation techniques, the least square method (LSE) and the GD method. The hidden layer is computed by the GD method of the feedback structure and the final output ( $\hat{R}_t$ ) is estimated by LSE. Initially, one solution is calculated and then it is optimized by readjustment of parameters by repeated application of the hybrid system.

Fig.2. An ANFIS architecture

### C. GA

This technique is proposed by Holland [15]. Later Koza used this approach (called his method genetic programming (GP)) to evolve programs to perform certain tasks (details, see [16]). By definition, GA is a technique based on the ‘Darwin’s Principle of Natural Selection’ and is used to solve optimization problems. The basic idea is to select the best, discard the rest and differs from other systems in the following way. GA does not require any assumptions such as linearity, stationarity, homogeneity or chaotic. Thus, to handle the complex multi-dimensional behaviors of a system, this approach has been used efficiently in literature (e.g. [10, 15-17] and others). Fig.3 flowchart shows the basic steps involved in a GA process (see Table III, for the standard GA options). Each of steps brief explanation of Fig.3 (or Table III) are as follows:

**Step-1:** Create an initial population consisting of random chromosomes. To understand the GA process, e.g., for the model (1), consider the following random population of 6 chromosomes with 4 parameters each: (0.13, 0.01, 0.84, 0.68), (0.20, 0.74, 0.52, 0.37), (0.19, 0.44, 0.20, 0.83), (0.60, 0.93, 0.67, 0.50), (0.27, 0.46, 0.83, 0.70), (0.19, 0.44, 0.01, 0.42). Population size is chosen usually from 100-500. Larger population may produce more robust solution.

**Step-2:** Fitness scaling is used to provide a measure of how selected chromosomes perform in the problem

Fig. 3. A GA structure

TABLE III.  
COMMON GA OPTIONS

Step	Algorithm Option
1. Creation	Uniform, normal
2. Fitness scaling	Rank, proportional, top (truncation), linear scaling, shift
3. Selection	Roulette, stochastic uniform selection, tournament, uniform
4. Crossover	Binary-valued (single-point, two-point, n-point, uniform), real-valued (intermediate, line)
5. Mutation	Gaussian, uniform
6. Reinsertion	Pure, uniform, elitist, fitness-based

domain. Model (1) fitness is evaluated through a criterion like RMSE (CC, MAE can be also used). For (1), we get RMSE: 26.19, 32.09, 53.75, 20.18, 18.67 and 66.64. Using the linear-ranking process (e.g.) (details, see [18]), Fit(RMSE): 1.2, 0.8, 0.4, 1.6, 2.0, 0.

**Step-3:** Based on the step-2 results, choose parents for the next generation. To understand it, consider the following distribution:

RMSE:	26.19	32.09	53.75	20.18	18.67	66.64
Fit(RMSE):	1.2	0.8	0.4	1.6	2.0	0
pdf of RMSE:	0.2	0.13	0.06	0.26	0.33	0
cdf of RMSE:	0.2	0.33	0.39	0.65	0.98	1.0

It is observed that chromosome 5 is the fittest chromosome, because it occupies the largest interval, whereas chromosome 4 is the second least fit chromosome as the smallest interval. Chromosome 6 is the least fit interval that has a fitness value of 0 and get no chance for reproduction. Using (e.g.) the roulette wheel method (purpose is to eliminate the worst chromosomes and to regenerate better substitutes), selected 4 parents are: (0.20, 0.74, 0.52, 0.37), (0.13, 0.01, 0.84, 0.68), (0.27, 0.46, 0.83, 0.70), (0.13, 0.01, 0.84, 0.68). Next step is to produce offspring from selected parents by combining entries of a pair of parents (known as crossover) and also by making random changes to a single parent (known as mutation).

**Step-4 (GA operator-1):** Basic operator for producing new (improved) chromosomes is known as crossover (a version of artificial mating). It produces offspring that have some parts of both parents genetic material. Offspring are produced using the intermediate crossover method, because this is a method proposed to recombine of parents with real valued chromosomes (details, [18]). Thus, crossover offspring are: (0.16, 0.16, 0.85, 0.57), (0.13, 0.22, 0.76, 0.43), (0.13, 0.15, 0.83, 0.69), (0.26, 0.45, 0.84, 0.68).

**Step-5** (GA operator-2): Offspring are mutated after being produced crossover offspring and this GA operator increases the chance that the algorithm will generate better fittest RMSE than the step-4. GA creates 3 types of offspring: These are elite (number of best RMSE values in the current generation that are guaranteed to survive to the next generation), crossover and mutation. To understand it, consider an example: Suppose population size is 20 and elite count is 2. If crossover fraction is 0.8, then the distribution of offspring: 2 elites, 14 ( $18 \times 0.8$ ) are crossover offspring and the remaining 4 are mutation offspring. Just to know, a crossover fraction of 1 means, all offspring other than elite are crossover offspring, while a crossover fraction of 0 means that all offspring are mutation offspring. How offspring are produced under the mutation process, see [18]. The mutation offspring are found (0.16, 0.17, 0.85, 0.56), (0.13, 0.22, 0.76, 0.43), (0.13, 0.14, 0.83, 0.69), (0.26, 0.45, 0.84, 0.68) respectively.

**Step-6:** Once offspring have been produced using steps 4-5, offspring fitness (i.e. RMSE values) must be determined (procedure similar to step-2). We get improved RMSE: 23.37, 28.13, 24.11 and 18.62. If less offspring are produced than the original population size, then to maintain size, offspring have to be reinserted into the old population. By this step, it is determined which chromosomes will be replaced by offspring. Using (e.g.) the fitness-based reinsertion method, the following RMSE are found: 20.18, 18.67, 18.62, 23.37, 24.11 and 28.13. If termination criteria are not defined, GA returns to the step-3 and continues up to the step 6. It is satisfied when either maximum number of generations is achieved or when all chromosomes in the population are identical (i.e. converge). The creator sets this number before running GA, which ensures that GA does not continue indefinitely.

#### D. MR

This method is developed based on the assumption of linearity and its main aim is to minimize error. Model (1) parameters are estimated by  $\hat{\alpha}_i = (X'X)^{-1}(X'R_t)$ ,  $i=1,2,3$ , where  $X$  includes  $T_t$ ,  $RH_t$  and  $CL_t$  and  $\hat{\alpha}_0 = \bar{R}_t - \hat{\alpha}_1 \bar{T}_t - \hat{\alpha}_2 \bar{RH}_t - \hat{\alpha}_3 \bar{CL}_t$ .

Thus, 8 if-then fuzzy rules were learned. Total parameters (44) = premise parameters (12) + consequent parameters (32), where premise parameters is calculated by # of inputs * # of mfs * # of parameters of Gaussian distribution and consequent parameters is calculated by # of mfs * # of parameters of Gaussian distribution * # of fuzzy rules.	1) <i>Population size</i> -1500, generated at random from the uniform probability distribution. 2) <i>Fitness function</i> -RMSE of model (1). 3) <i>Fitness scaling</i> -Linear ranking process. 4) <i>Selection</i> -Roulette wheel. 5) <i>Crossover</i> -fraction: 0.90; Intermediate method. 6) <i>Mutation</i> -fraction: 0.05; Uniform method. 7) <i>Reinsertion</i> -The fitness-based reinsertion method. 8) <i>Termination Criteria</i> - Maximum # of generations, assumed 300.

#### IV. DESIGN OF CONSIDERED TECHNIQUES

The first 70% data for each selected stations are used as the training period and the rest 30% as the testing period (see Fig.4). To reduce error, an error and trial approach is used to find the computational settings for each selected AI techniques, which are reported in the Table IV.

#### V. RESULTS AND DISCUSSION

Systems performances have been measured by statistical measures, RMSE and coefficient of determination ( $R^2$ ). Note that RMSE is a measure of the accuracy of prediction through representing the degree of scatter and  $R^2$  is a measure of the accuracy of prediction of the trained network models. Higher  $R^2$  value indicates better prediction. All computational works were carried

TABLE V.

	$R^2$	0.91	0.92	0.93	0.91	0.91	0.93	0.89	0.90

out using the programming code of MATLAB (version 7.0). Table V summarizes training and testing results achieved for selected approaches, which clearly reveal efficiency of the proposed techniques. In terms of both measures RMSE and  $R^2$ , for all stations, ANFIS performed better (i.e. good match between actual and predicted) than other models, followed by GA. It is found that ANN and MR models performances are almost same for all considered cases. See the Fig.4, to understand our findings graphically, where only the ANFIS model and the GA model performances (to avoid clumsiness in figure) are shown with observed  $R_i$ .

#### VI. CONCLUSION

Rainfall forecasting is important for many areas of human activity such as agriculture, water resources, hydroelectric power projects, happening of droughts or floods and others. This paper modelled the complex multi-dimensional behaviors of monthly monsoon rainfall for a number of Bangladeshi stations, namely Barishal, Chittagong, Dhaka, Khulna, Rajshahi and Sylhet using several soft computing techniques. We considered ANN, ANFIS and GA processes and results obtained by these models are compared to the linear multiple regression model to show advantages of proposing the AI models. Findings suggest that the ANFIS model and the GA model can be used to forecast monthly monsoon rainfall more accurately than the ANN model and the statistical model. We believe the findings of this paper will be useful to the individuals for formulating wise policies related rainfall in the context of our country, Bangladesh. Our next plan is to model the daily monsoon rainfall data, which have significance in the field of agriculture, transportation, sports, tourism activities and others. This is left for future research.

**Abstract** — This paper presents performance analysis of beamforming algorithm for canceling multiple channel noise depending on variation of hidden layer of the multilayer feedforward network and the number of epoch (also known as number of iteration). We consider the learning rate variation of the multi layer perception (MLP) to determine the adaptive learning rate of the network. An MLP has been considered to perform beam-forming, which is an array of sensors connected to the MLP inputs. We use the Backpropagation algorithm as the learning rule for MLP and improving the signal quality. This involves a desired signal whilst removing any noise or interference signals which may come from different sources [1].

**Index Terms** — DSPs,  $\mu$  LMS, MLP, AM, BSS, Nyquist Sampling Rate.

## I. INTRODUCTION

Various signal processing techniques have been proposed over the years for noise reduction in the environment. The explosive growth of digital signal processing algorithms and technologies has given an impetus to the application of these techniques to the real world. Digital signal processors (DSPs) have shrunk tremendously in size while their processing capabilities have grown exponentially. This has enabled the use of DSPs in a variety of portable hearing enhancement devices such as hearing aids, headsets, hearing protectors, etc. There is an approach for electrical noise reduction. These electrical noise reduction techniques are applied in hearing aids, cochlear implants, etc. where the signal and ambient noise are recorded using microphone. Noise reduction techniques such as spectral subtraction and the  $\mu$  LMS algorithm are applied and the listener hears only the signal [2]. One of the important assumptions of this technique is that the listener is acoustically isolated from the environment. In this research, beam-forming technique is used for noise cancellation and performance is analyzed for various hidden layers in feedforward neural network and number of iteration

(epoch). Backpropagation algorithm is used to improve the signal quality and to train the data [3].

## II. ARCHITECTURE OF THE PROPOSED SYSTEM

The arrangement for the neural network based on beamforming is depicted in Fig. 1. From the Fig. 1 it is clear that there will be a neuron for each array element (AE). A beamforming is an array of sensors connected to the MLP inputs. The electromagnetic signal impinges each antenna at different time. This time difference is effectively a delay on the signal and the physical spacing of the antenna elements is used to calculate the required delays. In this case the linear array will consist of 6 elements which process the desired signal has been contaminated with noise.

Fig. 1 Neural network for beamforming

### A. Multilayer Feedforward Neural Network

Fig. 2 represents the fully connected feedforward three layers MLP. Fig. 2 is known as a 7-4-3 architecture because it has 7 input nodes, 4 hidden nodes, and 3 output nodes. In general, the input layer has not performed any computation; it just acts as a buffer. The neural network architecture will be

optimized by trial and error. In this system, 6 neurons have considered in the input layer, 3 neurons in the hidden layer and 1 neuron in the output layer. A bipolar sigmoid transfer function is used in each layer due to its ability to solve nonlinear problems. The short-term representation of a signal is obtained by windowing (Hamming window). Sampling rate of this signal is higher than the Nyquist sampling rate.

Fig. 2. Three layer MLP

### B. Beamforming Technique

Beamforming technique is currently used in numerous radio communication systems, radar and sonar to eliminate interference and jamming. A Beam-former is another name in spatial filtering where an array of sensors together with appropriate signal processing can either direct or block the radiation or the reception of signals in specified directions. Fig. 3 represents the block diagram of a simple beamformer. At first, it samples the propagating wave field in space, is typically used for processing narrowband signals [4].

The output of the sensors are weighted and then summed to produce the output of the overall beam-former. The beam-former output at time  $k$ ,  $y(k)$  is given by a linear combination of the data at the  $M$  sensors at time  $k$ .

$$y(k) = \sum_{i=1}^m (W_i u_i(k))^* \quad \text{where } * \text{ represents complex}$$

conjugate. It is conventional to multiply the data by conjugate of the weights to simplify notation.

Fig. 3. A general beamforming system

## II. SYSTEM IMPLEMENTATION

Different steps to implement the system are given below.

Fig. 4. Implementation steps

According to the Fig. 4 to create a desired signal AM wave is selected. This signal arrives at each antenna at given time intervals. A random noise is added to this signal when it arrived at each antenna. Desired signal created is represented by the following equation.

$$d\_signal = (A \times (1 + m \times \cos(\omega_m t)) \times (\cos(\omega_c t))) \quad (1)$$

Then the noisy signal is represented by the following equation.

$$d\_signal = (A \times (1 + m \times \cos \omega_m t \times \cos \omega_c t)) + (rand() \% 1000) / 1000 \quad (2)$$

where  $A$  = carrier amplitude of the desired signal  
 $m$  = modulation index of the desired signal.  
 $\omega_m$  = angular modulation frequency of the desired signal.  
 $\omega_c$  = angular carrier frequency of the desired signal

The difference between these two signals is the angle of arrival (i.e. the delay of the signal between antennas). The equation which generate interference signal is shown below.

$$i\_signal = i_A \times (1 + i_m \times \cos j \omega_m t \times \cos j \omega_c t) \quad (3)$$

where,  $i_A$  = carrier amplitude of the interference signal.

$i_m$  = modulation index of the interference signal.

When the interference signal arrived at the antenna, end noise is added to the interference signal. Thus interference equation is same as (2). The signal to impinge on the antenna is composed of both the desired signal and the interference signal. The input signal to arrive at each antenna will be the superposition of the two signals. This was created by summing the desired signal and the interference signal. The input signal of each antenna is given by the following equation.

$$Input = d\_signal + i\_signal \quad (4)$$

The amplitude of the desired signal is not known but due to the 'sigmoid' transfer function the output amplitude level lies between -1 to 1. The normalized data transfer equation

$$Target(t) = 2 \times (d\_signal(t) - minn) / (maxn - minn) - 1 \quad (5)$$

where  $d\_signal$  is the current value,  $minn$  and  $maxn$  is the minimum and maximum value of the desired signal respectively. Finally Backpropagation algorithm is used to train the desired data [5]. We have considered learning rate 0.01 and the mean square error (MSE) 0.001.

#### IV. RESULT AND DISCUSSION

The trained network is simulated with only one input signal to produce an output. The variables that were changed for the AM signal were the carrier frequency. For each of the test wave the modulation

frequency was set between 20 Hz to 20KHz. The carrier frequency was set between 535 KHz and 1605 KHz (i.e. typical range of radio station frequency). The modulation depth had a range of 0 to 1, and the carrier amplitude has no specific range.

##### A. Sample Input

In Table I, five signals are considered as input signal.

##### B. Correlation Value Calculation and its Graphical Representation with Respect to Feedforward Network

Table II contains the correlation values of the five input signals. In feedforward network, we have considered 6 nodes in the input layer and 1 node in the output layer. But hidden layer nodes vary from 1 to 7. With respect to this variation, we have calculated correlation values for five input signals.

##### C. Correlation Value Calculation and Graphical Representation with Respect to Epoch

On the other hand we conducted experiment with respect to the epoch/number of iteration. One complete pass through the training set of data is known as one epoch (also known as iteration). Table III presents the correlation values of five input signals and Fig. 6 shows the graphical representation of correlation values with respect to the number of epoch and input signals.

Fig. 5. Correlation values for variation of hidden layer nodes

##### D. Correlation value calculation and graphical representation with respect to learning rate.

We have tested the performance with respect to the different learning rates. One complete pass through the training set of data is known as an epoch (also known as number of iteration). Table-IV presents the correlation values of five input signals and Fig.7 presents the graphical representation of correlation values with respect to the different learning rates. From the Table II, it is clear that the 6-3-1 combination produced the best correlation value of 0.9922. Its graphical representation with respect to the input signals and hidden layers is shown below.

Fig. 6. Correlation values for different epoch

Fig. 6 shows the correlation value for different epoch values and also shows that if the number of epoch increases then the performance of the MLP also increases respectively. For less than 100 epochs, correlation value between the desired signal and output signal is not satisfactory.

Fig-7 shows the correlation value maximum for learning rate 3. After the learning rate of 3 has been reached, the accuracy of the MLP rapidly decreases as the learning rate increases. In general, the preference of the network gradually decreases as the learning rate is reduced from the optimum value of 3. At 300000 epochs, a correlation value 0.9942 is obtained and that is the average highest result achieved in this experiment. If we increase the number of iteration, but carrier amplitude of the interference signal is twice than the carrier amplitude of the desired signal, then it returns low correlation value. In Test-4, 50000 epoch returns low correlation value of 0.9857.

Fig.7. A graph to show the correlation values for different learning rate values.

## V. CONCLUSION

According to our observation, it is possible to say that an MLP with 6 input neurons, 3 middle neurons and 1 output neuron should be used with a learning rate of 3, and an epoch value of 30,000. With this arrangement a normalized correlation value of approximately 0.9945 can be obtained between the transmitted desired signal and the MLP output for Test-2 signal. This can be a much higher correlation than the correlation between the signal which arrives at the array and the output signal. For the learning rate 3, the network represents the highest correlation value. So, we conclude that learning rate 3 is the adaptive learning rate. Therefore this report has shown that it is possible to use an MLP to produce exceptional results for beam-forming algorithm. The optimized network produces exceptional results not only for the data that was trained with but also for the whole range of signals used in AM radio broadcasting. The MLP has shown that it has the ability to reproduce the desired signal by attenuating any signals arriving at different angles. Unfortunately, the research was subject to time limitations and further work would be able to enhance the work. By using alternative method like blind source separation (BSS), it would be possible to compare the various methods and find a better solution.

# Recurrent Neural Network Classifier for Three Layer Conceptual Network and Performance Evaluation

Md. Khalilur Rhaman and Tsutomu Endo

Kyushu Institute of Technology, 680-4 Kawazu, Iizuka, Fukuoka, 820-8502, Japan.  
rhaman@dumbo.ai.kyutech.ac.jp, endo@pluto.ai.kyutech.ac.jp

**Abstract**—Contextual analysis in dialog is a hard problem. In this paper three layers memory structure is adopted to address the challenge which we refer to as Three Layer Conceptual Network (TLCN). This highly efficient network simulates the human brain by episodic memory, discourse memory and ground memory. An extended case structure framework is used to represent the knowledge. The knowledge database is constructed by the collection of target system information and utterances. This knowledge is updated after every dialog conversation. A Recurrent Neural Network classifier is also introduced for classifying the knowledge for the target system. This system prototype is based on doctor-patients dialogs. 78% disease classification accuracy is observed by this system prototype. Disease identification accuracy is depending on number of disease and number of utterances. This performance evaluation is also discussed in details.

**Index Terms**—Three Layer Conceptual Network, knowledge representation, Neural Network.

## I. INTRODUCTION

This paper presents a dialog processing architecture. It utilizes three layer conceptual network (TLCN) instead of traditional natural language processing architecture. This architecture is developed by RHAMAN [1] from the idea of memory model of NOMURA[2]. NOMURA's model was a framework for memory management but RHAMAN developed architecture for a real time system and introduced a discourse algorithm which was related to [3], [4], [5]. It is a very efficient and unique model which can simulate the human brain. We used the traditional modules for input and response generation but developed an extended case frame model of BRUCE [6] and SHIMAZU & NOMURA [7] for handling the knowledge database. Case frame network is very useful for unstructured and ambiguous languages like Japanese. However, most systems deal with rather simple sentences, in which the analysis is a relatively easy task. Our extension of case frame architecture reduced the complexity using formalism. In this paper we propose a Neural Network Classifier to classify the diseases of our system prototype. ELMAN [8] and LAWRENCE [9] are considered to apply in this application. This is an initiative to introduce Neural Network in Three Layer Conceptual Network.

## II. THREE LAYER CONCEPTUAL NETWORK

TLCN is the three layer memory model proposed by RHAMAN[1]. It is a concept to use the knowledge like a human brain. The layers are: 1) Ground Memory, 2) Discourse Memory and 3) Episodic memory. In the network all the knowledge and their relationships are represented in Ground Memory. Discourse memory provides the most basic, useful and recently used knowledge. Episodic Memory is a User interface. It contains the knowledge to understand the input dialogs and generate response dialogs. However, each memory is not simply an accumulation of the contents of other memories. It is a structured memory coherently organized by merging old and new knowledge. The process relates to what is called knowledge learning. Fig. 1 describes the processing of the TLCN.

Fig. 1. Processing of TLCN

## III. MEMORY MODULES

### A. Ground Memory Module

The ground memory of GMM contains all kind of knowledge. This is the main data source of the system. It stores knowledge related to linguistic knowledge such as dictionary, and grammar, and non-linguistic knowledge such as disease information, previous dialog information, and procedural knowledge which relates inferring a fact from a collection of facts. In Fig. 2. the nodes represent the case structures and the edges represent their relationship.

The knowledge is classified in predefined classes. For this system prototype the nodes are classified on each disease. A class can be a property of other classes. The GMM manager is an algorithm that searches the disease information in Ground memory when it requested by the Dialog Manager and also finds the discourse knowledge requested by Discourse memory module. Ground memory is always updated after every conversation but never delete anything.

Fig. 2. Case structure and their relationship

### B. Discourse Memory Module

Discourse memory provides situational and contextual information for an utterance environment. It contains the nodes with different frequency. The frequency is calculated depending on the uses of knowledge. In our proposed system we used three frequencies: medium, high and very high. We standardize the frequency three after examining with other frequencies. We found better response using the frequency three. The very high frequency is determined by the mostly used classes, recently used classes and seasonal disease classes. The high frequency nodes are determined by the basic information of the patient and his past medical record. Medium frequency nodes are determined by the medium uses of classes. The knowledge and their frequency of discourse memory are different for different patients. The Fig. 3 represents the frequency of nodes.

Fig. 3. Frequency of nodes

### C. Episodic Memory Module

It is the module that receives input from the user and provides output to the user. The input processor receives the input text dialog and understands. Episodic memory stores the meaning of ongoing segment of utterances. As understanding proceeds, the essence of episodic memory assimilated into discourse memory and the essence of discourse memory assimilated into ground memory. In the same way the output processor receives case frames from dialog manager and generates the appropriate text for user. To understand the dialog the input processor used some grammatical modules, text normalization unit, Semantic classifier and a converter for case structured knowledge. Episodic memory contains all the linguistic information and the recent conversation with present user. EMM manager includes the entire previous dialog, responses with the case structure of new dialog and classifies in the pre-defined groups. It sends these case structures to the discourse memory module. Episodic memory is a temporary memory. It updates only for the ongoing process requirement. After every conversation with a user, it refreshes the memory.

## IV. TLCN-DP ARCHITECTURE

The TLCN dialog processing architecture system is illustrated in Fig. 4. This architecture provides efficient integration of component modules. Text input utterances are sent to dialog understanding unit named episodic memory module (EMM) which first normalizes the sentences and produces some case frames then these case frames are sent to EMM manager which integrates the previous dialogs case frames and structures by the assimilation and instantiation of discourse memory and ground memory to understand the dialog. Then the input dialog is classified in some classes and is sent to Dialog Manager (DM). DM searches this knowledge in discourse memory with the help of discourse memory module (DMM) manager and finds the disease information. DM will make the decision whether the disease is identified or not enough information in discourse memory or have to ask more question for confirming the disease. If the information is not enough in discourse memory then DM sends the input knowledge to ground memory module (GMM) manager. GMM manager does the same job as DMM manager and sends the disease information to DM. If DM finds that the patients information is not enough for matching a disease for the Recurrent Neural Network it will generate a question type response case structure for the dialog generator. Dialog generator will ask the question to the patient. If the dialog manager found the goal it will give advice or suggested medicine name to the dialog generator. Then the dialog generator generates a text dialog for the patient.

Fig. 4. TLCN Dialog Processing System

## V. TLCN-DP: COMPONENT TECHNOLOGIES

The TLCN-DP system was based on doctor-patient dialog, the statistics of which are given in Table I. These diseases information have been collected from some medical web link [10] [11] [12].

TABLE I  
TRAINING CORPUS STATISTICS

	Number
Diseases	25
Sentences for each disease	80
Normalized Sentences for each disease	180
Vocabulary Size	2000

### A. Text Understanding

The text understanding component of the TLCN-DP consists of language understanding module and the language generation module. The understanding module normalizes the input text and converts the output into a language-neutral meaning representation a case frame. The language generation module produces the response text from the meaning representation. In this section we discuss four component of language understanding technology: i) text normalization, ii) case frame representation, and iii) classification.

### B. Text normalization

Text normalization is an essential step for minimizing noise variations among words and utterances. The text normalization component is essentially based on using synonyms and other forms of syntactic normalization. The main steps include stemming, using a synonyms dictionary, and removal of confusions, non-alphanumeric and non-white space characters.

### C. Case frame Model

The extended case frame model we used is an understanding model consisting of predicates, semantic case relations (roles), modalities, and conjunctive relations [7]:

*sentence* = *simple\_sentence*|*sentence* +  
*conjunctive\_relation* + *sentence*  
*simple\_sentence* = *predicate* + *case\_relations* +  
*modalities*  
*case\_relations* = *object*|*method*|*direction*|*timeand*  
*space*|*supplement*|*modification*  
*modalities* = *tense*|*aspect*|*manner*|*intention*|*guess*  
|*attitude*|*negation*|*ability*|*necessity*|...  
*conjunctive\_relation* = *time*|*cause*|*reason*|*result*|  
*contrast*|*goal*|*assumption*|

- 1) Case Relations: One characteristic of this model is the relatively large collection of case relations. The collection includes; 1) basic cases like Fillmore's case system, 2) case relations such as extent, manner, and degree, which appear as adverbial phrases, and 3) additional cases represented by the inflection of a certain verb.
- 2) Modalities: Semantic structures must include information on modality such as tense, aspect, intention, manner, attitude and assumption. Real (not toy) sentences convey much of this type of information. Unfortunately, however, most understanding systems and linguistic theories have not dealt sufficiently with modalities.
- 3) Conjunctive Relations: A sentence generally consists of several sub-sentences, each of which represents a unit event. In the model, event relations are expressed by conjunctive relations such as time, cause, reason, result, goal, assumption, contrast and circumstance. These are essential for understanding a sentence, and must be organized into semantic structures.

### D. Extended Case frame Representation

An extension of case structure model is proposed as a linguistic model for representing the text meaning structure. Thus the case frames represent a representation scheme for episodic memory. The traditional case structure is a structure for a unit sentence which consists mainly in relations between noun and verb. This is not sufficient to represent structures of real sentences which sometimes have complex noun phrase and compound sentences. Also our proposed case structure has to have facilities for representing other structures involving relations between two nouns and two verbs etc. It has been designed to integrate those structures into one linguistic model. Its nature is hierarchical with respect to the way constituents are connected, iterative with respect to conjunction and recursive with respect to embedding. Using this formalism, the syntactic and semantic structures of sentences can be represented uniformly.

In our proposal every noun has six properties: adjective, delimiter, preposition, auxiliary verb, adverb and verb.

Noun can be related by either verb or preposition. This case frame representation makes the matching algorithm simple and efficient. It's depicted in Fig. 5.

Fig. 5. Extended case frame structure

### E. Knowledge Representation

In TLCN-DP the nodes are classified in 9 properties: 1) Disease, 2) Symptom, 3) Environment Cause, 4) Physical Cause, 5) Other Cause, 6) Tests, 7) Treatment & Medicine, 8) Future Effect and 9) Prevention.

Disease is the head node. All the other nodes are related with disease. Fig. 6. explains symptom and cause used to find the goal disease. Then pharmaceutical tests confirm the disease (if any tests exist). After that the TLCN-DP will give detail to the patient detail including treatment, medicine, effect, carefulness & prevention.

If any utterance from patients dialog contains any data related to body then it will be treated as Symptom. If any utterance contains any data about treatment or Medicine then it will be treated as Treatment. If any utterance contains any data about test then it will be treated as Test oriented. Otherwise it will be treated as Cause oriented. Classifier sends the classified utterances to the DM manager.

Fig. 6. Relationship of knowledge

Fig. 7. shows the knowledge representation where the disease is the head classes and others are the daughter

classes. This also explains how case frames can be related with each other.

### F. Classifier

Recurrent Neural Network Classifier is used to identify a disease. The inputs of this classifier are the Indexes of classified knowledge properties and their amplitudes.

Recurrent Neural Network: Recurrent Neural Network is a class of neural network where connections between units form a directed cycle. This creates an internal state of the network which allows it to exhibit dynamic temporal behavior.

Elman Recurrent Neural Network: A recurrent network with feedback from each hidden node to all hidden nodes. When training the Elman network back propagation-through-time is used rather than the truncated version used by Elman, i.e. in this paper Elman network refers to the architecture used by Elman but not the training algorithm. An overview of Elman Network can be seen in the Fig 8.

Fig. 8. Elman Recurrent Neural Network

Back-propagation-through-time has been used to train the recurrent networks. Elman networks using: four word inputs, 7 hidden nodes, the quadratic cost function, the learning rate schedule shown below, an initial learning rate of 0.2 and we use the random weight initialization strategy. The Recurrent Network we used for this application is depicted in Fig. 9. Where S indicates Symptom, EC indicates Environment Cause, PC indicates Physical Cause, OC indicates Other Cause, T indicates Tests, H indicates Hidden node, D indicates Disease and NI indicates Not Identified.

- 1) Target Output: Targets outputs were 0.1 and 0.9 using the logistic activation function. This helps avoid saturating the sigmoid function.

Fig. 7. Knowledge representation

Fig. 9. Disease Classifier

- 2) Weight Initialization: Random weights are initialized with the goal of ensuring that the sigmoids do not start out in saturation but are not very small (corresponding to a flat part of the error surface). In addition, several (20) sets of random weights are tested and the set which provides the best performance on the training data is chosen. In our experiments on the current problem, it was found that these techniques do not make a significant difference.
- 3) Learning Rate Schedules: Relatively high learning rates are typically used in order to help avoiding slow convergence and local minima.
- 4) Activation Function: Symmetric sigmoid functions often improve convergence over the standard logistic function. For our particular problem we found that the difference was minor and that the logistic

function resulted in better performance.

- 5) Cost Function: We used quadratic cost function.

$$E = \frac{1}{2} \sum_k (y_k - d_k)^2 \quad (1)$$

Where  $y$  and  $d$  correspond to the actual and desired output values,  $k$  ranges over the outputs.

- 6) Sectioning of the Training Data: We investigated dividing the training data into subsets. Initially, only one of these subsets was used for training. After 100% correct classification was obtained or a pre-specified time limit expired, an additional subset was added to the working set. This continued until the working set contained the entire training set. The data was ordered in terms of sentence length with the shortest sentences first. This enabled the networks to focus on the simpler data first. Elman suggests that the initial training constrains later training in a useful way.

#### G. Dialog Manager

In our TLCN-DP architecture, we have incorporated a response module to help patients to find the goal disease. Dialog manager provides case frame response to the language generator. It analyzes the result and selects the type of system response. The system responses are divided in mainly three types: 1) response before disease identification, 2) after disease identification and 3) failed to identify.

- 1) Response before disease identification: In this type of response, first the dialog consider the symptom and the causes of height match disease which are the minimum similar to the other selected diseases. Response module selects case frames for symptoms and

cause. After 10 conversations it select case frames for Pharmaceutical tests (if there any for height match disease) and also the effect and prevention oriented case frames for height 3 matching diseases.

- 2) After Disease Identification: After Disease Identification the dialog manager provides case frames for treatment including Medicine, Effect, and Prevention for the specific disease to the language generator. It can also provide more case frames for detail of this disease by the requirement of patients.
- 3) Failed to identify: If the dialog manager doesn't get any information about any diseases, it generates failure notification.

#### H. Language Generator

It generates the sentences by arranging the parts of speeches of the case frames. And send the output to the user.

### VI. SYSTEM

We developed a prototype system for real-time medical advices application, called TLCN-DP, to help the people who have to go to the hospital frequently. First we selected some keyword for classification of the utterances. Then we have trained the semantic classifier using a corpus. We collected the disease information from some medical books and some medical web link. By the Question Answering information we trained the Recurrent Neural Network Classifier. We built the ground memory with case frame by this information.

#### A. PERFORMANCE EVALUATION

Evaluation of dialog system performance is a complex task and depends on the purpose of the desired dialog metric. We have trained our system with mostly common 25 diseases from [10], [11], [12] where 9 are mainly related with age, 8 are related with season and the other of 8 diseases are related with food, accident, habitual, health condition and location. The real doctor-patient dialog conversation is collected for this evaluation. The dialogues have been collected from various books on medical interviews and some frequently asked questions- answering medical web links. 80 patients dialogs were simulated with this system prototype where 10 patients were tested 3 times and 15 patients 2 times and 20 patients only once. Table 2 presents the existing disease identification accuracy with the number of dialog conversation. According to the result analysis table; we found that the system achieved a very satisfactory result for 10 to 20 diseases. For 15 diseases we found 78% accuracy of disease identification. For less than 10 diseases the system can identify with very few dialog conversation. 69% accuracy achieved only for 6 utterances. The success of recurrent neural network is always more than 90% for existing disease.

TABLE II  
DISEASE IDENTIFICATION EVALUATION

Diseases	Utterances					
	5	6	7	8	9	10
10	51%	69%	82%			
15	33%	38%	58%	70%	78%	
20	15%	22%	34%	49%	59%	65%
25			20%	26%	42%	51%

### VII. CONCLUSION

In this paper we presented some architecture and technologies. The main underlying strategy is to adopt 1) Three Layer Conceptual Network, 2) uses of case frame, 3) dialog matching, 4) disease identification and 5) response generation. In addition of these fundamental strategies, we investigated a variety of linguistic constraints.

Still, there is a big problem to understand the dialog and it takes a plenty of time so there are some scope to improve this section. We can also use Neural Network to improve efficiency of the conceptual network, adopt some module to train this system by the real time conversation of a doctor and patient. And in future we plan to use voice dialog rather than text dialog.

This is only beginning of Neural Network with Three Layer Conceptual Network. Our goal is make human-computer successful interaction. We strongly believe this research is a new breed of natural-language dialog processing.

# An Energy Saving Program for Bangladesh, for Reducing Load Shedding, and for Continuity of Power for IT Sector

Shahriar Khan

School of Engineering and Computer Science, Independent University, Bangladesh, 14/2 A,  
Baridhara North Road, Baridhara, Dhaka - 1212, email: khandhaka@gmail.com

**Abstract** — The success of computers, IT, and telecommunications hinges greatly on the inexpensive and uninterrupted availability of power. Even with the gradual depletion of fossil fuel, and the rise in fuel prices, there has been insufficient effort towards saving electricity and making the most of remaining fuel reserves. It is time to adopt energy saving programs in Bangladesh, creating awareness that extravagant consumption is detrimental to national, global, and long-term interests. Such energy saving programs have been implemented to various extents in countries like Brazil, Norway, New Zealand, and the USA. With its high population density, low development, poor economic infrastructure, and dynamic river network, Bangladesh provides a unique backdrop to an Energy Saving programs. Such a program should reduce load-shedding, distribute electricity among more users, and divert electricity to productive uses like irrigating fields and preventing manufacturing stoppage. Continuity of electricity would also save our huge investment in generators and UPS equipment. An Energy Saving program should be well-understood and researched by policymakers and experts. An important part of such a program should be changing consumer behavior, such as turning off appliances when not in use. Power-hungry air-coolers develop acclimatization and dependence in users, who then perceive normal outside temperatures as uncomfortable. Low-power alternatives to air-coolers are ceiling fans and ventilator fans on walls. LED lights, compact fluorescent lamps, and IT and telecommunications are to be promoted as efficient uses of electricity. Urban sprawl to distant suburbs should be contained in favor of compact townships, which are better adapted to buses. Buses should be promoted over smaller cars, which should be promoted over larger hungry cars and SUVs. This paper pursues such common sense approaches, together with recommendations by experts, and implementation by policymakers.

**Index Terms** — Energy, Power, Load shedding, Power Outage, Air conditioner, Fossil Fuel, Conservation.

## I. INTRODUCTION

The success of computers, IT, and telecommunications depends greatly on the inexpensive and uninterrupted availability of power. The recent increases in fuel prices and load sheddings have been an awakening that the days of inexpensive fossil fuel are on the way to being over. In response to the energy crises, countries such as Brazil, New Zealand, and Norway, have implemented energy savings programs with various degrees of success.

Hungary has documented significant health and environmental benefits from its energy savings program [1]. In Canada, the power generation companies have become important participants in their energy savings programs [2].

With the decline of local and global fuel reserves, actions to save energy and maximize fuel utilization are long overdue for Bangladesh. Such a program is to have a two-pronged approach. Firstly, there should be understanding and research among planners of an energy saving program. Secondly, there should be implementation of the program by policymakers, taking concrete steps, such as enacting legislation and conducting media campaigns.

## II. LIMITED FOSSIL FUEL

The limited nature of fossil fuel reserves (oil, gas, coal), and the need to ultimately transition to alternative sources is well recognized. However, in Bangladesh and worldwide, there has been insufficient effort to conserve energy, and make the most of remaining fuel reserves [3].

The price of oil is dictated both by geopolitical conditions, and by scarcity of reserves [4]. Most oil and gas reserves of the world have already been discovered, and there has been a shift to deeper oil wells, in our search for economically viable reserves. Even with the latest technology such as Directional Drilling, and Logging While Drilling, and underground sensors like Radio frequency and Magnetic Resonance Imaging, we can economically extract at best about two-thirds of oil in a reserve [5,6]. About a decade ago, natural gas was burnt as a by-product of oil-production, in the US and Canada, because of its lack of economic viability. Amidst the increasing scarcity and demand, natural gas itself has become widely viable economically, even in the US and Canada. In Bangladesh, the energy resources advisor recently declared that no further gas-powered power stations would be constructed, because of depleting gas reserves [7].

### A. Alternative Energy

There is no source that quite provides the ease and energy density of fossil fuel. Common-sense approaches dictate that we maximize utilization of our remaining reserves, as most alternative energy sources cannot come close to fossil fuel in economic viability. Solar energy requires major investment in large areas of silicon panels, and the laws of physics dictate that no more than about a third of solar energy incident on a solar panel is converted to electricity. Solar panels covering a household rooftop would be barely enough to supply the household requirements (without air conditioning), and would need batteries for use at night. Wind energy requires large investment and maintenance for turbines. Air flow over Bangladesh is obstructed by the Himalayas in the North, and wind speeds here are too low to give any viability to wind turbines. Airplanes running on solar energy, wind energy, or batteries are almost inconceivable. Nuclear power and its lead shielding would be too heavy for flight, and would have to run on the principle of propellers rather than jet propulsion.

### B. Biodiesel

Recently, there has been an initiative in the West, to produce biodiesel from grains. In some countries, gasoline must be mixed with 2.5 % biodiesel by law. This has been cited as the primary cause of the dramatic increases in the price of rice and other foods. In Indonesia thousands of square kilometers of forests have been clear-cut to make way for growing grains for biodiesel.

It is evident that production of biodiesel uses up land that could have been otherwise used for edible grains. In addition clear-cutting of forests for biodiesel is detrimental to the environment. A Saving Energy program would ease the pressure on biodiesel, and its negative consequences.

## III. BACKDROP OF BANGLADESH

With its high population density, low development, and poor economic infrastructure, Bangladesh provides a unique backdrop to energy and electricity saving programs. Electricity is vital for economic development, but only about 20 percent of the population has access to it (25 percent of urban population and 10 percent of rural) [8,9,10]. Other problems in the power sector include high system losses, delays in completion of new plants, low plant efficiencies, shortage of natural gas, erratic power supply, electricity theft, blackouts, etc. These factors contribute to Bangladesh's per capita electricity consumption being among the lowest in the world at about

110 kWh per person (Table 1, and Figure 1). Shortfalls sometimes go up to 500 MW (as of August 2005), requiring new plants and fossil fuel the country can barely afford [11, 12]. The availability of gas is already in decline, and has been predicted to last until about 2011. Although power generation capacities cannot be increased overnight, energy saving programs can be initiated to distribute the electricity among more people.

Fig 1. Electricity Demand from 1995 to 2006 for Bangladesh

TABLE 1  
ELECTRICITY CONSUMPTION PER CAPITA IN NEIGHBOURING COUNTRIES (KWH).

India	474
Pakistan	431
Sri Lanka	336
Bangladesh	110
Nepal	65

### A. Load-shedding and Back-up Power

Insufficient supply of electricity, such as during peak demand, is normally met by disconnecting selected areas, otherwise known as "load-shedding." This is understandably unpopular, and a socio-political factor during important events and sports [8,9]. Affluent areas are less subjected to load-shedding, and public protests for lack of electricity turned violent in the mid-2006 [10].

### B. Back-up Power

Load-shedding requires heavy investment in generators and UPS equipment for both domestic and industrial consumers. Without such equipment, there is significant loss in commercial and industrial productivity, such as for irrigation and manufacturing. Such investments in back-up power are almost unheard of in the West.

#### IV. ENERGY EFFICIENCY PROGRAMS

The discrepancy between electricity production and demand, coupled with dwindling global fossil fuel reserves and global warming, strongly favor new policies for reducing electricity consumption. In response to the energy crises, many countries have implemented energy savings programs with varying degrees of success. Hungary has experienced significant health and environmental benefits from its energy savings program [1]. In Canada, the power generation companies have become important participants in their energy savings programs [2].

Bangladesh should have an energetic Energy Saving programs designed by scientists and policymakers. There should be well-founded policies, and promoting awareness that extravagant electricity consumption is detrimental to national, popular, global, and long-term interests.

Such an Energy Saving program should consist of two parts: (a) research and investigation by researchers (b) planning, policy-making, and implementation by policymakers.

##### *A. Research and Planning*

For the success of any Energy saving program, there should be an appropriate understanding of the issues by planners and policymakers. Research may be conducted on issues which require clarification. In the context of Bangladesh, the foremost planner and implementer of an energy savings program is the government. It is also possible for the government to subcontract the planning of the program to others, such as a non-profit organization, or academia.

##### *B. Changing Consumer Behavior*

The essence of a Save Energy program is changing consumer behavior, such as turning off lights and appliances when not in use. Such programs have been successfully implemented in Brazil, California, New Zealand, Norway, Canada, and the U.S.A., where demand was reduced by 3-20%. Numerous websites have come up promoting saving of electricity [13,14].

Lighting and air conditioning can be practiced in moderation. Lights can be turned off when away for 5 minutes or more. Stickers can be posted near switches saying, "Turn off Lights when Out for 15 Min"

Air conditioners can be turned off, when away for an 15 or more. Increasing the thermostat by just one degree results in significant savings. Often, much of a house or office is cooled or lit, when only one room is in use. These behaviors may be targeted for change, thorough user-friendly messages in the media.

#### V. AIR CONDITIONING AND ACCLIMATIZATION

Recent worldwide and local warming of the weather, has been met with by increased usage of air conditioners, ACs. Air conditioners are very power-hungry by nature, and may comprise much or most of a household bill. In the US, 5 % of all electric energy goes to ACs [15]. Although similar statistics for Bangladesh are not readily available, warming of the weather, and increased per-capita income has increased the popularity of ACs in recent years. The case against air-coolers is that the body becomes dependent and "acclimatized" to the colder temperatures, with inability to tolerate normal outside warmth and humidity [10]. Those who spend much or most of the time under an air-cooler, begin to perceive outside heat and humidity as uncomfortable.

Acclimatization produces the desire to be under an AC at other times, such as inside a car (up to several hours a day, in our sprawling cities and traffic jams). Lowering dependence on the car AC, and measures such as blocking sunlight at the windows are major potentials for energy reduction.

Humans are capable of surviving in extreme temperatures, ranging from the cold of the Arctic, to the 40s °C in the tropics. From anecdotal evidence, when moving from a cold country to a warm country or vice versa, the body adapts in about 2 weeks, if not less. These are other examples of acclimatization.

ACs inherently operate in closed rooms with little or no ventilation. In the daytime and with high human occupancy, closed rooms tend to be a few degrees warmer than the outside air, putting the burden on the AC to first cool the room to the outside temperature. This equalization of inside and outside temperatures and humidity could otherwise be efficiently done by a ventilating fan at the windows or near the ceiling.

Ceiling fans and table fans provide circulation of air and evaporation of sweat, hence cooling the body, with much lower power consumption (Table 2).

TABLE 2  
COMPARISON OF COOLING METHODS [17,18,19]

	Size	Power
Air cooler,	10,000 BTU	1300 watts
Ceiling fan	48" fan	75 watts
Floor fan	Various sizes	15-95 watts

With the multi-storied buildings coming up in large cities, there is less wind movement near the lower floors. Ventilator fans at walls would be very useful in expelling the warm and humid air in people-inhabited rooms. An

energy saving program should promote ventilator fans at walls in preference to ACs.

#### A. The "Heat" of Direct Sunlight

High temperatures and humidity are not to be confused with the perception of "heat" from direct sunlight. Direct sunlight can be uncomfortable and dangerous, whereas one can be acclimatized to normal outside temperatures and humidity of the shade. A body receives its full requirement of Vitamin D from sunlight from only about 5 minutes of direct exposure per day.

There is good reason to be concerned about the thinning Ozone layer, and the increasing ultraviolet rays we are exposed to nowadays. Direct sunlight can be associated with nausea and discomfort, among many other effects, and should be blocked to counter discomfort. The ozone layer over certain places like New Zealand has deteriorated to the point that even Bangladeshis get sunburnt from half an hour's exposure to the sun.

Sunlight in a car may be blocked with reflectors and shades at the windows.

### VI. LIGHTING

Much of the lighting locally and globally is with energy-inefficient incandescent light bulbs of 60 to 100 watts. Light Emitting Diodes (LEDs) have been introduced in pilot projects in Bangladesh and India [20]. LEDs have very low power consumption, and better adaptability to batteries but have much higher initial cost (Table 2) [21]. There is little or no medical evidence that low lighting cause deterioration of vision.

TABLE 2  
WATTAGE AND COSTS OF DIFFERENT LIGHTS

	Wattage	Cost
Bulb	60 to 200	Tk 20-40
Fluorescent	7 to 20	Tk 170-250
LED	(18 LEDs) 2 W	US\$ 27

An Energy Saving program can replace incandescent bulbs with Compact Fluorescent Lamps, CFLs, which use 50 – 80 % less energy [22]. Although, the CFL is more expensive initially, they last about 10 times longer than incandescent bulbs, and are less expensive in the long run. A single 18 watt CFL used in place of a 75 watt incandescent will save about 570 kWh over its lifetime. In California, consumers installed nearly eight million CFLs during their crisis period, resulting in demand reduction of almost 500 MW.

Lights activated by motion and infra-red sensors are household items in the West, but at about \$20 a piece, they are not yet affordable to Bangladeshi customers.

Prices may be brought down further, spurred by rising electricity prices, and widespread manufacture in Asia.

#### A. Festival lights

Display and festival lights, consisting of thousands of little bulbs, are another example of conspicuous and avoidable consumption. The government of Bangladesh had discouraged such festival or display lighting in 2007, but their use has continued ever since. Power consumptions of a single lighting can be about 10 KW, assuming 15,000 bulbs of 0.6 watt each.

### VII. TELECOMMUNICATION

Applications of telecommunication, such as telephones (mobile and fixed), telemedicine, the internet, television, radio, etc. are efficient uses of electricity, as they reduce our dependence on fuel-dependent traveling [23,24,25]. Over the next few years, as traveling continues to be expensive in terms of fossil fuel, telecommunication will be an increasingly affordable substitute to traveling.

### VIII. CONTAINING URBAN SPRAWL

Dhaka has sprawled over distant suburbs like Uttara, Bashundhara, Purbachol, Gazipur, and Tongi. This type of urban sprawl promotes the need for cars, rather than buses. Carrying numerous passengers, buses are efficient modes of transportation, but are only adapted to compact cities, rather than spread-out cities with distant suburbs. An Energy Saving program should discourage and contain the urban sprawl taking place in Dhaka and other suburbs.

The popularity of heavier and fuel-hungry Sports Utility Vehicles has continued for decades in the West. The price increases of fuel in 2008 has forced consumers to step back from such conspicuous consumption. An energy saving program should encourage buses in preference to cars.

### VIII. PROPOSED SAVING ELECTRICITY PROGRAM

Summarizing, a proposed Saving Energy program may have the following.

- Awareness that fossil fuels are a limited resource, to be used with care.
- Media campaigns (TV, radio, newspapers) creating awareness among the masses that extravagant consumption are detrimental to national, global, and long-term interests.
- Campaign to "switch off" appliances that are not being used. Post stickers near switches saying, "Turn off Lights when Out for 5 Min"

- Awareness that extravagant consumption may prevent field irrigation, or cause manufacturing disruptions in the under-developed country of Bangladesh.
- Reduce or Avoid usage of Festival Lights
- Discourage air conditioners, or increase AC thermostat temperatures. Realization that the human body is easily adaptable to heat, and easily acclimatizes itself to its surroundings.
- Ceiling and Ventilator fans are to be used in preference to ACs, which lead to temperature acclimatization, and dependence.
- Direct sunlight, such as in a car, should be blocked with reflectors and shades at windows
- Urban sprawl should be contained, and compact cities, favorable to buses should be encouraged.
- Large cars and SUVs should be discouraged in favor of smaller cars, which in turn should be discouraged in favor of buses.
- Media campaigns should create awareness that our children and our children's children will be the beneficiaries or victims of our actions today.
- Recognition that one should not misuse energy and electricity just if one can afford it.

## VIII. CONCLUSION

The success of computers, IT, and telecommunications hinges greatly on the inexpensive and uninterrupted availability of power. Although wastages of electricity and energy are obvious to most of us, there has not been sufficient common-sense approach to the problem. Conspicuous consumption has continued unabated in Bangladesh and worldwide. Energy saving policies must be envisioned and implemented, as a common sense response to the continuing depletion of fossil fuel.

**ABSTRACT** — In this paper, a novel multiple slot microstrip patch antenna with enhanced bandwidth is presented. The design adopts contemporary techniques namely; probe feeding, inverted patch structure and multiple slotted patch. The composite effect of integrating these techniques and by introducing the novel multiple shaped patch, offer a low profile, wide bandwidth, high gain and compact antenna element. The proposed patch has a compact dimension of  $0.707 \lambda_0 \times 0.354 \lambda_0$  (where  $\lambda_0$  is the guided wavelength of the center operation frequency). With the proposed concept, an antenna prototype is simulated and analyzed. The proposed antenna achieves a fractional bandwidth of 27.15% (1.91 to 2.51 GHz) at 10 dB return loss while maintaining a maximum gain of 10.5 dBi. The design is suitable for array applications especially for base station.

**Index Terms** — Broadband antenna, microstrip patch antenna, probe fed.

## I. INTRODUCTION

The current demand of wireless communication systems and their miniaturization, antenna design becomes more challenging in present days. The main reason of microstrip patch antenna to attract wide interest is because of its inherent characteristics such as light weight, low profile, low cost, mechanically robust, simple to manufacture, easy to be integrated with MIC/MMIC and others RF devices [1], [2]. In spite of its several advantages, microstrip patch antennas suffer from low gain and a narrow impedance bandwidth. To overcome its limitation of narrow impedance bandwidth and low gain, many techniques have been suggested e.g., for probe fed stacked antenna, microstrip patch antennas on electrically thick substrate, slotted patch antenna and stacked shorted patches have been proposed and investigated [3]-[5].

The size of microstrip patch antenna is basically determined by its resonance length and width. The reduction of the patch size can be achieved by using patch substrate material with very high permittivity and small substrate height [6]. But, in this case, the low radiation efficiency will reduce the antenna gain. By using two stacked patches with the walls at the edges between the two patches, one can obtain high gain [7].

Recently, aperture-coupled fed stacked patch antenna [8] have been investigated and bandwidths up to 69% have been reported, however, the major drawbacks are the level of back radiation due to the use of a resonant aperture and the surface wave excitation. The use of L-shaped or F-shaped probes have also been proposed yielding to wide impedance bandwidths [9], [10]. In [9], an L-probe fed stacked U-Slot patch antenna was proposed with a bandwidth up to 44.4% being achieved. V-slotted rectangular microstrip antenna with a stacked patch has been shown that it is able to achieve bandwidths as high as 47% [11]. However, feeding techniques in these designs especially of the probes have increased complexity of the design and fabrication process. In this paper, a novel multiple slotted patch is investigated for enhancing the impedance bandwidth and gain.

## II. ANTENNA LAYOUT AND STRUCTURE

The geometry of the proposed antenna structure is shown in Fig. 1. The proposed multiple slotted patch antenna structure is composed of rectangular patch, air substrate and a vertical probe connected to the patch. For a microstrip antenna, the patch width  $w$  and length  $l$  that support the operation at the required resonant frequency can be designed using the formulas as given in [12] as

$$w = \frac{\lambda_0}{2\sqrt{\frac{\epsilon_r + 1}{2}}} \quad (1)$$

$$l = \frac{\lambda_0}{2\sqrt{\epsilon_r}} - 2\Delta l \quad (2)$$

where

$$\Delta l = 0.412h \frac{(\epsilon_r + 0.3)\left(\frac{w}{h} + 0.264\right)}{(\epsilon_r - 0.258)\left(\frac{w}{h} + 0.8\right)} \quad (3)$$

$$\epsilon_e = \frac{\epsilon_r + 1}{2} + \frac{\epsilon_r - 1}{2\sqrt{1 + 12\frac{h}{w}}} \quad (4)$$

The location of the probe point example, if  $(x_1, y_1)$  for matching to 50 ohm can be determined as

$$x_1 = \frac{w}{2} \quad (5)$$

$$y_1 = \frac{l}{\pi} \cos^{-1} \frac{w\sqrt{5(\epsilon_r - 1)}}{3\epsilon_r l} \quad (6)$$

where  $0 \leq y_1 < l/2$  [13].

While for a microstrip antenna, it is found that the patch length can still be designed using formulas (1) to (6) for the required resonant frequency. However, the patch width calculated by formula (1) usually needs to be widened to ensure the excitation and matching using the probe feed.

In this design, the inverted rectangular patch, with dimension of  $0.707 \lambda_0 \times 0.354 \lambda_0$  is supported by a low dielectric superstrate with dielectric permittivity  $\epsilon_r$  and thickness  $h_1$ . An air-filled substrate with thickness  $h$  is sandwiched between the superstrate and a ground plane.

The proposed patch integrates with multi slots on the same radiating element are embedded in parallel on the radiating edge of the patch symmetrically with respect to the centerline of the patch. The multiple slots of the patch are shown in Fig. 1(a), where,  $l_1$  and  $w_1$  are the length and width of the slots. The patch is fed by a direct connected probe along the centerline at a distance  $f_p$  from the edge of the patch as shown in Fig. 1(b). Table 1 shows the optimized design parameters obtained for the proposed patch antenna. A Rogers RT 5880 Duroid™ dielectric substrate with dielectric permittivity,  $\epsilon_r$  of 2.2 and thickness,  $h_1$  of 1.5748mm has been used in this research. An Aluminum plate with dimensions of  $1.473 \lambda_0 \times 1.326 \lambda_0$  and thickness of 1 mm is used as the ground plane.

Reducing the size of the antenna is one of the key factors to miniaturize the wireless communication devices. However, reducing the antenna size will usually reduce its impedance bandwidth as well. Therefore designing a small antenna with a wide impedance bandwidth which satisfies future generation wireless application is a challenging work, especially having stable radiation patterns across the operating frequency band. In this paper, the use of probe feeding technique, multiple slotted on the patch with thick air-filled substrates provide the wide bandwidth and gain enhancement and the use of parallel slots reduce the crosspolarization. The multi slots of the proposed patch

introduce a capacitive reactance, which counteracts the inductive reactance of the probe pin and produces second resonance of the patch to achieve a wide bandwidth.

Fig. 1. Geometry of the proposed patch antenna: (a) Top view and (b) side view.

TABLE I  
PROPOSED PATCH ANTENNA DESIGN PARAMETERS IN  
MILLIMETERS (MM)

Dimensions	$w$	$l$	$w_1$	$l_1$
(mm)	96	48	14.5	42
Dimensions	$w_2$	$h$	$h_1$	$f_p$
(mm)	7	12.5	1.5748	8.5

### III. RESULTS AND DISCUSSION

A simulator “Ansoft HFSS” based on finite-element method (FEM) has been used to calculate return loss, impedance bandwidth, radiation pattern and gains. Fig. 2 shows the simulated result of the return loss of the proposed antenna. The two closely excited resonant frequencies at 2.0 GHz and at 2.35 GHz as shown in the figure gives the measure of the wideband characteristic of the patch antenna. The simulated impedance bandwidth of

27.15% from 1.91 GHz to 2.51 GHz is achieved at 10dB return loss ( $VSWR \leq 2$ ).

Fig. 2. Simulated return loss of the proposed patch antenna.

The simulated radiation patterns at the second resonant frequency in the  $xz$ -plane and  $yz$ -plane are plotted in Fig. 3. For the sake of brevity, only simulated radiation pattern for second resonant frequency is given in this paper.

Fig. 3. Normalized radiation pattern of proposed patch antenna at resonance frequency 2.35 GHz.

As shown in Fig. 3, the designed antenna displays good broadside radiation patterns in the  $xz$ -plane and  $yz$ -plane at second resonant frequency. It can be seen that 3-dB beamwidth of  $52^\circ$  and  $46^\circ$  for  $xz$ -plane and  $yz$ -plane respectively at 2.35 GHz. The crosspolarization level is lower than about -43dB in  $xz$ -plane. The proposed antenna exhibits better crosspolarization than the design reported in [14]. Notable, the radiation characteristics of the

proposed antenna are better to those of the conventional patch antenna.

The simulated gain of the proposed patch antenna at various frequencies is shown in Fig. 4. As shown in the figure, the maximum achievable gain is 10.5 dBi at the frequency of 2.2GHz and the gain variation is 1.57dBi between the frequency ranges of 1.91GHz to 2.51GHz (i.e. a gain bandwidth of 27.15%).

Fig. 4. Simulated gain of proposed patch antennas at different frequencies.

#### IV. CONCLUSION

A multiple slotted patch antenna for enhancing bandwidth and gain was successfully designed in this paper. Simulation results of a wideband microstrip patch antenna covering 1.91 to 2.51 GHz frequency have been presented. Techniques for microstrip broadbanding, gain enhancement, and crosspolarization reduction are applied with significant improvement in the design by employing proposed slotted patch shaped design, inverted patch, and probe feeding.

The proposed microstrip patch antenna achieves a fractional bandwidth of 27.15% (1.91 to 2.51 GHz) at 10 dB return loss. The maximum achievable gain of the antenna is 10.5 dBi. The proposed patch has a compact dimension of  $0.707 \lambda_0 \times 0.354 \lambda_0$ . The design has demonstrated that patch with multiple slots and probe fed can be used to form an antenna with the broad bandwidth of 27.15%, furthermore due to its high gain, and broad bandwidth more applications can be anticipated.

# Analysis of Antennas for the Wireless Communication and Radar Applications

Md. Osman Goni, Abu Md. Numan-Al-Mobin, Md. Hasanur Rahman

Department of Electronics and Communication Engineering, Khulna University of Engineering & Technology, Khulna-9203, Bangladesh

**Abstract** — This paper signifies the distributed electromagnetic simulation for different thin wired antennas or structures mounted on earth or vehicles or space shuttle for communication purposes. A lot of electromagnetic analysis softwares are available commercially. This paper presents some simulation results of different antennas using Wire-MoM based on thin-wire approximation. The method gives frequency domain results of currents and fields which is further converted into time domain for better understanding.

**Index Terms** — Antenna feeds, Antenna measurements, Antenna proximity factors, Antenna radiation patterns, Antenna transient analysis.

## I. INTRODUCTION

Electromagnetic fields can be predicted by experiment, analysis and computation. The last mentioned technique, otherwise known as numerical simulation is the most recent and rapidly advancing. The modeling of electromagnetic processes on computer can help us understand how products work and hopefully lead to better products as in the philosophy of computer-aided design (CAD).

The numerical computation for distributed electromagnetic simulation and optimization is the very cost effective than the direct experimental method.

For idealized geometry, the calculation of electromagnetic fields generated by power line conductors at each specific location is a trivial algebraic task. However, the presence of man made and natural objects, uneven profile of ground surface, and non-homogeneous conductivity of the ground at different depths affect the resulting distribution of magnetic and electric fields.

One of the earliest applications of a numerical electromagnetic (EM) analysis to the antenna design and lightning study [1] modeled a lightning channel attached to a tall structure. A time-domain code was used in that study. A similar time-domain code was also used in a study on induced voltages on a distribution line [2] over perfectly conducting ground. A recent study also employs a similar time-domain code [3] to model the wired antennas with induced current and voltage in each wire and a lightning channel. Moini *et al.* applied the time-domain approach utilizing the Thin-Wire Time-Domain code (TWTD) [2],[4].

However, more authors have applied the Numerical Electromagnetic Code (NEC-2) [5], a frequency-domain code to lightning electromagnetic pulse (LEMP) studies or lightning surge analysis. Heidler *et al.* [6] used NEC-2 to

analyze induced voltages on conductor loops illuminated by LEMP.

Cristina and Orlandi [7] employed NEC-2 to evaluate the EM field inside a building struck by lightning. Chai *et al.* [8] employed this code to study field inside a wire-array lightning protection system for a lunch vehicle when it is struck by lightning. Baba and Ishii applied the frequency-domain approach utilizing the Numerical Electromagnetic Code (NEC-2) [9],[10].

For practical purposes, one of the classes of models applied recently in lightning studies is the so-called electromagnetic models [11]. They are usually based on thin-wire antenna approximation and involve a numerical solution of Maxwell's equations using the method of moments [12] to find the current distribution along the lightning channel, from which electromagnetic fields can be computed.

## II. NUMERICAL MODEL

Different types of return-stroke current models are used to determine the return-stroke current. As a part of a general investigation into the physics of lightning, as a mechanism by which return strokes currents at ground can be determined from remotely measured electric and magnetic fields, and hence by which either currents of individual strokes or statistical distributions of the stroke currents can be obtained, and as a mechanism for calculating realistic fields to be used in "coupling" calculations such as to determine the lightning-induced voltages appearing on electric utility or telecommunication lines when lightning occurs near those lines.

1) The first defined class of models, gas dynamic or "physical" models, is primarily concerned with the radial evolution of a short segment of the lightning channel and its associated shockwave. Principal model's outputs include temperature, pressure, and mass density as a function of the radial coordinate and time.

2) Electromagnetic Field Theory Approach models, or second class models, are usually based on the so-called lossy thin wire antenna approximation of the lightning channel.

3) The third class of models is the distributed circuit models, also called RLC transmission line models. These models are used to determine the channel current versus

time and height and can therefore also be used for the computation of remote electric and magnetic fields.

4) The last class is the engineering models in which a spatial and temporal distribution of the channel current (or the channel line charge density) is specified based on such observed lightning return-stroke characteristics as current at the channel base, the speed of the upward propagating wave front, and the channel luminosity profile.

In this paper Field Theory Approach is adopted for the evaluation of the effects. For numerical solution computer program “Wire-MoM” is used which is based on Method of Moments (MoM). Here the computed results are obtained in frequency domain for a step current input.

In “Wire-MoM” two methods are used for the solution of the numerical analysis. They are:

1) LU decomposition.

In linear algebra, the LU decomposition is a matrix decomposition which writes a matrix as the product of a lower and upper triangular matrix. The product sometimes includes a permutation matrix as well. This decomposition is used in numerical analysis to solve systems of linear equations or calculate the determinant.

2) Conjugate gradient method.

We have used here the LU decomposition method.

### III. NUMERICAL ELECTROMAGNETIC SIMULATION

#### A. Simulation-1: Dipole Antenna

For the dipole antenna, fed with the ideal 5V voltage source at the frequency range 200MHz – 1200MHz. Finding of the current distribution along the antenna at the frequency at which the antenna would radiate most efficiently. Plotting of 3D antenna radiation pattern at that frequency and the graphical representation on the calculation of the power budget. Here the structure frequency limit is approximately 660 MHz.

TABLE I  
SIMULATION PARAMETERS FOR 1M DIPOLE ANTENNA

Structure	Excitation	Output
No. of Wires=1 No. of Connections=0 No. of Basis id.=21 Ground plane at z=0 No. of Impedance elements= 0	No. of Frequencies=15 No. of Voltage sources= 1 No. of Current sources= 0 Plane wave excitation= Yes	No. of Far-field directions=7381 No. of Near-field points=100 Saving Current for No. of wires=1 Saving S-parameters=Yes

Here the 1m dipole antenna made of a perfect conductor with the radius of 1mm was represented by a vertical cylindrical conductor. The model simulating the current and frequency response measurement of the single vertical conductor representing the dipole is shown in Fig. 1.

Fig. 1. Wired-Structure of the dipole antenna with the voltage source at the middle of the wire.

The simulation was run over the frequency range from 200 MHz to 1200 MHz with a step of 71.429 MHz. Computation is done in 2 minutes and 20 seconds.

#### 1. Result for Simulation-1

The frequency domain plot of  $I(f)$  is done under the 11th basis function corresponding to the feeding point on the antenna. The total current is computed in absolute value of the current. The plot of total current in time domain is shown in Fig. 2. Now the current on each segment of the wire is available at the frequency 258.56 MHz.

Fig. 2. Plot of current in time domain for dipole antenna.

The 3D radiation pattern for the dipole antenna is shown in Fig. 3. Here the dipole antenna is approximated with the thin wire.

Fig. 3. 3D Radiation pattern of the dipole antenna

## 2. Power Budget Computation for Dipole Antenna

The graphical representation for the input power, radiated power and dissipated power versus frequency is shown in Fig. 4(a). The input power and radiated power have the same magnitudes. And the plotting of the efficiency is shown in Fig. 4(b).

Fig. 4. Dipole antenna analysis (a) frequency vs power, (b) frequency vs efficiency.

## B. Simulation-2: Grounded Monopole Antenna

For the grounded monopole antenna, fed with the ideal 5V voltage source at the frequency range 200 MHz – 1200 MHz. Plotting of the total current curve in the time domain. Finding of the current distribution along the antenna at the frequency at which the antenna would radiate most efficiently. Here the structure frequency limit is approximately 480 MHz.

TABLE II  
SIMULATION PARAMETERS FOR GROUNDED MONOPOLE ANTENNA

Structure	Excitation	Output
No. of Wires=1 No. of Connections=1 No. of Basis id.=16 Ground plane at z=0 PEC No. of impedance elements =1	No. of Frequencies=30 No. of Voltage sources= 1 No. of Current sources= 0 Plane wave excitation=Yes	No. of Far-field directions=3751 No. of Near-field points=36 Saving Current for No. of wires=1 Saving S-parameters= Yes

Here the 1m long grounded monopole antenna made of a perfect conductor with the radius of 1mm was represented by a vertical cylindrical conductor.

The model simulating the current and frequency response measurement of the single vertical conductor representing the grounded monopole is shown in Fig. 5.

Fig. 5. Grounded monopole antenna with the voltage source at the bottom of the wire.

The simulation was run over the frequency range from 50MHz to 1500MHz with a step of 50 MHz. Computation is done in 2 minutes and 23 seconds.

## Result for Grounded Monopole Antenna

The frequency domain plot of current is done under the 11th basis function corresponding to the feeding point on the antenna. The total current is computed in absolute value of the current. The plot of total current in time domain is shown in Fig. 6. This current on each segment of the wire is available at the frequency 153.1 MHz.

Fig. 6. Plot of current in time domain for grounded monopole antenna.

### C. Simulation-3: Monopole Antenna Mounted on a Car at Low Excitation

For the monopole antenna mounted on a car, fed with the ideal 5V voltage source at the frequency range 1MHz – 150MHz. Plotting of the total current curve in the time domain. Finding of the current distribution along the antenna at the frequency at which the antenna would radiate most efficiently and also the graphical representation on the calculation of the power budget. Here the structure frequency limit is approximately 10 MHz.

TABLE III  
SIMULATION PARAMETERS FOR 2M MONOPOLE ANTENNA MOUNTED ON A CAR AT LOW EXCITATION

Structure	Excitation	Output
No. of Wires=80	No. of Frequencies=8	No. of Far-field directions =3751
No. of Connections=113	No. of Voltage sources= 1	No. of Near-field points=144
No. of Basis id.=513	No. of Current sources= 0	Saving Current for No. of wires=80
Ground plane at z=0 PEC	Plane wave excitation= Yes	Saving S-parameters = Yes
No of Impedance elements=1		

Here 2m long monopole antenna made of a perfect conductor with the radius of 0.005mm was represented by a vertical cylindrical conductor. The model simulating the current and frequency response measurement of the 2m long monopole antenna mounted on a car at low excitation is shown in Fig. 7.

Fig. 7. Wired-Structure of the monopole antenna mounted on vehicle fed with the ideal 5V voltage source.

The simulation was run over the frequency range from 1 MHz to 150 MHz with a step of 50 MHz. Computation is done in 2 minutes and 43 seconds. The simulation was run over the frequency range from 1 MHz to 150 MHz with a step of 50 MHz. Computation is done in 22 minutes and 11 seconds.

#### 1. Result for Simulation-3

The frequency domain plot current under the 640th basis function corresponding to the feeding point on the antenna. The total current is computed in absolute value of the current. The plot of total current in time domain is shown in Fig. 8.

Fig. 8. Plot of current in time domain for low voltage excitation.

## 2. Power Budget Computation for Monopole Antenna Mounted on a Car

The computation of input power, radiated power and dissipated power versus frequency is shown in Fig. 9(a) and the plotting of efficiency in frequency domain is shown in Fig. 9(b).

Fig. 9. Monopole antenna analysis (a) power vs frequency, and (b) efficiency vs frequency.

### D. Simulation-4: Patch Antenna Mounted on a Rocket at Low Excitation

For the patch antenna mounted on a rocket, fed with the ideal 5V voltage source at the frequency range 1 MHz – 300 MHz. Plotting of the total current curve in the frequency domain. Finding of the current distribution along the antenna at the frequency at which the antenna would radiate most efficiently and also the graphical representation on the calculation of the power budget. Here the structure frequency limit is approximately 89 MHz.

TABLE IV  
SIMULATION PARAMETERS FOR PATCH ANTENNA MOUNTED ON A ROCKET AT LOW EXCITATION

Structure	Excitation	Output
No. of Wires=368	No. of Frequencies= 8	No. of Far-field directions=3751
No. of Connections=521	No. of Voltage sources= 1	No. of Near-field points= 27
No. of Basis id.=889	No. of Current sources= 0	Saving Current for No. of wires=368
Ground plane at z=0	Plane wave excitation=Yes	Saving S-parameters= Yes
No. of Impedance elements=0		

Here 0.237m wide and 0.67m long patch antenna was represented by the horizontally aligned cylindrical conductors. And the height of Rocket is taken as 3m long. The wire radius is 0.001m and antenna thickness is 0.002m which is shown in Fig. 10.

Fig. 10. Wired-Structure of the patch antenna mounted on rocket fed with the ideal 5V voltage source.

The simulation was run over the frequency range from 1 MHz to 300 MHz with a step of 42.714 MHz. Computation is done in 6 minutes and 15 seconds.

### 1. Result for Simulation-4

The frequency domain plot current under the basis function corresponding to the feeding point on the antenna. Here the total current is computed in the absolute value of the current which is shown in Fig. 11.

The computation of the input power, radiated power and the dissipated power versus frequency is shown in Fig. 12(a) and the plotting of efficiency is shown in Fig. 12(b).

Fig. 12. Patch antenna analysis (a) frequency vs power, (b) frequency vs efficiency.

## IV. CONCLUSION

During the past one year, we have gained a great deal of experience and insight into current and voltage calculations on different antennas and structures, the electromagnetic field calculations and fields of lightning return stroke current modeling. The experimental evaluation for the lightning transient study is much expensive than the numerical solutions. The authors of this paper carried out the numerical electromagnetic analysis of various antennas

used in wireless communication and radar. As the MoM automatically computes the electromagnetic coupling between the conductors so no coupling model was required and the solution by MoM is more accurate than the time domain EMTP solution. The analysis shows that the amount of current and voltage induced on the antenna elements are also of large magnitude for the degradation and disruption of the transmission information. The result and analysis also provides that a large amount of current and voltage are generated by the Lightning Over-Voltage which implies the installation of surge arrester of lightning current arrester for the protection of the base station.

**Abstract**—The least-mean-squares (LMS) algorithm which updates the filter coefficients by gradient-based method is the most popular adaptive filtering one. In this paper we propose a novel amplitude banded (AB) technique with LMS on Godard (ABGodard) and Sato (ABSato) algorithms for the equalization of communication channels. The non-linear properties of the AB technique with LMS algorithm are inherited into the ABGodard and ABSato algorithms, resulting in an improvement of equalization performance in favor of the ABSato algorithm. Mean square error (MSE) as well as bit error rate (BER) are investigated on a simple communication channel model. Observations on simulations show that ABGodard and ABSato algorithms provide better performance than the standard Godard and Sato algorithms, respectively. The parallel structure of the Sato and ABSato algorithms provides a further performance improvement. This is also observed from MSE and BER performances.

**Index Terms**—Least-Mean-Square, Non-linear Adaptive Algorithm, ABGodard Algorithm, ABSato Algorithm, Blind Equalization.

## I. INTRODUCTION

The physical channel introduce a distortion to the transmitted signal. To recover the original signal, channel equalization plays an important rule in digital communication systems. To reduce or ideally to eliminate completely the inter symbol interference (ISI), adaptive equalization [1] is required. Although conventional equalization techniques rely on training sequence based equalization, they suffer from the trade-off between the sequence length and the capacity of the link. To avoid this problem and when the training sequence is not available, blind equalization technique [2] can be used. Thus the blind channel equalization is the great deal of attention for its importance in digital communication systems. The Godard [3] and Sato [4] adaptive algorithms are widely used blind algorithms for equalization of a channel. They are commonly derived based on measuring the output of the channel in case of lacking explicit knowledge of its input.

Blind adaptive equalizers are often composed of two distinct sections: (i) an adaptive filter adapted by linear adaptive algorithm (ii) followed by a non-linear estimator to improve the filter outputs, the improved output of the filter is taken to improve the estimator output in the adaptation process at the next iteration.

In the adaptation process, a linear adaptive LMS algorithm is used for the Godard and Sato equalizers. Recently, Shimamura et.al [5] derived a new non-linear adaptive algorithm, called amplitude banded LMS (ABLMS) algorithm. The adaptation of the ABLMS algorithm considers the amplitude information of the channel output to select the coefficients of the equalizer as non-linear switching pattern. The ABLMS algorithm exhibits better performance than the conventional LMS algorithm. In this paper, we set out to apply the AB technique [6] in blind adaptive algorithm to obtain better performance. Actually, we propose the AB version of the Godard and Sato algorithms. In the proposed ABGodard and ABSato algorithms, the amplitude information is deployed to select the coefficients to be updated. Based on the amplitude level of the received sequence, the equalizer coefficients are (for each iteration) selected from the elements of the coefficient matrix, and then updated. Since the AB technique itself provides the capability of non-linear classification [7] and the increase of division number of the AB technique enhances its non-linearity, thus it is expected that the proposed ABGodard and ABSato algorithms provide better performance than the Godard and Sato algorithms, respectively and the increase of division number provides a further improved performance.

## II. CHANNEL MODEL AND BLIND EQUALIZER

In this paper, it is assumed that the channel model is given by

$$u(k) = \sum_{i=0}^L h_i x(k-i) + v(k) \quad (1)$$

where  $h_0, h_1, \dots, h_L$  are the channel coefficients,  $u(k)$  is the transmitted sequence, and  $v(k)$  is a white Gaussian noise uncorrelated with  $x(k)$ . The channel output  $u(k)$  becomes the input for the equalizer. Figure 1 shows a block diagram of the blind equalizer [8]. In Figure 1,  $y(k)$  is the transversal filter output to the equalizer input  $u(k)$ .  $y(k)$  plays a key rule in the cost function of blind adaptation. For the Sato algorithm,  $y(k)$  is applied to estimate the transmitted sequence  $x(k)$  as  $\hat{x}(k)$ . For most of the blind algorithms, the LMS algorithm can be commonly utilized

Fig. 1. Block diagram of the blind equalizer

to update the coefficient vector with the information of the estimation error,  $e(k)$ .

### III. AB BLIND ALGORITHM

The two proposed algorithms, ABGodard and ABSato, are described in this section.

#### A. ABGodard Algorithm

In implementing the ABGodard algorithm, the cost function minimization is considered as the same as that of the Godard algorithm. The cost function of the ABGodard algorithm is

$$J(k) = E[|y(k)|^p - R_p]^2 \quad (2)$$

where  $y(k)$  is the transversal filter output,  $p$  is a positive integer and  $R_p$  is a positive real constant defined by

$$R_p = \frac{E[|x(k)|^{2p}]}{E[|x(k)|^p]} \quad (3)$$

where  $E$  denotes expectation. The error signal can be calculated as

$$e(k) = y(k) |y(k)|^{p-2} (R_p - |y(k)|^p) \quad (4)$$

For the adaptation of the ABGodard algorithm, a  $Q \times M$  coefficient matrix  $\mathbf{Z}_{\text{abg}}(k)$  is considered, the elements of which are given by  $e_{i,j}(k)$ ,  $i = 1, 2, \dots, Q$ ,  $j = 1, 2, \dots, M$ .  $\mathbf{Z}_{\text{abg}}(k)$  is initialized at  $k = 0$  and all the elements are set to zero at initial condition. In the adaptation process of the algorithm, the elements of  $\mathbf{Z}_{\text{abg}}(k)$  are updated as the pattern of switching of the elements to be updated. Among the  $Q \times M$  elements of  $\mathbf{Z}_{\text{abg}}(k)$ , only  $M$  elements,  $e_{r(s),s}(k)$ ,  $s = 1, 2, \dots, M$  are selected for each iteration and a coefficient vector,  $\mathbf{w}_{\text{abg}}(k) = (e_{r(1)1}(k), e_{r(2)2}(k), \dots, e_{r(M)M}(k))^T$ , where  $r(s)$  is an integer and determined on the basis of the amplitude level of each element  $u_{k-s+1}$  of the input vector  $\mathbf{u}(k)$ , is formed for  $s = 1, 2, \dots, M$  as follows:

- if  $|u_{k-s+1}| \leq A_{\text{max}}/Q$ , then  $r(s) = 1$ .
- if  $A_{\text{max}}/Q < |u_{k-s+1}| \leq 2A_{\text{max}}/Q$ , then  $r(s) = 2$ .
- if  $2A_{\text{max}}/Q < |u_{k-s+1}| \leq 3A_{\text{max}}/Q$ , then  $r(s) = 3$ .

• . . .

- . . .
- if  $(Q-1)A_{\text{max}}/Q < |u_{k-s+1}|$ , then  $r(s) = Q$ .

Here,  $A_{\text{max}}$  denotes the maximum amplitude of the channel output and  $Q$  corresponds to the number of divisions used to partition the amplitude of the channel output.  $A_{\text{max}}$  should be measured from the received sequence before the equalizer is implemented. Accurate estimation of  $A_{\text{max}}$  is desired, but slightly inaccurate estimation may be also acceptable. This is because the range of the amplitude corresponding to  $r(s) = Q$  is not severely restricted, and occurs with the lowest probability compared with the other range cases.

As an example, consider that the equalizer length is  $M=5$  and the input vector is given by

$$\mathbf{u}(k) = [0.35 \quad -1.7 \quad 0.70 \quad 0.55 \quad 0.15]^T$$

If we consider the division number  $Q=4$ , then the 4 by 5 coefficient matrix is prepared as follows

$$\mathbf{Z}_{\text{abg}}(k) = \begin{bmatrix} e_{11}(k) & e_{12}(k) & e_{13}(k) & e_{14}(k) & e_{15}(k) \\ e_{21}(k) & e_{22}(k) & e_{23}(k) & e_{24}(k) & e_{25}(k) \\ e_{31}(k) & e_{32}(k) & e_{33}(k) & e_{34}(k) & e_{35}(k) \\ e_{41}(k) & e_{42}(k) & e_{43}(k) & e_{44}(k) & e_{45}(k) \end{bmatrix}$$

The value of  $A_{\text{max}}$  is assumed to be 0.8. Since each element of  $\mathbf{u}(k)$  produces  $(r(1) = 2, r(2) = 1, r(3) = 4, r(4) = 3, r(5) = 1)$ , the coefficient vector  $\mathbf{w}_{\text{abg}}(k)$  becomes  $\mathbf{w}_{\text{abg}}(k) = [e_{21}(k), e_{12}(k), e_{43}(k), e_{34}(k), e_{15}(k)]^T$ . This vector is updated by the Godard algorithm, and then the updated coefficients  $e_{21}(k+1), e_{12}(k+1), e_{43}(k+1), e_{34}(k+1), e_{15}(k+1)$  are inserted into the coefficient matrix  $\mathbf{Z}_{\text{abg}}(k+1)$ . For the next iteration, a coefficient vector is again prepared based on the elements of the input and then updated by the Godard algorithm. In such a way all the elements of  $\mathbf{Z}_{\text{abg}}(k)$  are updated for all input data. For selection of the filter coefficients in such a way at each iteration, the filter provides better output, which helps to estimate more accurate desired signal than that at the previous iteration. At the  $k^{\text{th}}$  iteration, the adaptive equations for the ABGodard algorithm are given by

$$y(k) = \mathbf{u}(k)^T \mathbf{w}_{\text{abg}}(k) \quad (5)$$

$$e(k) = y(k) |y(k)|^{p-2} (R_p - |y(k)|^p) \quad (6)$$

$$\mathbf{w}_{\text{abg}}(k+1) = \mathbf{w}_{\text{abg}}(k) + \mu e(k) \mathbf{u}(k) \quad (7)$$

where  $\mu$  is the step size and  $\mathbf{w}_{\text{abg}}(k+1)$  is the coefficient vector. From the definition of the cost function  $J(k)$  in (2) and (3), we see that the equalizer adaptation according to the ABGodard algorithm does not require carrier phase recovery. The algorithm therefore tends to converge slowly.

#### B. ABSato Algorithm

In implementing the ABSato algorithm, the cost function minimization is considered as the same as that of the

Sato algorithm. That is, the ABSato algorithm consists of minimizing a nonconvex cost function

$$J(k) = E[(\hat{x}(k) - y(k))^2] \quad (8)$$

where  $y(k)$  is the transversal filter output and  $\hat{x}(k)$  is an estimate of the transmitted sequence.  $\hat{x}(k)$  is given by

$$\hat{x}(k) = \gamma \text{sgn}[y(k)] \quad (9)$$

where the function  $\text{sgn}()$  is the signum function which returns the sign of the argument.  $\text{sgn}[y(k)]$  is 1 if  $y(k)$  is positive, 0 if  $y(k)$  is zero and (-1) if  $y(k)$  is negative. The constant  $\gamma$  sets the gain of the equalizer, which is defined by

$$\gamma = \frac{E[x^2(k)]}{E[|x(k)|]} \quad (10)$$

and the adaptation is taken in the same way as the ABGodard algorithm.

#### IV. PERFORMANCE EVALUATION

The performances were experimented on a channel model whose transfer function is given by

$$H(z) = 1.0 + 0.5z^{-1}. \quad (11)$$

Figure 2 shows the mean square error (MSE) conver-

Fig. 2. MSE performance of Godard, Sato, ABGodard and ABSato on channel (11) with SNR=40dB

gence plots of the Godard, Sato, proposed ABGodard and proposed ABSato algorithms on channel (11) with SNR=40dB, step size  $\mu=0.025$ , numbers of divisions  $Q=4$ , filter order  $M=4$  and number of input data  $N=3000$ . Figure 2 indicates that commonly the AB versions provide better performance, while the ABSato algorithm results in a smaller MSE level. According to this result, we decided to select the ABSato algorithm and investigated the performance of the ABSato algorithm furthermore. Figure 3 illustrates the BER performance of the Sato and

Fig. 3. BER performance of Sato and ABSato on channel (11)

ABSato algorithms on channel (11), where the step size  $\mu=0.031$ , number of division  $Q=2$ , number of input data  $N=100000$  and filter order  $M=6$  were used. Figure 3 also suggests that the ABSato algorithm is better than the Sato algorithm even for BER performance. Figure 4 shows the

Fig. 4. BER performance of Sato and ABSato on channel (11) with division number  $Q=2,4$

BER performance of the Sato and ABSato algorithms on the same channel based on division numbers  $Q=2$  and  $Q=4$ , where the step size  $\mu=0.031$ , number of input data  $N=1000000$  and filter order  $M=6$  were used. Figure 4 suggests that as the division number  $Q$  is increased, the performance of the ABSato algorithm is improved.

#### V. FILTER STRUCTURE

To improve the performance of the ABSato algorithm, another filter structure is considered in this section.

Fig. 5. Parallel Sato-ABSato equalizer

#### A. Parallel Structure

Figure 5 depicts the parallel structure of the Sato and ABSato equalizers. In the parallel structure, two linear transversal equalizers; LTE(I) and LTE(II), are updated by the ABSato and Sato algorithms with  $e(ak)$  and  $e(k)$ , respectively. The comparator provides  $f(k)=e(ak)$  if  $(e(ak))^2 \leq (e(k))^2$  otherwise  $f(k)=e(k)$ . The parallel equalizer provides output  $y(ak)$  when  $f(k)=e(ak)$  and  $y(k)$  when  $f(k) = e(k)$ .

#### B. Performance Evaluation

The performances of the parallel Sato-ABSato equalizer were investigated on the same channel. Figure 6 shows the MSE convergence plots of the Sato, ABSato and parallel Sato-ABSato equalizers with the SNR=40dB,  $M=8$ , step size  $\mu=0.025$  and  $Q=4$ . Figure 6 clarifies that the parallel structure of the Sato and ABSato algorithms provides better performance than non-parallel structure algorithms.

Fig. 6. MSE performance of Sato, ABSato and Parallel Sato-ABSato on channel (11) with SNR=40dB

Figure 7 shows the BER performance of the Sato, ABSato

Fig. 7. BER performance of Sato, ABSato and Parallel Sato-ABSato on channel (11)

and parallel Sato-ABSato algorithms with  $M=8$ , step size  $\mu=0.025$ ,  $Q=4$  and  $N=100000$ . Figure 7 suggests that even for BER, the parallel combination of the Sato and ABSato algorithms improves the performance. From figure 6 and 7 we can confirm that the parallel structure enhances the performance of the ABSato algorithm with the support of the Sato algorithm. Additionally we checked the performance of the parallel equalizer with the Godard and ABGodard algorithms, which is constructed in same way as in Figure 5. The performance of the parallel Godard-ABGodard equalizer was, however, worse than that of the parallel Sato-ABSato equalizer.

#### VI. CONCLUSION

In this paper, ABGodard and ABSato algorithms have been proposed for blind channel equalization. Simulation results have demonstrated that the ABGodard and ABSato algorithms perform better than the Godard and Sato algorithms, respectively, for simple communication channel equalization. The ABSato algorithm behaves more accurately than the ABGodard algorithm, and the increased division number and the use of parallel structure enhance the performance of the ABSato algorithm further.

**Abstract** — The fast growth in communication systems has resulted congestion in lower frequency bands and system designers are forced to explore higher and higher frequencies. Rain is a dominant source of attenuation at higher frequencies and consequently degrades the system performance in tropical and subtropical regions. The knowledge of rain fade and its performance is essential in order to optimize system capacity and meet quality and reliability. This paper has investigated performance of earth-to-satellite link due to rain fades operating in a subtropical country Bangladesh. The rain intensity data are derived from forty years measured annual rainfall data. The converted rain intensity data is used to estimate rain fades at C, Ku and Ka-bands. The rain fade is also estimated using ITU-R recommended rain intensity. Noise generated during rains is predicted for all three bands and carrier-to-noise ratios are estimated to compare the performances of earth-to-satellite link at different frequency bands in a subtropical region.

**Index Terms** — Rainfall Data, Rain Fade, Link Budget, Earth-to-satellite, CNR.

## I. INTRODUCTION

The very fast growth in communication systems has brought saturation to the most desirable frequency band (1 to 10 GHz). This fact has led to the utilization of higher frequencies extending the radio frequency spectrum into the millimeter wavelength region. Rain is a dominant source of attenuation at higher frequencies. Attenuation due to rain at frequencies above 10 GHz, mainly leads to outages that compromise the availability and quality of service, making this one of the most critical factors in satellite link design. The design of new telecommunication systems requires the knowledge of rain fade in order to optimize system capacity and meet quality and reliability criteria [1].

In the design of a radio communication system, one of the major concerns is to assess system unavailability also called outage time. Unavailability or outage time is the amount of time during which the system's performance will be below some threshold value or that it will not be usable. For designing a reliable system, the amount of outage time has to be kept below some objective. In microwave systems, outages can occur either due to equipment failure or it can be propagation outage. In modern systems, the equipment outage time can be made negligibly small by using standby equipment and

automatic protection switching systems. However, at higher frequencies, attenuation by rain can cause an outage, which can not be easily protected. Therefore the practical way of achieving a reliable radio system at those frequencies where there is substantial rain attenuation is to design the system in such a way that the expected amount of rain outage is below some objective [2].

For a reliable communication system, unavailability time during a year has to be kept at 0.01 percent [6]. This corresponds to availability time of 99.99 percent during a year. Therefore rainfall with one-minute integration time is very important parameter to predict attenuation at 0.01% of time availability. The long term cumulative annual rainfall data are available for most of the countries of the world. This paper has presented the cumulative rainfall data collected for forty years in four different parts of Bangladesh. Using appropriate conversion model, the long-term annual rainfall data has been converted to rain intensity data. The rain intensity proposed by International Telecommunication Union (ITU-R) as well as converted data are used to predict the rain fade for earth-to-satellite at C, Ku and Ka-Bands. This paper has investigated performance of earth-to-satellite link due to rain fades at different frequency bands operating in Bangladesh.

## II. ANNUAL RAIN STATISTICS

Bangladesh has a subtropical monsoon climate characterized by wide seasonal variations in rainfall, moderately warm temperatures, and high humidity. Most parts of the country receive at least 2000 mm of rainfall per year. It locates at 88° to 93° longitude (East) and 20° to 27° Latitude (North). Because of its location just south of the foothills of the Himalayas, where monsoon winds turn west and northwest, Bangladesh receives the heavy average precipitation which classify into four distinct regions. They are as North-West, North-East, South-West and South-East. The annual rainfall data collected from 1948 to 1988 for two regions are shown in from Figure 1 [7]. The mean annual rainfall of North-East is 2635 mm, North-West is 1821 mm, South-East is 2937 mm and South-West is 1768 mm[7].

(a)

(b)

Figure 1: Variations of annual rainfall data measured and forecasted for forty years in (a) South East region and (b) in North East region of Bangladesh.

### III. CONVERSION OF RAIN STATISTICS TO RAIN INTENSITIES

Common rain attenuation prediction methods require 1-min rain rate data, which is scarce in the tropical and subtropical region [2]. However, yearly rainfall data are available at many meteorological stations. A method for converting the available rainfall data to the equivalent 1 min rain rate cumulative distribution (CD) would be very useful for radiowave engineers. For this reason 1 min rain rate CD can be estimated by the use of Chebil model and long-term mean annual rainfall data. His model is as follows:

$$R_{0.01} = M \quad (1)$$

where  $a$  and  $b$  are regression coefficients. In Chebil model the regression coefficients  $a$  and  $b$  are defined as [3]  
 $a = 12.2903$  and  $b = 0.2973$  (2)

Chebil has developed his model based on measured values of  $M$  in Malaysia, Indonesia, Singapore, Brazil and Vietnam. He showed that his model is the best estimate of

the measured data [3,4]. Using Chebil model, long-term mean annual rainfall data has been converted to 1 min rain rate data and are presented in Table 1.

Table 1: Measured mean annual rainfall and converted corresponding rain intensity at four regions in Bangladesh.

Name of Region	Measured Mean Annual Rainfall, mm	Converted Rainfall rate $R_{0.01}$ , mm/hr
South East	2937	132
South West	1768	114
North East	2635	128
North West	1821	115
ITU-R Map [6]	-	95

The highest rain intensity is observed at south east region of Bangladesh at 132 mm/hr and lowest at south west is 113 mm/hr. The rain intensity recommended by ITU-R map is found 95 mm/hr for Bangladesh[6] which is far lower than converted rain intensity from measured long term annual rainfall.

### IV. RAIN ATTENUATION STATISTIC FROM RAINFALL RATE

The following procedure provides estimates of the long-term statistics of the slant-path rain attenuation at a given location for frequencies up to 55 GHz. The following parameters are required:

- $R_{0.01}$  : point rainfall rate for the location for 0.01% of an average year (mm/h)
  - $h_s$  : height above mean sea level of the earth station (km)
  - $\theta$  : elevation angle (degrees)
  - $\phi$  : latitude of the earth station (degrees)
  - $f$  : frequency (GHz)
  - $R_e$  : effective radius of the Earth (8 500 km).
- The geometry is illustrated in Figure 2 where  
 A = frozen precipitation  
 B = rain height  
 C = liquid precipitation  
 D = Earth-space path

Step 1: Determine the rain height,  $h_R$ , as given in Recommendation ITU-R P.839.

Step 2: For  $\theta \geq 5^\circ$  compute the slant-path length,  $L_s$ , below the rain height from:

$$L_s = \frac{(h_R - h_s)}{\sin \theta} \quad \text{km} \quad (3)$$

For  $\theta < 5^\circ$ , the following formula is used:

$$L_s = \frac{2(h_R - h_s)}{\left(\sin^2 \theta + \frac{2(h_R - h_s)}{R_e}\right)^{1/2} + \sin \theta} \quad \text{km} \quad (4)$$

Figure 2: Schematic presentation of an earth-space path given the parameters to be input to the attenuation prediction process.

If  $h_R - h_s$  is less than or equal to zero, the predicted rain attenuation for any time percentage is zero and the following steps are not required.

Step 3: Calculate the horizontal projection,  $L_G$ , of the slant-path length from:

$$L_G = L_s \cos \theta \quad \text{km} \quad (5)$$

Step 4: Obtain the rainfall rate,  $R_{0.01}$ , exceeded for 0.01% of an average year (with an integration time of 1 min). If this long-term statistic cannot be obtained from local data sources, an estimate can be obtained from the maps of rainfall rate given in Recommendation ITU-R P.837. If  $R_{0.01}$  is equal to zero, the predicted rain attenuation is zero for any time percentage and the following steps are not required.

Step 5: Obtain the specific attenuation,  $\gamma_R$ , using the frequency-dependent coefficients given in Recommendation ITU-R P.838 and the rainfall rate,  $R_{0.01}$ , determined from Step 4, by using:

$$\gamma_R = k (R_{0.01})^\alpha \quad \text{dB/km} \quad (6)$$

Step 6: Calculate the horizontal reduction factor,  $r_{0.01}$ , for 0.01% of the time:

$$r_{0.01} = \frac{1}{1 + 0.78 \sqrt{\frac{L_G \gamma_R}{f}} - 0.38 (1 - e^{-2L_G})} \quad (7)$$

Step 7: Calculate the vertical adjustment factor,  $v_{0.01}$ , for 0.01% of the time:

$$\zeta = \tan^{-1} \left( \frac{h_R - h_s}{L_G r_{0.01}} \right) \quad \text{degrees}$$

$$\text{For } \zeta > \theta, \quad L_R = \frac{L_G r_{0.01}}{\cos \theta} \quad \text{km}$$

$$\text{Else,} \quad L_R = \frac{(h_R - h_s)}{\sin \theta} \quad \text{km}$$

$$\text{If } |\varphi| < 36^\circ, \chi = 36 - |\varphi| \quad \text{degrees}$$

$$\text{Else, } \chi = 0 \quad \text{degrees}$$

$$v_{0.01} = \frac{1}{1 + \sqrt{\sin \theta} \left( 31 \left( 1 - e^{-(\theta/(1+\chi))} \right) \sqrt{\frac{L_R \gamma_R}{f^2}} - 0.45 \right)}$$

(8)

Step 8: The effective path length is:

$$L_E = L_R v_{0.01} \quad \text{km} \quad (9)$$

Step 9: The predicted attenuation exceeded for 0.01% of an average year is obtained from:

$$A_{0.01} = \gamma_R L_E \quad \text{dB} \quad (10)$$

Step 10: The estimated attenuation to be exceeded for other percentages of an average year, in the range 0.001% to 5%, is determined from the attenuation to be exceeded for 0.01% for an average year:

$$\text{If } p \geq 1\% \text{ or } |\varphi| \geq 36^\circ: \quad \beta = 0$$

$$\text{If } p < 1\% \text{ and } |\varphi| < 36^\circ$$

$$\text{and } \theta \geq 25^\circ: \beta = -0.005(|\varphi| - 36)$$

$$\text{Otherwise: } \beta = -0.005(|\varphi| - 36) + 1.8 - 4.25 \sin \theta$$

$$A_p = A_{0.01} \left( \frac{p}{0.01} \right)^{[-(0.65 + 0.03 \ln(p) - 0.04 \ln(A_{0.01}) - \beta(1-p) \sin \theta)]} \quad \text{dB} \quad (11)$$

This method provides an estimate of the long term statistics of attenuation due to rain. Considering Singapore Satellite ST1 located at 88° East longitude and earth station at Dhaka at 90° longitude (East) and 24° Latitude (North), the elevation angle is 61.8°. Using above methodology from step1 to step10 and the rain rates derived in Table 1, rain fades have been estimated for South-East region and other region as well as those recommended by ITU-R and presented in Fig. 3 and Fig. 4. All cases the signals are assumed as vertically polarized and the regression coefficients are given as table Table 2.

Table2: Regression Coefficients for Estimating Specification Attenuation.

vertical	C-band (6GHz)	Ku-band (14GHz)	Ka-band (20GHz)
$\alpha$	1.265	1.128	1.065
$k$	0.00155	0.0168	0.0691

Figure 3: Variations of predicted rain fade for C-Band at different percentage of time of the year.

At C-band, attenuation due to rain is predicted 0.3 dB for 0.01% of the time of the year. But the same at Ku-band and Ka-band are predicted as 13.8 dB and 39.2 dB respectively. The difference between C and Ku-band rain fade is almost 13.5 dB and C and Ka-band is about 38.8 dB for the design of earth-to-satellite microwave link with 99.99% reliability. Hence to design reliable earth-to-satellite microwave link is very critical at Ku and Ka-bands and needs careful and accurate estimation of rain attenuation in Bangladesh.

**Comparison with ITU-R and Worst case in Different Band**

Figure 4: Variations of predicted rain fade for all three frequency bands at different percentage of time of the year.

All three bands, rain attenuation are also estimated based on ITU-R recommended rain. All rain fades at 0.01% are presented in Table 3. It is obvious that ITU-R predicted rain attenuation are much lower than those predicted using measured rain rate in all cases. The differences are 0.1 dB at C-band, 2.5 dB at Ku-band and 6.9 dB at Ka-band.

Table 3: Estimated rain fades for all three frequency bands.

	4 GHz	12 GHz	20 GHz
$A_{0.01\%}$	dB	dB	dB
ITU-R	0.25	11.3	32.3
Measured	0.31	13.8	39.2

## V. LINK BUDGET AT CLEAR AIR AND DURING RAIN

The atmospheric absorption has been estimated using ITU-R proposed graph for elevation angle  $61.8^\circ$  using the equation (12) and presented in Table 4.

$$\text{Atmospheric Absorption, [AA]} = [\text{AA}]_{900} * \text{cosec}(\text{El}) \quad (12)$$

Link Budget has been calculated for Earth-to-satellite downlink at three bands using ITU-R proposed rain rate and converted measured rain rate for Bangladesh. The receive signal level as well as Carrier-to-noise ratio has

Table 4: Atmospheric absorption losses at three frequency bands

Frequency	[AA]
4 GHz	0075 B
12 GHz	011 dB
20 GHz	0.40 dB

been estimated both clear air condition and raining conditions and are tabulated in Table 5. The noise power is calculated using equation (13).

$$N = K T_{\text{sky}} B_w \quad (13)$$

K is Boltzmann constant

TS is sky temperature and is assumed as  $140^\circ$ .

Bw is noise band width and 36 MHz at C, Ku and Ka-bands.

Noise temperature increased during rain is estimated equation (14) as follows:

Sky noise temperature due to rain

$$T_{\text{sky.rain}} = 273(1 - 10^{-A/10}) \text{ K} \quad (14)$$

Hence, total system noise temperature in rain,

$$T_{\text{s.rain}} = T_{\text{LNA}} + T_{\text{sky.rain}} \quad (15)$$

Finally, increase of noise temperature due to rain in different polarization,

$$N = 10 \log (T_{\text{s.rain}} \cdot T_{\text{s}}) \quad (16)$$

It is observed that ITU-R recommendation underestimates the rain rate measured in Bangladesh and consequently the

link budget estimation introduces significant errors specially at Ku and Ka-bands. Even though C/N ratio is 3-4 dB higher in Ku and Ka-bands than C-band during clear air condition. But during the rains C/N ratios falls to 8.6 dB at C-band and -4.36 dB at Ku and -24.13 dB at Ka-bands. These estimation are based on ITU-R recommended rain rates. But the above estimation is done based on converted measured rain rate and C/N ratio is fallen to -6.8 dB at Ku-band and -31.1 dB at Ku-band. These prediction shows that using of Ku and Ka-bands is very challenging and critical in this region. However the measured rain rate data is converted from measured long term annual rainfall data, it is too preliminary to comment correctly. Therefore it is recommended to measure rain intensity and rain drop size distribution urgently for the design of reliable microwave link in Bangladesh.

## VI. CONCLUSION

Rain is a dominant source of attenuation at higher frequencies in tropical and subtropical regions. Therefore accurate estimation of rain fade is very essential in order to design reliable microwave links in such regions. This paper has predicted rain fades in a subtropical country Bangladesh using rain intensity data derived from forty years measured annual rainfall data. It is observed that rain fade is not significant at C-band, but is very critical at Ku and Ka-bands. This paper has also investigated performance of earth-to-satellite link due to rain fades. Noise generated during rains is predicted for all three bands and carrier-to-noise ratios are estimated to compare the performances of earth-to-satellite link at different frequency bands. From observation, it is found that C/N ratio is 3-4 dB higher in Ku and Ka-bands than C-band during clear air condition. But during the rains C/N ratios falls to 8.6 dB at C-band and -4.36 dB and -24.13 dB at Ku and at Ka-band respectively. These estimation are based on ITU-R recommended rain rates. But the C/N ratio falls to -6.8 dB at Ku-band and -31.1 dB at Ka-band based on converted measured rain rate. These prediction shows that using of Ku and Ka-bands is very challenging and critical in this region. However the measured rain rate data is converted from measured long term annual rainfall data, it is too preliminary to comment correctly. Therefore it is recommended to measure rain intensity and rain drop size distribution urgently for the design of reliable microwave link in Bangladesh.

## Abstract

*Fault detection is a difficult and complex task in WSN because of there are many factors that influence data and could cause faults. Large-scale sensor networks impose energy and communication constraints, thus it is difficult to collect data from each individual sensor node and process it at the sink to detect faulty sensors. The proposed approach saves energy and improves network lifetime by detecting data faults locally in cluster head and therefore reducing the number of transmissions required to convey relevant information to the sink. This paper presents a novel approach for detecting sensors which produce faulty data in a distributed way as well as identifying the type of data faults using trust concepts to gain a high degree of confidence. We validate our method with simulations results.*

**Keywords:** Wireless Sensor Networks, Distributed Fault Detection, Trust, Reputation.

## 1. Introduction

The main task of each sensor node in a Wireless Sensor Network (WSN) is to monitor the environment and report the current status of the environment to a center called base station. If a sensor becomes faulty for any reason, then false and unreal data are reported to the center by the sensor. Based on false data, the base station may make inaccurate and faulty decisions leading to serious inefficiencies of the whole network..

Fault diagnosis is one of the main challenges and building blocks of many dependable protocols. In fact, once faulty units are identified, the remaining units can be isolated from the rest of the system, and the computation can proceed, although with reduced performance [1].

Sensor nodes are powered by batteries, which are considered as constrained resources. It is very expensive for the base station to collect information from every sensor and identify faulty sensors in a centralized manner. Different applications may require the fault detection to be conducted in a real-time mode

with low latency or high throughput. Therefore, a localized and distributed generic algorithm for each node is highly preferred in wireless sensor networks.

This paper presents a novel approach for detecting sensors which produce faulty data in a distributed way as well as identifying the type of data faults with a high degree of confidence using reputation concepts.

The rest of paper is organized as follows. Section 2 presents the most related works. Section 3 introduces reputation and trust concepts. In Section 4 faults are modeled and the proposed algorithm to model faults is discussed. Section 5 explains the suggested fault detection algorithm in detail. Section 6 demonstrates evaluations on injected faults in a data set. In Section 7 the proposed algorithm is applied to a real world data set. The complexity of the proposed algorithm is discussed in Section 8 and finally in Section 9 the paper is concluded.

## 2. Related Work

Methods of fault detection based on simplified algorithms such that they could be implemented on a single sensor node are investigated in [2][3]. Both have approaches based on two relationships of correlation: the correlation of a node's measurement and its neighbor's measurements, and the correlation of a node's measurement and its own previous measurement. In [2], a naive bayes algorithm employed which maintains counters of the number of times a particular pair occurs over the history of the sensor network. This approach requires large numbers counters and large amounts of training data. On the other hand, [3] keeps track of the same relationships by only maintaining counters of the differences between the pairs of values. Their claim is that the differences are sufficiently representative of the interesting behavior from the sensors.

However, there are some kinds of faults which require cooperative-diagnosis among a set of sensor nodes. A large portion of faults in WSNs are in this category. For example, Detection method proposed in [4] is to identify faulty sensor nodes in event detection

application. The detection method is based on the assumption that sensor nodes in the same region should have similar sensed value unless a node is at the boundary of the event region. It takes measurements of all neighbors of a node and uses the results to compute the probability of the node being faulty.

Zhang et als. [6] present a different technique for detection of faulty nodes. Each sensor node generates an alert when it observes an inconsistency between itself reading and neighbor reading and then sends alert to sink. Sink makes a graph such that there is an edge  $xy$  in the graph iff  $x$  and node  $y$  are suspicious of each other. Then to each node faulty/non-faulty flag is assigned such that this assignment doesn't affect the consistency of the graph. All of valid assignments is created and the nodes that are marked faulty in all these assignments are labeled as faulty nodes. This approach works in centralized manner then it can not scalable very well.

Chen et als. [7] present a distributed scheme for fault detection. Their scheme have some phases. In the first phase, each sensor compares its reading with neighbors' values and declares itself *locally good* if its value matches with the majority of its neighbors. In the second phase, those nodes that are *locally good* and have a majority of its matching neighbors also *locally good* are declared *globally good*. In the last phase, neighbors of *globally good* nodes that do not agree with those nodes are labeled *faulty*. This scheme is not easily scalable and it has considerable overhead due to high exchange of information between neighbors.

Ding et als. [8] introduce a faulty sensor identification algorithm. Their algorithm is localized but it has too communication overhead. In the algorithm, the reading at a sensor is compared with its neighbors' median reading. If the difference is large, the sensor is very likely to be faulty. Although this algorithm works for large size of sensor networks, the probability of sensor faults needs to be small. If half of the sensor neighbors are faulty and the number of neighbors is even, the algorithm cannot detect the faults well. The location of sensors is needed that it requires GPS or complex techniques for this purpose.

### 3. Trust Concept

The problem of producing reliable information can be diminished to a basic question: "how the sensor nodes trust each other?". Trust is the expectation of one entity about the actions of another [9].

There is much confusion between trust and reputation. When entities face uncertainty, they tend to trust to entities that have high reputation.

Reputation is not a physical quantity but it is a belief; it can only be used to statistically predict the future behavior of other nodes and cannot define deterministically the actual action performed by them.

Trust is a subjective expectation a node has about another node's future behavior. This can be obtained by taking the statistical expectation of the probability distribution representing the reputation between the two nodes. Note that, unlike reputation, the trust metric is simply a number.

We have used the RFSN method for calculating the reputation; more details on RFSN can be found in [9].

### 4. Fault Models

A fault can be introduced into sensor at every point in the sensor network: from failures in the sensor itself, to software bugs and computational errors, to lossy communication [10]. Faults are application and sensor type dependent. There is no significant list of features to consider for fault modeling. The set of models to be used for fault detection contain models for both good and faulty data. Ni et als. [10] categorize the existed faults as: outlier, stuck-at, spike, excessive noise, calibration fault, hardware fault, low battery, and clipping. Sharma et als. [11] categorize faults differently as: NOISE, SHORT and CONSTANT. These three faults have been observed in the four data sets from WSN deployments by others as well [11][12][13]. We start by focusing on a small set of sensor data faults that have been observed in real deployments. We select categorization introduced in [11] to compare our results with their results has achieved on the same dataset [14].

The three types of faults that we intend to detect, as well as how they can be detected, are as follows.

- 1) **SHORT:** A sharp change in the measured value between two successive data points.

*Detection method:* we set an acceptable range for every hours of day and every season. If the reading value is outside this range and the difference between current and previous reading value is above a threshold, it is labeled as outlier.

**NOISE:** The variance of the sensor readings increases. Unlike SHORT faults that affect a single sample at a time, NOISE faults affect a number of successive samples.

*Detection method:* Compute the standard deviation of sample readings within a window  $w$ . If it is above a certain threshold, the samples are affected by the NOISE fault.

- 2) **CONSTANT:** The sensor reports a constant value for a large number of successive samples. The reported constant value is either very high or very

low compared to the “normal” sensor readings.

- 2) *Detection method*: if for several consecutive time intervals the read value by a sensor is invariant then we must check the read values by the sensor’s neighbors. If most of the fault free sensors have variant values in these time intervals then this sensor has constant fault.

## 5. The Proposed Fault Detection Algorithm

First we assume all sensor nodes are divided to some clusters that each cluster has a cluster head.

For fault detection, we have two types of nodes, some sensor nodes (SN) and a cluster head node (CN) in our algorithm as it is shown in Figure 1.

Figure 1. A cluster of SNs and CN

Sensor nodes perform environment sensing and send reading values to the cluster node. Cluster node sends the fusion of all SN data in the cluster to the sink. We assume the cluster node is in the radio range of sensors in the same cluster, meaning that if a sensor broadcasts a message, it can be received by CN in the cluster. SNs are also equipped with the fault detection algorithm and are responsible for detecting faults and reporting them to the CN.

Each SN maintains 3 tables:

1. *Neighbor Data Table (NDT)*: contains data readings of neighbor sensors.
2. *Fault Table (FT)*: contains the neighbor sensors’ faults that detected by the SN. Entry of fault free nodes in this table is “HEALTHY” flag.
3. *Neighbor Reputation Table (NRT)*: contains reputation of neighbor sensors from perspective of the sensor which maintain this table.

The following actions are performed in each cluster. Each sensor broadcast its reading to all neighbors. Each SN receives these data and puts the neighbors reading in its *NDT* then updates its *NRT* considering the difference between its reading and neighbors reading and with comparing the threshold (this threshold is calculated regard to the acceptable difference between values that is application-dependent). SN calculates the reputation for each its neighbors. Actually, each SN puts the number of difference and the number of similarity values

in  $NVote_j$  and  $PVote_j$  respectively ( $j$  is the neighbor  $id$ ), and then it calculates the reputation (or trust) value using statistical expectation and Beta distribution. Now each neighbor has a reputation value which is built by this SN. Based on the fault modeling algorithm described in the previous section, SN detects the fault and puts it in the corresponding fault part in *FT*. In the initially phase all of entry of *FT* is fulfilled by “HEALTHY” word. After  $T$  timeslot each sensor sends *FT* and *RT* to the CN. To detect probably fault of  $S_i$ , CN applies majority voting algorithm on the opinions of some  $S_i$  neighbors (which have reputation value more than threshold) about  $S_i$ .

In reality, *FT* of each neighbor of  $S_i$  that has reputation value more than threshold in the  $RT_i$  (Reputation Table of sensor  $i$ ) is checked by CN to detect final fault detection for  $S_i$ . The final detected fault for  $S_i$  is the majority of trusted neighbors opinions. For example if the result of these opinions be fault type NOISE about fault of  $S_i$ , then the detected fault for this sensor labeled as NOISE.

The final fault table that is constructed by CN is sent to the sink every  $T$  time slot which is specified regard to the network policy and needed accuracy. If we want to monitor fault of sensors frequently then we must set  $T$  to a low value but in this case the generated traffic for sending the *FT* and *RT* to the CN and final *FT* to the sink is increased.

## 6. Evaluation of our method

We analyzed a data set from real-world deployments to detect data faults in sensor traces. The sensor traces contain measurements from a variety of phenomena – temperature, humidity, light, pressure. Authors in [11] used these data set and others to faults prevalence in sensor traces. Also, they detect SHORT, NOISE and CONSTANT faults in these data sets. Then we can compare our results with this reference.

Before we can evaluate the faults detection in real world dataset using the methods discussed in the previous section, we need to characterize the accuracy and robustness of these methods. To do this, we injected faults of the types discussed in section 4 into a real-world data set. We can specify the injected fault with a flag in the data set. By this action we can check what fraction of the injected faults is detected by our method. Injecting faults into a data set gives us an accurate “ground truth” that helps us better understand the performance of a detection method [11].

Similar to [11] we use three metrics to understand the performance of various methods: the number of faults detected, false negatives, and false positives.

### 6.1. Fault injection and validate our method

We want to compare our results with [11], then we use the way for injecting faults that introduced in [11]. To inject SHORT faults, we change value of a sensor  $i$  and replace it by:

$$Val^{new}(S_i) = Val^{old}(S_i) + Val^{old}(S_i) \times C$$

where parameter  $C \in N$  can be a constant or variant.

To inject NOISE faults, we pick a set of successive samples  $W$  and add a random value drawn from a normal distribution,  $N(0, \sigma^2)$ , to each sample in  $W$ . We vary the intensity of NOISE faults by choosing different values for  $\sigma$ .

To inject constant fault we change value of a sensor  $i$  in some successive samples to a constant value.

There are some detection methods that are discussed in [11] and we need them for the purpose of comparing their results to ours. In [11], authors explore three qualitatively different detection methods Linear Least-Squares estimation (LLSE), Hidden Markov Models (HMM), and a rule-based method that leverages domain knowledge to develop heuristic rules for detecting faults. Finally they combine the above methods to build a hybrid method namely Hybrid(I).

Figure 2 compares the accuracy of the SHORT rule, LLSE, HMM, and Hybrid(I) and our method(T) for SHORT faults. The labels used for different detection methods are: **R**: Rule-based, **L**: LLSE, **H**: HMM, **U**: Hybrid(U), **I**: Hybrid(I), **T**: Our method.

As it is shown in Figure 2, our proposed method has detected SHORT faults accurately. Two reasons can create false negatives and false positives. First, when there is inconsistency between the sensed data and reported data to the neighbors by a faulty sensor. In this case, it is possible that the fault or type of fault cannot be detected correctly, leading to false negative.

Second, when the sensors that their reputation are very high (much more above threshold), work badly or have some faults. In this case although the reputations of these sensors are reduced but their reputations are still above the threshold for some periods and they can participate in voting. If there are a lot of these sensors then the final decision can affect them leading to some false negatives and false positives. This condition rarely happens and we have very few false positives or false negatives. To overcome this problem, we can give weight ( $w$ ) to the reputations of sensors. The recent reputation value of a sensor is more important than its old reputation value. We apply this as follows:

$$Re p^{new}(S_i) = w \times Re p^{current}(S_i) + (1 - w) \times Re p^{old}(S_i)$$

Some simulations and their results showed that the proper value for  $w$  is 0.8. With this solution, the results are shown in Figure 3. The two above reasons are used for other faults i.e. NOISE and CONSTANT.

Figure 2. Comparison of methods for injected SHORT faults

Figure 3. Comparison of methods with our weighted method (wT) for injected SHORT faults

The appearance of NOISE faults are shown in the Figures 4. Figure 4 is a plot of comparison between discussed methods and our weighted and simple methods. As you can see the wT method is more accurate and we can trust to it more than T method because the current reputations considered more than old reputations.

Figure 4. Comparison of methods for injected NOISE faults

The proposed method can also detect CONSTANT faults as well as two previous faults. This is shown in Figure 5.

Figure 5. Detection of injected CONSTANT faults

## 7. Faults in a Real world data set

Now we apply our algorithm in a real world data set.

We verified that our proposed method works accurately and showed it in the above figures.

### 7.1. Great Duck Island (GDI) Data Set

We looked at data collected using 30 weather motes on the Great Duck Island over a period of 3 months [14].

We apply our algorithm on the temperature, light, and pressure of this data set and plot results in the following figures. Also, in these figures we compare our method with other detection methods which are applied in this data set and are discussed in the [11].

Figure 6. SHORT faults in GDI data set on humidity

Figure 7. SHORT faults in GDI data set on pressure

Figure 8. SHORT faults in GDI data set on light field

Figure 9. Percentage of faults in GDI data set

All of the above diagrams provide evidence that we can trust the results and faults that are created by our proposed method. This is a major factor to the special sensor networks which do vital and important actions such as health monitoring and battlefield and alike.

## 8. Complexity of Algorithm

Having presented our algorithms for modeling and detecting data faults based on reputation and trust, the complexity of the proposed algorithms are presented here.

A common benchmark for fault detection algorithms is the amount of communications each algorithm creates in the network. Higher communication traffic is unacceptable because it reduce the lifetime of sensor nodes and thus the lifetime of the network. We have measured the generated traffic in the network by our algorithm and discuss about it for evaluating our algorithm. To begin with, let us assume that:

$n$  is the total number of sensors,  $m$  is the number of clusters,  $B$  is the number of neighbors which are located in the radio range of a sensor, considered as a fraction  $n/m$ .

$T_{total}$  is the total time from start till now. This time is a formal unit of measurement to estimate the number of times that for example a sensor sends its data to the cluster head.

The complexity of our method for one cluster is:

$$[(\frac{n}{m} \times B) + (\frac{n}{m} \times \frac{1}{w}) + \frac{1}{w}] \times T_{total}$$

Since  $B$  can be a fraction of  $n/m$  then the total complexity is: (Although  $B$  can also be considered a constant between [3,9] for small and medium size clusters but we discuss the worst case.)

$$[(\frac{n}{m} \times B) + (\frac{n}{m} \times \frac{1}{w}) + \frac{1}{w}] \times T_{total} \approx O(n^2)$$

The communication overhead generated by SNs that send their reading data to each other in a cluster is  $\frac{n}{m} \times B$ . Sending  $FT$  and  $RT$  from every SN to the CN

need a communication thereby the needed

communication for a cluster is  $(\frac{n}{m} \times \frac{T_{total}}{w})$  such that

$w$  is a predefined period of time to sending  $RT$  and  $FT$  to the cluster head. And in  $w$  the cluster head must send their  $FT$  to the sink.

In contrast to other methods the complexity of our algorithm is independent of the failure probability of a sensor; this is an advantage in fault prone environment and fault prone equipments because in these cases this probability is high.

Our algorithm is scalable because fault detection in the first stage is done locally in SNs and in the next stage the final fault detection based on reputations is done in the cluster head.

However our algorithm has some overheads due to maintaining three tables in SN. Other discussed algorithms have overhead too. But our goal was to detect faults, their types and locations with a high degree of confidence using the reputation and trust concept, and our goal may justify the probably additional imposed overheads. In our algorithm one of the main tasks are done by cluster head and we assume these nodes which number of them is constant and low have more resource such as memory and power.

## 9. Conclusion

Fault diagnosis is an important challenge in WSNs. This paper presented how faulty sensors are detected and their types of fault are identified with a high degree of confidence using trust and reputation concepts. All SNs and CN in a cluster are principally responsible for fault detection in a distributed manner in a cluster. With simulations we showed the superiority of our algorithm to related algorithms with respect to accuracy and trustworthiness of results. The complexity of our algorithm was shown to be acceptable with considering main task of our algorithm that is fault detection with high degree of trust. It was also discussed that our algorithm is scalable thereby it can be used in vast environments with a lot of sensors.

# Variability Model and Management for Web Service: a Petri Net Based Approach

Li Xingyu, Hu Hao, Lü Jian  
StateKey Laboratory for Novel Software Technology,  
Nanjing University, Nanjing, Jiangsu, China  
{lixu,myou,jianlu}@ics.nju.edu.cn

## Abstract

*Variability management is an efficient solution to support service's reuse, but most of the existing variability models pay attention to service's functions and care little about the service's behavior that how these functions are invoked. In this paper, we provide a variability model based on Petri net that both the variable functions and the invocation constraint of these functions are handled. We use General Service to refer the service developed with variability for reuse; by variability binding service instance will be generated for use. Variable functions are modeled by transitions of Petri net; the service behavior is shown by the firing of transitions.*

## 1. Introduction

Variability is the ability of a system to be efficiently extended, changed, customized or configured. Building variability in web service can make the service developed with more adaptability and reusability. The existing variability models pay attention to service's functions, the variability and commonality are depicted, and static dependencies between variable functions are analyzed. But these models care little about the service behavior which is the invocation orders of these functions at runtime. At the same time, Petri net has already been used to model web service from the behavior point of view [8]. To strengthen the variability management of web service, we try using Petri net to model service with variability in this paper; both the variable functions and the invocation sequences of these functions are handled.

In this paper, we actually choose WF-net [1] which is a special case of Petri net to model the life cycle of service, it has only one input place  $i$  and only one output place  $o$ . The only one input place  $i$  corresponds to the call of service while the outplace  $o$  corresponds

to the exiting from service. Transitions of WF-net are extended to model both the service common functions and variable functions; service behavior is shown by the firing transitions; the sequence and choice structures are used to model the invocation order constraint of variable functions. The graphical expression of Petri net gives both the service developer and consumer an intuitionist view of service.

*General Service* is used to mention the service developed with variability for reuse, and *service instance* is the concrete service used by consumer.

The rest of this paper is organized as follows. Section 2 introduces variability issues and formal definition of General Service based on Petri net; Section 3 gives the variability management details that how to generate a service instance from the general service due to consumer's requirements; a case study is learned in Section 4; related work is discussed in Section 5; Section 6 is the conclusion of this work.

## 2. General Service with variability

### 2.1. Variability issues

When a variability model is given, there are some basic elements that a model should contain: they are variation point, variants, and dependencies. The variation point and variants capture the variability of service; and the dependencies constraint these variability.

**2.1.1. Variation point.** In this paper variable functions of service are modeled as variation points. The "variable function" has two meanings in web service: the function can appear in a service instance or not; the function appears in every service instance but there are various ways to implement such function. Since in the service realization, functions are represented by methods, we use service method directly instead of service function in the model.

To facilitate the service development, a classification to variation point is given. By whether a variation point is visible to end user or not there are external type and internal type; by whether a variation point is essential for the service there are mandatory type and optional type. Such definition follows Klaus Pohl [9].

Then variation point can be classified as: external and mandatory type, external and optional type, internal and mandatory type, internal and optional type.

Petri net transitions are extended to model these types' variation points. Seen as Figure 1. Then original transitions of Petri net correspond to common service methods.

Figure 1. four types variation points

**2.1.2. Variant.** For every variation point, there can be one or more corresponding variants to show how the variability varies. For the mandatory type variation point, there are two or more corresponding variants; and for the optional type variation point, there can be one or more variants.

**2.1.3. Dependencies.** There are three type dependencies between variability issues; they are dependencies between variation points, between variation point and its variants, and between variants of the same VP. In the existed variability models, the dependency between variation points are modeled from the static point of view that can only constraint the selection of variation point. In this paper we use Petri net to constraint both the execution dependencies and the selection dependency of variation points.

*Dependency between variation points.* Require dependency, which means one variation point's execution depends on another one's successful execution, it is modeled by the sequence structure of Petri net. Exclude dependency, the execution of one variation point at runtime excludes another one's execution, if variation point A excludes variation point B, it also means B excludes A, it is modeled by the choice structure of Petri net.

*Dependency between variation point and its variants.* For a variation point, there can be one or more variants corresponding for it. These variants are classified to mandatory type and optional type, that mandatory variants are bound once its variation point is selected while the *optional* ones are not.

*Dependency between variants that belong to same variation point.* For variants that belong to one variation point, they can be mutually exclusive or coexist with each other at runtime. We use *1to1* constraint to mention the previous situation that only one variant can be chosen at runtime, and *1to m* constraint to mention the latter situation that most *m* variants can be chosen at the same time.

Figure 2. VP is a variation point, v1 to vn are its variants

## 2.2. Formal definition of General Service

After the prepare work, here we give the formal definition of general service and the dependencies of variability issues based on Petri net.

**Definition 1 (General Service):** A general service  $GS$  is a tuple  $(I_{GS}, P_{GS}, M_{GS}, P, T, F, i, o, TM)$  with

- $I_{GS}$  is the identification of  $GS$ ,
- $P_{GS}$  is a set of properties related to  $GS$ ,
- $M_{GS} = M_C \cup M_V$  is a set of public available methods of  $GS$ ,  $M_C$  is the set of common methods and  $M_V$  is the set of variable methods;
- $P$  is a finite set of places,
- $T = T_C \cup T_V$  is a finite set of transitions, such that  $T_C$  is the set of common transitions,  $T_V$  is the set of four types variable transitions, and  $P \cap T = \emptyset$ ,
- $F$  is a set of directed arcs and  $F \in (P \times T) \cup (T \times P)$ ,
- $i$  is the input place of  $GS$ , where for no  $t \in T$ , such that  $(t, i) \in F$ ,
- $o$  is the output place of  $GS$ , where for no  $t \in T$ , such that  $(o, t) \in F$ ,
- $TM = TM_C \cup TM_V$  is a labeling function, such that  $TM_C : T_C \rightarrow M_C \cup \{\varepsilon\}$  label a common transition with a service method's name, or  $\varepsilon$  when there is no corresponding method;  $TM_V : T_V \rightarrow M_V$  label variable point to a variable method's name,

Let  $t^*$  be a fresh identifier not in  $GS$ , the new labeled Petri net

$GS^* = (P, T \cup \{t^*\}, F \cup \{(o, t^*), (t^*, i)\}, i, o, TM \cup \{t^* \rightarrow \tau\},)$  is Strongly Connected.

Definition 4 to 7 are the prepare definitions of the Definition 8.

**Definition 4 (Service State)** The service state  $r$  of the general service  $GS$  is a set denoting the marking of the net. For every service behavior model,  $\{i\}$  is the initial marking  $M_0$  denoting service creation while  $\{o\}$  is the state of service completion.

**Definition 5 (Firing transitions)** A transition in the general service  $GS$  can be fired under Life Cycle State  $r$  when the transition is enabled. A transition  $t$  is enabled if 1) each input place of  $t$  has a token; 2) the method  $m$  associated with  $t$  is invoked. After the performance of  $t$  which is in fact the execution of the method  $m$ , all the input places are removed and the output places are added to the new Life Cycle State  $r'$ . This can be represented by  $r|t\rangle r'$ , and  $r'$  is directly reachable from  $r$ .

**Definition 6 (Reachability Graph)** A Reachability Graph  $G$  is a tuple  $(\bar{r}_0, E)$ , in which  $E \subseteq \bar{r}_0 \times \bar{r}_0 \times TM(T)$ ,  $(r_i, r_j, TM(t)) \in E$ , if and only if  $r_i|t\rangle r_j$ .

**Definition 7 (Method Sequence)** A legal Method Sequence  $\langle m_1, \dots, m_n \rangle$  can be derived from its Reachability Graph of  $GS$  by an algorithm based on depth-first-search framework. The set of all the legal method sequences of  $GS$  is denoted as  $LMS_{GS}$ .

**Definition 8.1 (Dependency between variation point):** for variation points  $VP_A$  and  $VP_B$ , their corresponding methods in variability model are  $m_A$  and  $m_B$ ,

- $VP_A$  Requires  $VP_B$ , means for any  $lms \in LMS_{GS}$ , if  $m_A \in lms$ , then  $m_B \in lms$ , and  $lms$  always shown as  $\langle \dots, m_B, \dots, m_A, \dots \rangle$ ;  $VP_A$  Excludes  $VP_B$ , means for any  $lms \in LMS_{GS}$ , if  $m_A \in lms$ , then  $m_B \notin lms$ ; and if  $m_B \in lms$ , then  $m_A \notin lms$ .

**Definition 8.2 (Dependency between variants and its variation point):** for mandatory type variant  $v$ , after the variants binding of the variation point it belongs to, there will always:

- $\exists lms \in LMS_{GS}$ , that  $v \in lms (1 \leq i \leq n)$

**Definition 8.3 (Dependency between variants):** for variants  $v_1, v_2, \dots, v_n$  that belong to one variation point, after the variants binding replace the variation point with its corresponding variants,

- The dependency between them is *1to1*, then for any  $lms \in LMS_{GS}$ , if  $v_i \in lms (1 \leq i \leq n)$ , then  $v_j \notin lms (j \neq i)$ ; the dependency between them is *1tom*, then for any  $lms \in LMS_{GS}$ , then most  $m (1 < m \leq n)$  of these variants can appear in  $lms$ .

### 3. Variability binding management

When consumer needs a concrete service to use, it can generate a service instance from the general service by variability binding. To do the binding work, a Petri net based model is given for the consumer to describe its requirements which include such information: the functions needed, and the invocation trend of these functions.

**Definition 9 (Service Request):** A service request  $SR$  is a tuple  $(I_{SR}, P_{SR}, M_{SR}, P, T, F, i, o, TM)$  with

- $I_{SR}$  is the service identification that the consumer requires,
- $P_{SR}$  is a set of properties of the required service,
- $M_{SR}$  is the set of methods that this  $SR$  requires,
- $P$  is a finite set of places,
- $T$  is a finite set of transitions, and  $P \cap T = \emptyset$ ,
- $F$  is a set of directed arcs and  $F \in (P \times T) \cup (T \times P)$ ,
- $i$  is the input place of  $SR$ , where for no  $t \in T$ , such that  $(t, i) \in F$ ,
- $o$  is the output place of  $SR$ , where for no  $t \in T$ , such that  $(o, t) \in F$ ,
- $TM : T \rightarrow M \cup \{\varepsilon\}$  is a labeling function, label transitions with methods' name of  $SR$ ,  $\varepsilon$  shows there is no corresponding method for this transition;

Let  $t^*$  be a fresh identifier not in  $SR$ , the new labeled Petri net  $SR^* = (P, T \cup \{t^*\}, F \cup \{(o, t^*), (t^*, i)\}, i, o, TM \cup \{t^* \rightarrow \tau\})$  is strongly connected.

The related definition of service request, e.g. Reachability graph and Method sequence are same to the general service.

The binding work includes three phases: check whether all the mandatory type variable points are contained in the service request; verify whether the variation points chosen by consumer follows the dependencies constraint defined in general service; reply these chosen variation points with their variants.

### 4. Case study

In this section, we use a travel assistant service example to show how this approach works.

Suppose the scenario is that: an online travel assistant can provide functions such as ticket book and hotel book to facilitate travelers. So several travel companies decide to supply such service to their customers, but these companies have different requirements for the service due to their financial constraints or management strategies. And for the same company there may be different types of users such as common users or VIP users that different quality services are needed for them. In such situation, service with variability is needed to depict and handle these companies' requirements instead of develop individual services for every company.

First, by collect different companies' requirements or by the experience, the developer can get the

knowledge that what functions the travel assistant service should have, then by analysis, these functions are divided to common ones and variable ones. For a travel assistant, the common functions are: login, user's personal information update, and logout; the other six functions are variable ones.

How to get the variable functions is not the attention of this paper, here we just suppose the travel assistant should have such functions: login, authorize, update user's personal information, ticket book, hotel book, pay for the book, cancel book, and make log record for the user's operation. The variation points are seen in table 1, the general service of travel assistant is shown as Figure 3.

**Table 1.** variation points of travel assistant

VP	Type	Variants			Dependencies between VP	
		variant		Dependency between variants	Require	Exclude
		mandatory	optional			
Authorize	IO	common user	vip	1to1		
TicketBook	EM		train, fly	1to1		
LogRecord	IO	localDataBase	globalDataBase	1to2		
HotelBook	EO	hotelBook			TicketBook	
Pay	EM	cash	creditCard	1to2	TicketBook, HotelBook	Cancel
Cancel	EO	cancel			TicketBook, HotelBook	Pay

**Figure 3.** general service of travel assistant

Then travel companies can generate service instance from the general one by their own requirements. For example a service request is given as Figure 4(a) shown, it contains the mandatory variation point “TicketBook” in general service; in the general service, “Pay” requires “TicketBook”, since  $LMS_{SR} =$

{<Login, Ticketbook, Pay, Logout>, <Login, updatePersonalInfor, Ticketbook, Pay, logout >}, the service request follows such constraint; then by replacing variation points with their variants, the service instance used by consumer is shown as Figure 4(b).

**Figure 4.** service request and the service instance

## 5. Related Work

We do the comparison work from two aspects: the model point of view and the variability management of web service.

### *Variability model.*

Variability model and management has been well researched and successfully used in Software Product Line. There are several variability modeling techniques have been developed, e.g. FODA, featureRSEB, Cardinality-Based Feature Modeling, COVAMOF, OVM [2]. Among these models, Feature Diagram[10] is a mostly used foundation to describe variability. These model techniques model variability issues following function decomposition fashion.

Comparing to these models, we use Petri net as a formal basic to model variability, the model proposed in this paper can express both functional and behavior information that handles what is variable and constraints on how to vary.

### *Variability management of web service.*

Since web services refer to the networked and modular applications as well as a set of enabling technologies such as SOAP, WSDL, UDDI and emerging Web services flow specifications like BPEL4WS, there are existing work treat variability management of web service. e.g.. [3] [4] [5][6][7].

[3] analyzes three sources of variability in web service that are WSDL documents, web service endpoints, and web service business logic. In [4] variabilities are divided to two perspectives: an architecture-oriented to describe those aspects related to protocols, environments, distribution, and a task-oriented to describe the functions of a web service. For the architecture-oriented variability, WSDL elements, UDDI items, and protocol type are modeled as variation point; for the task-oriented variability service functions are modeled as variation point. In [7], types of variability are given as: workflow variability, composition variability, interface variability and logic variability. A systematic service oriented analyzes and design process is presented for developing highly adaptable services.

These works try to handle all variability involved with web service from service entity to related technologies. Compares to these works, we pay attention to individual service entity, a formal model is given base on Petri net that variability of the service's function and behavior are represented and managed.

[5] and [6] are about the service entity, they treat web service as member of a product family, feature diagram is used to describe service component with

variability, service behavior information are not mentioned.

[3] mentions service business logic variability like service behavior in our work but didn't illustrate details; in [4] service function are modeled to show if a function exist or not, but don't show how these functions are invoked; [7] gives a process to solve the logic variability of web service but lacks the model to capture such variability.

## 6. Conclusion

This paper gives a Petri net based approach to model and manage variability in web service. General Service is given to represent service with variability; for the service consumer, it gives its requirements shown as service request to describe what functions the consumer needs, and how these functions will be used (behavior); after the variability binding, a service instance is generated to service consumer for use.

Related tool will be developed next to support this approach.

# Feasibility of PKC in Resource-Constrained Wireless Sensor Networks

Al-Sakib Khan Pathan and Choong Seon Hong

Department of Computer Engineering, Kyung Hee University, South Korea

*spathan@networking.khu.ac.kr, cshong@khu.ac.kr*

## Abstract

*In this paper we present a detailed review of the works on public key cryptography (PKC) in wireless sensor networks (WSNs). In the early days of sensor networks, public key cryptography was thought to be completely unfeasible considering its computational complexity and energy requirements. By this time, several works have proved that the lightweight versions of many well-known public key algorithms can be utilized in WSN environment. With the expense of a little energy, public key based schemes could in fact be the best choice for ensuring data security in high-security demanding WSN applications. Here, we talk about the notion of public key cryptography in WSN, its applicability, challenges in its implementation, and present a detailed study of the significant works on PKC in WSN.*

## 1. Introduction

Security in wireless sensor network (WSN) has a great number of challenges, ranging from the nature of wireless communications, constrained resources of the sensors, unknown topologies of the deployed networks, unattended environment where sensors might be susceptible to physical attacks, dense and large networks, etc. Each of these issues in fact leads to different research direction. Nonetheless, considering all the different topics of research in WSN security, Public Key Cryptography (PKC) most probably is the hottest topic in recent times.

This is generally perceived that PKC is complex, slow, resource hungry, and as thus not at all suitable for use in ultra-low power network environments like wireless sensor networks. It is therefore a common practice to emulate the asymmetry of traditional PKC services by using a set of protocols based on

symmetric key cryptography (SKC). The main reason for using SKC is that it is comparatively less resource-hungry than PKC. However, with respect to key management, SKC could be inflexible and more difficult to handle than PKC. This is because often the keys for the sensors need to be generated in huge numbers and in many cases they need to be stored in the memories of the sensors prior to their deployment. Such type of pre-distribution of keys could really be cumbersome when a large sensor network with large number of sensors is to be deployed.

In contrast to the commonly held belief of the inefficiency and inapplicability of PKC in WSN, some researchers have come forward and proved that the lightweight versions of many well-known PKC schemes can be applied for tiny low powered sensors.

For implementing PKC-based schemes in WSN, there are mainly two approaches:

(a) Design and development of customized hardware so that they could be used in the sensor boards for supporting public key based operations and computations.

(b) Writing customized software or program that could support PKC operation or using lightweight versions of the public key based schemes.

A combination of hardware support and software optimization also works effectively for such types of implementations. So far, both from hardware and software perspectives, some works have already been done [1]. This paper presents a detailed survey on the applicable PKC-based schemes in WSN. The main objective of this work is to get a broad picture of the current research trend in applying high-standard cryptographic schemes in wireless sensor networks.

The rest of the paper is organized as follows: Section 2 briefly mentions the pros and cons of implementing public key cryptography in WSN, Section 3 presents the detailed survey on the feasible PKC-based schemes for wireless sensor networks, Section 4 discusses the advancements of sensor network technologies and future expectations, and Section 5 concludes the paper.

## 2. PKC in WSN: Pros and Cons

The sensors that build up the network are usually of inadequate memory, processing, and communication capabilities and their energy sources are also very limited. As an example, Crossbow MICA2 mote [2] is a well-known sensor node with an ATmega128L 8-bit processor at 8 MHz, 128KB program memory (flash), 512KB additional data flash memory, 433, 868/916, or 310 MHz multi-channel radio transceiver, 38.4 kbps radio, 500-1000 feet outdoor range (depending on versions) with a size of only 58 x 32 x 7 (mm). Usually it is run by TinyOS operating system and powered by 2 AA sized batteries. It could be realized that a device with this configuration cannot support security mechanisms that require executing a large amount of instructions. In addition, a sensor network usually contains a large number of sensors. The number of sensors in the network might directly affect the use of memory space of nodes, because often they store pre-distributed secret keys, keying information, or the codes to calculate pairwise secret keys between any pair of nodes in the network. Node failure due to high involvement in computation related activities is another problem that could also affect the network severely. If a node is busy relatively longer than other nodes (e.g., performing huge calculations related to security), it might lose its energy rapidly and can fail much sooner than other less active nodes.

Most of the sensor network applications need at least a certain level of security for the communications among the sensor nodes and the base station (BS). The minimum requirements for any type of secure communication are: data privacy, integrity, and authenticity. All of these could be provided by using efficient cryptographic mechanisms. SKC is usually viable on sensor nodes but the size and scalability issue sometimes makes its use inefficient. Again, because of the unattended feature of WSNs, often these networks are vulnerable to physical capture attack. If the nodes carry sensitive key information within themselves, the attackers could get that after physically capturing the sensors (if any other preventive mechanisms are not used). Considering this particular issue, it is much more efficient to use PKC as in this case the nodes only carry public key materials of the BS instead of private secret keys.

## 3. Review of PKC-Based Schemes in WSN

Most of the works related to PKC in WSN are conducted to fit the low-power characteristic of the sensor nodes. Both from software and hardware

perspectives, PKC-based schemes have shown reasonable performances. In this section, we present a detailed study on these exclusive research works.

### Gura et al. [3]

Gura et al., in their work [3], present a comparative analysis of Elliptic Curve Cryptography (ECC) and RSA on 8-bit CPUs. The authors note that they implemented ECC point multiplication and modular exponentiation on two exemplary 8-bit platforms in assembly code. As the first processor, they chose a Chipcon CC1010 8-bit microcontroller which implements the Intel 8051 instruction set. The CC1010 contains 32KB of FLASH program memory, 2KB of external data memory, and 128 bytes of internal data memory. As the second processor, they took an Atmel ATmega128 processor which is frequently used for sensor network research (for example in Crossbow motes). The ATmega128 is an 8-bit microcontroller based on the AVR architecture and contains 128KB of FLASH program memory and 4KB of data memory. For ECC, they implemented point multiplication for three SECG-standardized elliptic curves with some optimizations. For RSA, they implemented RSA-1024 on both of the chosen processors and RSA-2048 on the ATmega128 with some optimizations. Their experimental findings show that on both platforms, ECC-160 point multiplication outperforms the RSA-1024 private-key operation by an order of magnitude and is within a factor of 2 of the RSA-1024 public-key operation. In summary, Gura et al.'s work for the first time gave the practical idea about the applicability of PKC algorithms in small resource-constrained devices.

### Malan et al. [4]

[4] presents the first known implementation of elliptic curve cryptography over  $F_{2p}$  for sensor networks based on 8-bit, 7.3828 MHz MICA2 mote [2]. In this work the authors first demonstrate that the secret-key cryptography is tractable on MICA2 by instrumentation of TinyOS operating system. Then with their method of implementation of multiplication of points on elliptic curves, they argue that PKI (public key infrastructure) for distribution of secret keys is also tractable. The results show that public key based scheme is viable for the modern-era sensors. Breaking the myth of the inapplicability of public key cryptography in sensor networks, this work shows that public keys can be generated within 34 seconds, and that shared secrets can be distributed among nodes in a sensor network within the same, using just over 1

kilobyte of SRAM and 34 kilobytes of ROM, which could easily be provided by the state-of-the-art sensor nodes.

#### **Gaubatz et al. [5]**

In [5], the authors propose a custom hardware assisted approach which makes PKC feasible in WSN. In order to validate their claim, they present proof of concept implementations of two different algorithms; Rabin's Scheme and NtruEncrypt.

Rabin's Scheme was proposed in 1979 in [6]. It is based on the factorization problem of large numbers and is therefore similar to the security of RSA with the same sized modulus. The size of the modulus determines the security of the cipher. The disadvantage of RSA is that the algorithm necessary to implement both encryption and decryption is computation intensive. Rabin's scheme has asymmetric computational costs. It is only necessary to perform a simple modular squaring operation to encrypt a message. Therefore encryption can be preformed relatively efficiently, while the computational cost of the decryption algorithm is comparable to RSA. This asymmetrical property of Rabin's scheme is of significant practical importance in applications such as wireless sensor networks where encryption must be done on very low powered devices. On the other hand, NtruEncrypt [7] claims to be highly efficient and particularly suitable for embedded applications such as smart cards or RFID tags, while providing a level of security comparable to that of other established schemes, in particular RSA.

Taking these asymmetric encryption techniques, the authors analyze the viabilities based on chip area, security level, delay, average power, energy per bit, and throughput. Overall, this work shows that it is possible to design PK encryption architectures with power consumption of less than 20  $\mu$ W using the right selection of algorithms and associated parameters, optimization, and low-power techniques. This work also notes that it might be possible to achieve even better performance for self-powered sensors as this work was based on a regular ASIC (Application-Specific Integrated Circuit) standard cell library that was not specifically optimized for low-power.

#### **Watro et al. [8]**

TinyPK system demonstrated in [8] shows that a PK-based protocol is feasible even for an extremely

lightweight sensor network. TinyPK is a software-based implementation of public key system tested on UC Berkeley MICA2 motes [2]. Incorporating the use of TinySec [9] or any other symmetric encryption service for sensor networks, TinyPK provides the functionality needed for a sensor and a third-party to mutually authenticate each other and to communicate securely. The mote authentication technique, proposed in this paper can be used either to collect evidence that a mote field is valid or to validate a specific mote and to link future traffic to that mote. The notion of a mote credential makes the task of a spoofing a mote network much more difficult than in an environment without credentials. In a TinyPK protected environment, a single stolen and reverse engineered mote cannot be used to impersonate other motes with different credentials. This level of protection is achieved with very little overhead and has been shown to operate on the most limiting of sensor network platforms.

#### **Du et al. [10]**

[10] investigates how to replace the public key authentication with symmetric key operations that are much more efficient. The authors show that due to a unique property of sensor networks, public keys do not need to be authenticated in the same way as it is done in the Internet environment (i.e., using certificates); instead, public keys can be authenticated using one-way hash functions, which are much more efficient than signature verification on certificates. Their scheme uses all sensors' public keys to construct a forest of Merkle trees of different heights. By optimally selecting the height of each tree, they can minimize the computation and communication costs. They also introduce a trimming scheme based on sensor deployment knowledge. The results show that their scheme can save up to 86% of the energy for the public key authentication operation in WSN.

#### **Wander et al. [11]**

In [11], the authors present an analysis of energy consumptions of PKC schemes in wireless sensor networks. They also consider the impact of public key cryptography on battery life and compare PKC to other factors influencing energy consumption, such as idle listening, data reception and transmission, symmetric cryptography, etc. They quantify the energy costs in an 8-bit microcontroller platform with RSA and Elliptic Curve Cryptography (ECC) (energy costs of digital

signature and key exchange computations for RSA-1024, ECDSA-160, RSA-2048, and ECDSA-224). This work shows that: with a given amount of energy, the authors were able to perform 4.2 times the number of key exchange operations (including mutual authentication) with ECC-160 compared to RSA-1024. Overall, this work presents a detailed picture of energy requirements for PKC operations in resource constrained sensors which could be used as a good reference paper for other similar works.

#### **Gaubatz et al. [12]**

[12] shows that special purpose ultra-low power hardware implementations of public key algorithms can be used on sensor nodes. The authors in this work selected three low-complexity PKC schemes (Rabin's scheme, NtruEncrypt, and Elliptic Curve) and for each of the schemes they developed three basic encryption architectures in TSMC 0.13 $\mu$  CMOS standard cell technology. For comparing the inherently different algorithms and their feasibility for ultra-low power implementations, they chose algorithm specific parameter sets to provide approximately the same level of security. For Rabin's scheme, a modulus of 512 bits was selected, which generally provides a security level of around 60 bits. In ECC architecture, for arithmetic operations, a 100 bit prime field was chosen which could provide a security level between 56 to 60 bits depending on the confidence level one puts into the assumption that no significant cryptanalytic progress has been made. Finally, for NtruEncrypt, system parameters  $(N, p, q) = (167, 3, 128)$  were chosen to get a security level of around 57 bits. After analyzing the architectures in conjunction with the full algorithm descriptions, they estimated the overall power and bandwidth requirements of encryption and signature primitives.

Overall, in this work, the authors show that PKC tremendously simplifies the implementation of many typical security services and additionally reduces transmission power due to less protocol overhead.

#### **Blaß and Zitterbart [13]**

Blaß and Zitterbart [13], in their work present efficient and lightweight implementations of PKC algorithms relying on elliptic curves. They checked their codes by running on popular 8-Bit ATMEGA128 microcontroller which is used for MICA2 platform.

For the lightweight implementation of ECC, one of

the most important factors is the key size. In case of ECC, key size means the size of underlying finite field that is; if 53 bit keys are to be used, the elliptic curve must be over  $F_{2^{53}}$ . If the key size is smaller, it provides less security but faster computation. After a detailed primary analysis, the authors chose 113 bit key that means a curve over  $F_{2^{113}}$ . The argument for choosing this curve was that it could offer about 16 times more security than 109 bit keys which could be considered as enough security for today's hardware. For making the entire implementation easier and lightweight, they also considered some other optimizations for memory savings, point multiplications, handcrafting a source to the target platform, sophisticated loop-unrolling, etc.

This work presents the results of the implementations of various ECC-based algorithms; ECDH (Elliptic Curve Diffie-Hellman), El-Gamal (which relies on traditional discrete logarithm problem and that has been adopted to elliptic curves and ECDLP), and ECDSA (Elliptic Curve Digital Signature Algorithm).

#### **Gupta et al. [14]**

In [14], the authors show that ECC not only makes public-key cryptography feasible on "mote"-like, embedded devices, but also it allows one to create a complete secure web server stack that runs efficiently within very tight resource constraints. They present their HTTPS stack, named Sizzle which has been implemented on multiple generations of the Berkeley/Crossbow motes where it runs in less than 4KB of RAM, completes a full SSL handshake in 1 second (session reuse takes 0.5 seconds), and transfers 1 KB of application data over SSL in 0.4 seconds.

Sizzle brings the Internet's dominant security protocol (SSL) to devices with significant computational, memory, and energy constraints. It uses highly optimized implementations of PKC to offer scalable key management and end-to-end security without sacrificing efficiency. Sizzle running on the Berkeley/Crossbow Mica2dot mote represents the world's smallest secure web server in terms of both physical dimensions and resource utilizations.

#### **Jing et al. [15]**

C4W presented in [15] is basically an identity-based public key infrastructure specially designed for WSNs.

Usually any Identity-Based Cryptosystem (IBC) requires heavy computations. However, to reduce the processing burdens, the IBC algorithm of C4W is made lightweight based on ECC optimization techniques in [3] and Combined Public Key (CPK) cryptosystem presented in [16]. The authors in this work show that their identity-based scheme consumes less energy as it is certificateless and thus it is efficient in terms of computation and communication costs.

### **Nyang and Mohaisen [17]**

A distributed and cooperative PK authentication is proposed in [17]. This work is mainly a theoretical work without practical implementation. To facilitate the proposed protocol, some modifications in the MAC frame are needed. In this cooperative mechanism, each node stores a limited number of hashed keys for other nodes which help in the authentication procedure during public key operation. According to [17], this scheme is free from any cryptographic operations, which is designed to make it fit for the constrained resources of the sensors. However the major drawback of the proposed method is that it is designed only for one hop authentication, which makes it impractical and inefficient for use in usual multi-hop WSNs. However, this scheme could be used for individual clusters with cluster heads, if clustering is used in the network. Hence, there remains enough scope of further investigation and enhancement of the protocol to make it feasible for traditional wireless sensor networks.

### **Murphy et al. [18]**

Murphy et al. [18] show that it is possible to implement PK algorithms on resource constrained sensor node platforms. Using a hardware/software co-design approach, they successfully map a public key cryptosystem based on Rabin's scheme onto the motes developed by Tyndall National Institute. The implementation was prototyped on 25mm cube modules provided by the Institute [19]. These cubes consist of several different programmable modules that are interchangeable. The cubes were configured so that each node included a low power 8-bit Atmel microcontroller, a Spartan-IIE FPGA, and a RF transceiver. For their implementation, the different modules were synchronized by a shared 4 MHz clock.

Their implementation mainly focused on efficient architectures that execute the public key algorithms using minimal resources. Their finding is that the

hardware implementation of the encryption algorithm is much faster than the software implementation. Software implementations of the algorithm are also realizable and have the benefit of low cost and high flexibility. However the time necessary to perform encryption and decryption is significantly increased by using a software-only approach.

### **Piotrowski et al. [20]**

Piotrowski et al. [20] investigate four types of nodes; MICA2DOT, MICA2, MICAz, and TelosB and estimate the power consumptions for RSA and ECC operations. Their work presents detailed results of the implementations of RSA-1024, ECC-160, RSA-2048, and ECC-224 on the mentioned platforms.

Based on the results, the authors conclude that: transmission power is not an important factor when comparing cryptographic algorithms. Even sending a 2048 bit RSA signature by a transceiver that requires 1.0  $\mu$ Ws/bit, needs not more than 2 mWs for one signature. This is at least one order of magnitude less than the energy consumption required for computation of the cryptographic operations. However, for large multi-hop networks, it might be important. In that case, a large signature increases the overall transmission power consumption in the network.

### **Yang et al. [21]**

In [21], the authors implement minimized multivariate PKC on Low-Resource Embedded Systems. They illustrate most of their minimization techniques on a current variant in the family of multivariate PKC called the Enhanced TTS (enTTS). TTS [22] is a consequence of the public-key cryptosystem TTM (Tame Transformation Method) and shares many of its superior properties, resulting in low signature delays, fast verification, and high complexity. To evaluate the performance of enTTS on modern sensor nodes, they benchmark enTTS on the Tmote Sky mote. Tmote Sky is equipped with an 8 MHz Texas Instrument MSP430 microcontroller and a Chipcon CC2420 2.4 GHz radio that supports IEEE 802.15.4 wireless low-power medium access control standard. A typical sensor node like the Tmote Sky mote has a small working RAM (10 KBytes in this case), a slightly larger read-only program memory (48 KBytes), and a relatively large flash memory (1 MBytes) for storing collected raw data and other auxiliary information for its operations. The results

from this work show that multivariate schemes could be better contenders against the established PKC schemes if they are a lot better customized and optimized for use in wireless sensor networks.

#### **Batina et al. [23]**

In [23], the authors present a low-cost PKC-based solution for security services such as key-distribution and authentication for WSNs. They propose a custom hardware assisted approach to implement ECC with the goal of obtaining stronger cryptography and minimizing the power consumption.

They also present the details of their designed Elliptic Curve Processor (ECP). Their ECP has the operational blocks: a Control Unit (CU), an Arithmetic Unit (AU), and Memory (RAM and ROM). In ROM, the ECC parameters and some constants could be stored. The RAM contains all input and output variables and it communicates with both the ROM and the ALU. The CU controls the scalar multiplication and the point operations. In addition, the controller commands the ALU which performs field multiplication, addition, and squaring.

With this hardware assisted approach, the authors present their analysis of ECC algorithm and some positive results to allow the use of PKC in WSNs.

#### **Bertoni et al. [24]**

A work on hardware implementation of PKC for elliptic curve over binary extension fields is proposed in [24]. The goal of this work is to evaluate the energy costs of different ECC implementations for low-end systems, and to propose a new hardware coprocessor architecture. In their implementation of the dedicated coprocessor, the operands had a size of 163 bits, while the existing data path was of 8 bits only. They designed two different hardware devices in VHDL, and synthesized them using the 0.18  $\mu\text{m}$  CMOS technology library by ST Microelectronics. Using the Synopsys tools Design Compiler and PrimePower, they obtained the area occupancy, the critical path, and the power consumption for each implementation.

By using their coprocessor, they show that achieving the goals of low energy consumption, reduced silicon area requirements, and significant speed-up (compared to software solutions) are possible. This could be a feasible hardware assisted solution to get improved performance of ECC implementations in WSNs without degrading other performance parameters.

#### **Arazi et al. [25]**

[25] presents an efficient ECC-based method for self-certified key generation in resource-constrained sensor nodes. In particular, the authors provide implementation results on the Intel Mote 2 sensor network platform [26] which demonstrate that such key generation can be established in the order of 60 msec while consuming less than 30 mJ.

The methodologies developed by the authors were implemented on Intel Mote 2 platform [26] which has an Intel PXA271 XScale processor running at a clock frequency ranging from 13 MHz to 416 MHz. The core frequency could be dynamically set in software, allowing the designer to carefully adjust the timing/power trade-off to optimize performance of a specific application.

For implementation of the algorithms, some of the functions used in TinyECC [27] were taken. This package targeted the MICAz platform and provided a basic library of ECC-based functions, including scalar multiplication and exponentiation operations. Also some customizations for the XScale processor (including 32-bit operation optimizations) were carried out. In addition, supplementary functions, e.g., Montgomery arithmetic, were added. All codes were written in NesC running on TinyOS operating system.

#### **Haque et al. [28]**

[28] proposes an efficient PKC based security architecture for WSNs with relatively less resource requirements. The proposed security architecture comprises basically of two parts; a key handshaking scheme based on simple linear operations and the derivation of decryption key by a receiver node. The architecture allows both base-station-to-node or node-to-base-station secure communications, and node-to-node secure communications. Analysis and simulation results show that the proposed architecture ensures a good level of security for communications in the network and could effectively be implemented using the limited computation, memory, and energy budgets of the current generation sensor nodes.

#### **Ugus et al. [29]**

In [29], Ugus et al. implement elliptic curve and finite field arithmetic operations on MICAz mote. The experimental results presented in this work show that scalar point multiplication with a random base takes

1.03s, while it takes only 0.57s in the case of fixed point multiplication, when 2 pre-computed points are employed. Moreover, they claim to achieve at least 44% faster operation than the best previous result for fixed point multiplication. The implementation of the elliptic curve EC-ElGamal encryption shows that the encryption operation only takes 1.19s, when in total 4 pre-computed points are utilized.

#### **Großschädl et al. [30]**

In [30], the authors implement two protocols. The first protocol employs a lightweight variant of the Kerberos key transport mechanism with 128-bit AES encryption. The second protocol is based on ECMQV, an authenticated version of the elliptic curve Diffie-Hellman key exchange, and uses a 256-bit prime field  $GF(p)$  as underlying algebraic structure. They evaluate the energy costs of both protocols on a Rockwell WINS node equipped with a 133 MHz StrongARM processor and a 100 kbit/s radio module. The evaluation considers both the processor's energy consumption for calculating cryptographic primitives and the energy cost of radio communication for different transmit power levels.

Their experiments show that the communication energy cost of Kerberos is between 39.5 mJ and 47.5 mJ (which basically depends on the transmit power level). In their architecture, three of the four Kerberos messages are encrypted. When using 128-bit AES, the overall energy required for encryption and decryption of the messages is less than 0.1 mJ. As a whole, the Kerberos protocol is characterized by high communication energy cost, while the energy needed for encryption or decryption is almost negligible.

They implement the ECDH/ECMQV key exchange using a 256-bit prime field as underlying algebraic structure in order to match the security level of Kerberos key transport with 128-bit AES encryption. According to their findings, a point multiplication over a 256-bit prime field takes approximately  $4.25 \cdot 10^6$  clock cycles on a StrongARM processor when implemented as their architecture. The results show that the overall energy cost of Kerberos key establishment is between 39.6 mJ and 47.6 mJ, while ECMQV key exchange requires an energy of between 79.0 mJ and 84.6 mJ. In other words, the energy consumption of ECMQV and Kerberos differs merely by a factor of between 1.78 (for high transmit power) and 1.99 (for low transmit power).

## **4. Other Works and Future Expectations**

Other than the mentioned works, [31] looks at several additive homomorphic public key encryption schemes and their applicability to WSNs. The authors in this work provide recommendations for selecting the most suitable PK schemes based on the topologies and the scenarios of WSNs. Also, in a recent work, Roman and Alcaraz [32] talk about the applicability of public key infrastructures in wireless sensor networks.

Although PKC in WSN is one of the relatively new areas, a lot of researchers have tried to deal with this issue within a short period of time. Considering all the works done so far, it can be realized that the abundant use of PKC in WSN is just a matter of time. Moreover, next generation sensor nodes are expected to have more energies. They can have ultra-low power circuitry with so-called power scavengers such as Heliomote [33], which allows continuous energy supply to the nodes. At least 8-20 $\mu$ W of power can be generated using MEMS-based power scavengers [34]. Also some other solar-based systems have been developed by this time which could even be able to deliver power up to 100mW for MICA Motes [35].

All these positive signs and achieved results indicate that: with the advancements of fast growing technology for sensors, PKC will no longer be impractical for WSNs, though still now it is expensive for the current generation sensor nodes.

## **5. Conclusions**

Public key cryptography is often ruled out considering the limitations of resources of sensors. The reason is that the data security is not the only requirement for wireless sensor networks. There are also many other aspects which require sharing of the same resources in the sensors. Hence, the main focus is to use cryptographic methods that can ensure the best level of security for sensor data with the least costs. Using of the lightweight versions of some PKC-based schemes can be the solution for this.

Various works presented in this paper show good signs of the practicality of public key cryptography. Based on our findings and current research trend, we can conclude this article with the comment that: public key cryptography is feasible for the current generation sensors with a little expense of energy. Advancements of sensor capabilities might allow abundant use of public key cryptography in wireless sensor networks in near future.

## Abstract

*The decentralized security management in a pervasive computing environment, requires apportioning the environment into several security domains. In each security domain, an administrator (we call it authority) is responsible for specifying the security policies of the domain. Overlapping of security domains results in the requirement of cooperative security management in the shared/ overlapping domains. To satisfy this requirement, we propose an abstract security model, as well as its supplementary calculus of composite authorities. The security model is based on deontic logic and is independent of the domains' heterogeneity. The model's policy language (we call it MASL) enables multiple authorities to specify their domain policies, including obligations and authorizations. Our proposed calculus of composite authorities, enables the security system to infer policy statements of composite authorities from the cooperating primitive authorities. The calculus offers three styles of cooperative administration including collaborative, disjunctive, and delegative administration. Abstraction and automated composite authorities' policy derivation are the main advantages of the proposed logical model.*

## 1 Introduction

In pervasive computing environments, resources like information and services are accessible anywhere and anytime via any devices. Thus, users may access resources and services remotely. There are different sorts of users and services and some of them may be unknown or not predefined [13]. The distribution of resources in these environments, forces us to employ decentralized security management. In this approach, the environment is divided into the number of domains based on different factors like geographical situation. For each domain, there is a security agent with an administrator (we call it *authority*) and each resource, like

a service, can register itself in one or more domains. Thus, the authorities are responsible for preserving the security of resources that are under their protection.

The requirement of policy specification in different domains by different authorities motivated us to propose a multi-authority version of deontic logic to specify security policies including obligation policies as well as authorization ones. The unresolved problem in multiple security domains is the overlapping of domains (which results in shared domains or subdomains) and their administration issues in such a situation. The main contribution of this paper is proposing a logical system to enable cooperative administration in the overlapping or shared domains. To this aim, three styles of cooperative administration are introduced; collaborative, disjunctive, and delegative administration. The axioms that enable us to infer security policies specified by composite authorities (which are obtained based on the cooperative administration styles), as well as the semantics of the proposed syntax, and a soundness proof of the logical system are described in the rest of this paper.

The rest of this paper is organized as follows. After introducing the relative researches in the next section, we introduce our proposed security model and its logical security policy language in section 3. In section 4, the calculus of composite authorities accompanying with three styles of administration is presented. Section 5 demonstrates our proposed process for enforcing obligation policies and access control. In section 6, we present a case study. Finally, in the last section, we conclude the paper.

## 2 Related Work

Using logics to tackle the problems of specifying and proving the security of distributed systems started from 1988 by Glasgow [8]. Since then, various sorts of logic have been used to model user beliefs and inference abilities, specification of security policies, context and temporal constraints, and historical interactions in distributed envi-

ronments like pervasive computing or ubiquitous environments.

The access control logic proposed by Abadi, Lampson, and others in [2], provides a logical system (based on the modal logic) for specifying composite principals, access control lists, and access delegation in distributed systems. The first attempt in providing a general framework for authorization made by Woo and Lam in [22]. They proposed the use of Default logic, which is a kind of non-monotonic logic, to specify authorization policies. Undecidability of the logic proposed by Woo and Lam, encouraged Jajodia, *et al.*, [10, 9] to define an authorization specification language (ASL) based on the stratified first-order logic that is not only decidable but also linear. Barker, *et al.*, [5] took a similar approach in specification of multiple types of policies (with emphasis on RBAC policies) using stratified Horn-clauses logic. Freedom in using constrained negation in this language in comparison with ASL [9], encouraged the authors to leverage a partial-deduction approach for specializing access control on deductive databases in [4]. Kushik, *et al.*, [15] introduced a constraint logic programming (CLP) based framework to determine access to partial or full ontologies in order to preserve confidentiality in open World Wide Web. In this framework, policies are CLP programs (which are stratified Horn clauses with constructive negation) that prevent disclosing sensitive portions of an ontology by renaming or hiding some concepts or relationships.

We propose and use a multi-authority version of deontic logic in this paper. Using deontic logic in access control was considered by Cuppens, *et al.* [6] for information flow control. Kagal, Finin, and others proposed a policy language called Rei [14] based on Semantic Web languages (RDF and DAML+OIL) for pervasive computing environments. In Rei, concepts of deontic logic like permission, obligation, and prohibition were used. However, this policy language does not support multiple administrators' policies resolution and also cooperative administration.

In this paper we propose a kind of modal logic (multiple-authority version of deontic logic) to provide a platform for specifying security policies by multiple administrators in pervasive and distributed environments abstract from implementation details. This enables us to infer composite authorities' policies from the policies specified by primitive administrators. Multiple security domains were introduced in some papers to split the environment into several administration domains. This concept is used in [13] as a security framework in a pervasive computing environment and it is used in [3] for mobile computing environments in controlling mobile users' accesses to their home and visiting (foreign) domains. Furthermore, a policy language named X-RABAC is proposed by Joshi, *et al.* [12, 18], for multi-domain environments. In these researches the security control on shared resources is realized through the specification

of mediation policies [19] and enforcing them for inter domains access control [21]. The approach proposed in this paper, tries to get rid of specifying inter domain security policies through automatic inference of composite authorities' policies. A composite authority is a representative of an administrator that states security policies of the shared domains based on the policies of the participating individual domains.

### 3 Logical Security Model

In distributed and pervasive computing environments, the environment is usually separated into multiple security domains [13, 20]. Each security domain has a security manager, henceforth called *authority*. In each domain a set of resources (objects) are protected based on the domain's security policies. The duty of an authority in a domain is composing the security policies of the domain. It is worthwhile to note that domains may have got overlapped with each other. In this way, the owner or creator of each resource (object) can register with one or more domains and rely on their authorities' policies to secure his/her resource.

To state security policies by each domain's authority, we need to establish a policy language. MASL (multi-authority security policy language), which is presented in this paper, is a logical language that enables authorities to compose their security policy rules, and to infer implicit policy rules from the explicit ones. MASL is a kind of modal logic languages that is founded on the multi authorities version of deontic logic to specify *authorization* as well as *obligation* policies. Statements like it is obligatory that (denoted by OB), permissible that (denoted by PE), and impermissible that (denoted by IM) can be specified by this logic.

#### 3.1 Multi-Authority Security Policy Language (MASL)

The alphabet of MASL includes a set of context and conditional propositions, a set of names (terms), a set of context and conditional predicates in which each predicate  $p_k^{i_k}$  is an  $i_k$ -ary relation on terms like  $p_k^{i_k}(t_1, t_2, \dots, t_{i_k})$ , a definite set  $AU$  of primitive authorities and composite authorities resulted from composing the primitive ones (using the calculus of authorities introduced later), deontic statuses symbols including OB, PE, and IM, the propositional primitive relators  $\wedge, \neg$  (we may use other abbreviations like  $\vee, \rightarrow$ , and  $\leftrightarrow$ ), and auxiliary symbols (, and ).

**Definition 1 (Formula)** A formula is defined as follows:

- every proposition like  $x_i$  is an atomic formula.
- if  $t_1, t_2, \dots, t_k$  are terms and  $p$  is a  $k$ -ary predicate, then  $p(t_1, t_2, \dots, t_k)$  is an atomic formula.

- if  $\alpha_i$  and  $\alpha_j$  are formulas then so are  $\alpha_i \wedge \alpha_j$  and  $\neg\alpha_i$  (and analogously  $\alpha_i \vee \alpha_j$ ,  $\alpha_i \rightarrow \alpha_j$ , and  $\alpha_i \leftrightarrow \alpha_j$ )
- if  $ds$  is a deontic status,  $u$  is an authority and  $\alpha$  is a formula then  $ds_u \alpha$  is a formula.

In this definition,  $ds_u \alpha$  intuitively means an authority  $u$  declares that the status  $ds$  is established for  $\alpha$ . For example,  $OB_u \alpha$  means  $u$  states that it is obligatory (necessary) to be the case  $\alpha$ .

Following the above language, if we suppose to have an access predicate,  $\mathbf{do}(s, o, a)$  on terms of subjects (or access requesters denoted by  $S$ ), objects (or resources denoted by  $O$ ), and actions (denoted by  $A$ ), security policy rules are defined as follows.

**Definition 2 (Security Policy Rule)** A security policy rule (or in short policy rule) stated by an authority  $u$  is a formula of the form:  $\alpha \rightarrow ds_u \beta$  where  $\beta ::= \mathbf{do}(s, o, a) | ds_v \beta$ ,  $\alpha$  is a formula,  $ds$  is a deontic status,  $u$ , and  $v$  are authorities,  $a \in A$  is an action term,  $s \in S$  is a subject term, and  $o \in O$  is an object term.

Note that a security policy of the form  $ds_u \mathbf{do}(s, o, a)$  can be defined on the object term  $o$  by authority  $u$ , if objects described by the term  $o$  are registered in the security domain of authority  $u$ . In fact, MASL does not control administrative rights on specifying security policies and we should do the above control at the implementation level. Furthermore, as we describe later in this paper, a security policy like  $ds_u(ds_v \mathbf{do}(s, o, a))$  is valid whenever an authority  $u$  has administration delegation right of authority  $v$ .

In specifying security policy rules by authorities using the above language, we have this assumption that each authority is not allowed to have inconsistent policy rules. The set of policy rules specified by authorities and the statements that are describing the context, construct the knowledge base (denoted by KB) in our model.

### 3.2 Proof Theory of MASL

The axioms (except the axioms of the composition of authorities) and inference rules of MASL are as follows.

- [A1.] If  $p$  is a tautology of propositional logic,  
then  $\vdash p$  (TAUT)
- [A2.]  $\vdash OB_u(p \rightarrow q) \rightarrow (OB_u p \rightarrow OB_u q)$  (OB-MK)
- [A3.]  $\vdash OB_u p \rightarrow \neg OB_u \neg p$  (OB-MD)
- [A4.]  $\vdash PE_u p \leftrightarrow \neg OB_u \neg p$  (PE-Def)
- [A5.]  $\vdash IM_u p \leftrightarrow OB_u \neg p$  (IM-Def)
- [R1.] If  $\vdash p$  and  $\vdash p \rightarrow q$ , then  $\vdash q$  (MP)
- [R2.] If  $\vdash p$  then  $\vdash OB_u p$  (OB-MO)

Axiom A1 (TAUT) subsumes propositional logic with in our logic. Axiom A2 (OB-MK) presents that if an authority like  $u$  states that a condition is obligatory, and its antecedent is obligatory from  $u$ 's view point, then the consequence is obligatory from  $u$ 's view point as well. Axiom A3 (OB-MD) tells if  $u$  states that  $p$  is obligatory, then its negation is not obligatory from  $u$ 's view point. The axioms A4 to A5 define the deontic statuses PE, and IM based on the OB (obligation) status. We can easily take one of these four statuses as a primitive and define others. Inference rule R1 (MP) is Modus-Ponens rule. Inference rule R2 (OB-MO) states that if something is a theorem, then its obligation from any other authority's point of view is also a theorem.

### 3.3 Semantics of MASL

To present the semantics of the proposed logic, we use a Kripke structure in which domain of objects and interpretation of names and predicates are included. Note that in this paper, quantifiers (like universal and existential ones) are from meta language and they do not belong to the MASL language. A Kripke-style structure of the presented logic is a 5-tuple like  $\mathcal{M} = \langle W, R, \Phi, \Delta, I \rangle$ , where:

- $W$  is a non-empty set of possible worlds. Each world is a global authorized state in the environment.
- $R$  is an interpretation function that maps each authority to a binary relation on  $W$ . This mapping function for primitive authorities is defined as  $r = AU \rightarrow \mathcal{P}(W \times W)$  and for composite authorities is defined as an extension on  $r$  which is presented in section 4. Each relation  $r(u)$  must be reflexive and serial, i.e., for all  $u \in AU : \forall w \in W : w \in r(u)(w)$  [reflexiveness] and  $\exists w' \in W, w' \in r(u)(w)$  [seriality]. However, reflexivity is enough, because, it redounds to seriality. Extension  $R$  of function  $r$  preserves the two properties.
- $\Phi$  is an interpretation function that maps each formula to a subset of possible worlds in which the formula is correct. This function for atomic formulas is defined as  $\phi = \text{Atomic Formulas} \rightarrow \mathcal{P}(W)$  and for complicated formulas is defined inductively as follows:

$$\begin{aligned}\Phi(p) &= \phi(p), \text{ if } p \text{ is an atomic formula} \\ \Phi(\neg\alpha) &= W - \Phi(\alpha) \\ \Phi(\alpha \wedge \alpha') &= \Phi(\alpha) \cap \Phi(\alpha') \\ \Phi(OB_u \alpha) &= \{w | R(u)(w) \subseteq \Phi(\alpha)\}\end{aligned}$$

- $\Delta$  is a non-empty set of objects in all worlds of  $W$ . We assume that all possible worlds have a shared domain of objects.
- $I$  is an interpretation function that in each world  $w$  assigns to every name (term)  $t$ , a set of objects in  $\Delta$ , i.e.,

$I(w)(t) = t_w^I \subseteq \Delta$ , to every predicate  $p(t_1, \dots, t_n)$ , an  $n$ -ary relation on  $\Delta^n$ , i.e.,  $I(w)(p) = p_w^I \subseteq \Delta^n$  which is a set of  $n$ -tuples  $t_{1w}^I \times \dots \times t_{nw}^I$ .

This function must satisfy this limitation that the interpretation of a name (term) must be identical in all worlds, i.e., for all  $w, w' \in W : I(w)(t) = I(w')(t)$ .

Function  $\Phi$  must satisfy this constraint that if  $p$  is a predicate,  $w \in \Phi(p)$  if and only if there exist a set of  $n$ -tuples in the world  $w$  that the function  $I$  assigns them to  $p$ .

**Definition 3 (Truth)** A formula  $\alpha$  in a model  $\mathcal{M} = \langle W, R, \Phi, \Delta, I \rangle$  at a world  $w \in W$  is true, denoted  $\models_w^M \alpha$ , if and only if  $w \in \Phi(\alpha)$ . Analogously,  $\alpha$  at a world  $w$  is not true, denoted  $\not\models_w^M \alpha$  iff  $w \notin \Phi(\alpha)$ .

Regarding to the above semantics and definition of truth, we can prove that the presented axiomatic system is sound, i.e., if  $\vdash \alpha$  then  $\models \alpha$ . The soundness proof can be obtained by proving that the axioms are sound and inference rules preserve soundness. Due to space limitation we do not present the soundness proof of the proposed logic in this paper.

## 4 Calculus of Cooperative Administration

To enable authorities to enact, manage and enforce security policies cooperatively in their shared security domain, three styles of cooperative administration are introduced in this section including collaborative, disjunctive, and delegative administration. Before getting through the details of these three cooperative administration styles, we introduce a virtual authority, i.e., *composite authority*, as an authority of a shared domain that is managed by cooperative approach.

**Definition 4 (Composite Authority)** By having a set of primitive authorities, and  $\&, \triangleright, |$  notions, and parenthesis as alphabets, a composite authority is defined as follows:

- each primitive authority is a composite authority.
- if  $u_i$  and  $u_j$  are composite authorities, then so are  $(u_i \& u_j)$ ,  $(u_i \triangleright u_j)$ , and  $(u_i | u_j)$ .

Adding composite authorities to the proposed security policy language, i.e., MASL, and promoting it with new axioms resulted from adding the concept of composite authorities, enables us to infer security policies specified by composite authorities on shared domains. Automation of policy derivation for shared domains based on the security policies of the participating individual domains is the main advantage of such a logic-based cooperative administration framework. In the rest of this section axioms, semantics and sample soundness proof of proposed axiomatic system are presented separately for each cooperative administration style.

Figure 1. Semantics of collaborative composition of authorities

### 4.1 Collaborative Administration

There exist some situations in which two authorities require to collaborate in making an access decision. For example whenever two authorities have overlapped domains may need to establish security policy on the shared under protection objects in concert.

In order to support this kind of composite authority we add  $u_i \& u_j$  notion to our calculus of authorities.

**Axioms:**

- $\vdash OB_{u_i \& u_j} \alpha \leftrightarrow OB_{u_i} \alpha \wedge OB_{u_j} \alpha$  (CAU)
- $\vdash OB_{u_i \& u_i} \alpha \leftrightarrow OB_{u_i} \alpha$  (CAI)
- $\vdash OB_{u_i \& u_j} \alpha \leftrightarrow OB_{u_j \& u_i} \alpha$  (CAC)
- $\vdash OB_{u_i \& (u_j \& u_k)} \alpha \leftrightarrow OB_{(u_i \& u_j) \& u_k} \alpha$  (CAA)

Axiom CAU demonstrates that whenever two authorities make a statement collaboratively, means both of them have the same statement separately and they agree upon. The CAI, CAC, and CAA axioms show that collaborative operator ( $\&$ ) is idempotent, commutative, and associative over authorities.

**Semantics:** The extension of interpretation function  $R$  in the proposed Kripke model for  $\&$  notion is as follows:  $R(u_i \& u_j) = R(u_i) \cup R(u_j)$

We may expect intersection instead of union in the interpretation of collaboration notion ( $\&$ ). Whereas, union of relations associated to the participating authorities results in decreasing the norms which are available in possible worlds from the resulted composite authority. In other words, if  $u_i$  states in the world  $w$  that  $\alpha$  is obligatory, and  $u_j$  states the inverse one (like  $IM_{u_j} \alpha$ ), in collaborative combination of  $u_i$  and  $u_j$  we cannot infer the obligation of  $\alpha$  in the world  $w$  anymore. It is clear that in all the worlds resulted from the union of the possible worlds of  $w$  from  $u_i \& u_j$  point of view,  $\alpha$  is not true, and hence  $OB_{u_i \& u_j} \alpha$  is not true. Figure 1 shows more precisely.

**Corollary 5** Assume,  $u_i$  and  $u_j$  are authorities. Then:

- $\vdash PE_{u_i \& u_j} \alpha \leftrightarrow PE_{u_i} \alpha \vee PE_{u_j} \alpha$
- $\vdash IM_{u_i \& u_j} \alpha \leftrightarrow IM_{u_i} \alpha \wedge IM_{u_j} \alpha$

The above corollary shows that for obtaining the collaborative obligation statement on something (e.g., doing an action on a object) we require to have each of authorities' obligation statement on it. However, for permission statement, having each of the participating authorities' permission statement is enough.

## 4.2 Delegative Administration

In this paper, by *delegation* we mean *administration delegation*.  $u_i \triangleright u_j$  denotes  $u_i$  on behalf of  $u_j$  privileges can enact statements. For example,  $OB_{u_i \triangleright u_j} \alpha$  means  $u_i$  states on behalf of  $u_j$  that  $\alpha$  is ought to be the case.

It is worthwhile to note that an authority for specifying statements on behalf of another authority needs to have a privilege. Using logic, abstracts us from these implementation details. However, we suppose that trust infrastructures like PKI or delegation network which is proposed in [11] handles delegation details.

### Axioms:

$$\vdash OB_{u_i \triangleright u_j} \alpha \leftrightarrow OB_{u_i} (OB_{u_j} \alpha) \quad (DAU)$$

$$\vdash OB_{u_i \triangleright u_i} \alpha \leftrightarrow OB_{u_i} \alpha \quad (DAI)$$

$$\vdash OB_{u_i \triangleright (u_j \triangleright u_k)} \alpha \leftrightarrow OB_{(u_i \triangleright u_j) \triangleright u_k} \alpha \quad (DAA)$$

Axiom DAU represents that in delegative administration of authority  $u_i$  on behalf of  $u_j$  rights, a case like  $\alpha$  is obligatory from  $u_i \triangleright u_j$  point of view if and only if in any state,  $u_i$  accepts that  $\alpha$  is obligatory from  $u_j$ 's point of view. Axioms DAI, and DAA impose that delegation operator ( $\triangleright$ ) is idempotent, and associative. Idempotency of delegation compels the relations  $R(u_i)$  in the proposed Kripke semantics to be reflexive.

**Semantics:** The extension of  $R$  to include delegative composition of authorities is defined as  $R(u_i \triangleright u_j) = R(u_i) \circ R(u_j)$ .

The relation composition reflects this fact that from  $u_i \triangleright u_j$  point of view, a world  $w'$  is (normatively) possible from a world  $w$  if and only if  $w'$  is (normatively) possible from other world like  $w''$  in  $u_j$ 's point of view and  $w''$  is (normatively) possible from  $w$  in  $u_i$ 's point of view (figure 2). Hence,  $OB_{u_i \triangleright u_j} \alpha$  is true at a world  $w$  when  $\alpha$  is true at every world possible from  $w$  by the composite relation.

**Corollary 6** Assume,  $u_i$  and  $u_j$  are authorities. Then:

$$\vdash PE_{u_i \triangleright u_j} \alpha \leftrightarrow PE_{u_i} (PE_{u_j} \alpha)$$

$$\vdash IM_{u_i \triangleright u_j} \alpha \leftrightarrow OB_{u_i} (IM_{u_j} \alpha)$$

The above results show that we can infer that a case  $\alpha$  is permissible or gratuitous from the view point of  $u_i$  on behalf of  $u_j$ , if permissible or gratuitous statement of  $u_j$  is permissible from  $u_i$ 's point of view. However, for obligatory or impermissible cases, we do more strict and obligatory statement of  $u_i$  over the obligation or impermissible statement of  $u_j$  is required.

Figure 2. Semantics of delegative authority with possibility relation composition.

## 4.3 Disjunctive Administration

Disjunctive administration can be employed when two authorities like to manage the underlying shared domain objects based on the administration opinion of each of them. In this way, each authority can make a statement instead of the whole authorities who are participated in the disjunctive administration of a domain (or subdomain).

In the proposed calculus of authorities,  $u_i | u_j$  denotes  $u_i$  and  $u_j$  enact disjunctively for their underlying domains.

### Axioms:

$$\vdash OB_{u_i} \alpha \vee OB_{u_j} \alpha \rightarrow OB_{u_i | u_j} \alpha \quad (JAU)$$

$$\vdash OB_{u_i | u_i} \alpha \leftrightarrow OB_{u_i} \alpha \quad (JAI)$$

$$\vdash OB_{u_i | u_j} \alpha \leftrightarrow OB_{u_j | u_i} \alpha \quad (JAC)$$

$$\vdash OB_{u_i | (u_j | u_k)} \alpha \leftrightarrow OB_{(u_i | u_j) | u_k} \alpha \quad (JAA)$$

In disjunctive administration, an obligation statement is derived when at least one of the participating authorities enact the obligation statement. This principle is appeared as axiom JAU in the proposed calculus. Idempotency, commutativity, and associativity of disjunction operation ( $|$ ) is added by the JAI, JAC, and JAA axioms respectively.

**Semantics:** The disjunction operation is interpreted as an intersection operation in possibility relation  $R(u)$  in the proposed Kripke structure as  $R(u_i | u_j) = R(u_i) \cap R(u_j)$ .

There is a justification similar to collaborative composition for having intersection of relations  $R(u_i)$  and  $R(u_j)$  instead of union for the semantics of disjunctive composition of authorities  $u_i$  and  $u_j$ .

**Corollary 7** Assume,  $u_i$  and  $u_j$  are authorities. Then:

$$\vdash PE_{u_i | u_j} \alpha \rightarrow PE_{u_i} \alpha \wedge PE_{u_j} \alpha$$

$$\vdash IM_{u_i} \alpha \vee IM_{u_j} \alpha \rightarrow IM_{u_i | u_j} \alpha$$

$$\vdash OB_{u_i | u_j} \alpha \rightarrow PE_{u_i} \alpha \wedge PE_{u_j} \alpha$$

## 4.4 Hybrid Administration

We can have the different combination of the three aforementioned administration styles together. Complicated

composition of authorities results in some axioms which are presented in the following.

**Axioms:**

$$\vdash \text{OB}_{u_i \triangleright (u_j \& u_k)} \alpha \leftrightarrow \text{OB}_{(u_i \triangleright u_j) \& (u_i \triangleright u_k)} \alpha \quad (\text{DDC})$$

$$\vdash \text{OB}_{u_i \triangleright (u_j | u_k)} \alpha \leftrightarrow \text{OB}_{(u_i \triangleright u_j) | (u_i \triangleright u_k)} \alpha \quad (\text{DDJ})$$

Axioms DDC and DDJ show the distribution of delegation operation ( $\triangleright$ ) on collaboration ( $\&$ ) and disjunction ( $|$ ) operations respectively.

#### 4.5 Soundness

All the axioms represented for cooperative policy derivation in the above are sound. Due to the space limitation, we just show the soundness proof of axiom DDC as a sample.

**Proposition 8 (Soundness of DDC)** *Axiom DDC is sound.*

**Proof** Suppose for some model  $\mathcal{M} = \langle W, R, \Phi, \Delta, I \rangle$  and some  $w \in W$ , we have  $\models_w^{\mathcal{M}} \text{OB}_{u_i \triangleright (u_j \& u_k)} \alpha$ . Then:

$$\begin{aligned} w &\in \Phi(\text{OB}_{u_i \triangleright (u_j \& u_k)}) \\ \text{iff } \forall w', [(w, w') \in R(u_i) \circ (R(u_j) \cup R(u_k))] &\rightarrow w' \in \Phi(\alpha) \\ \text{iff } \forall w', [\exists w'', (w, w'') \in R(u_i) \wedge ((w'', w') \in R(u_j) \vee \\ &(w'', w') \in R(u_k))] \rightarrow w' \in \Phi(\alpha) \\ \text{iff } \forall w', [(\exists w'', (w, w'') \in R(u_i) \wedge (w'', w') \in R(u_j)) \vee \\ &(\exists w'', (w, w'') \in R(u_i) \wedge (w'', w') \in R(u_k))] \rightarrow w' \in \Phi(\alpha) \\ \text{iff } \forall w', [(w, w') \in R(u_i) \circ R(u_j) \vee \\ &(w, w') \in R(u_i) \circ R(u_k)] \rightarrow w' \in \Phi(\alpha) \\ \text{iff } \forall w', (w, w') \in R(u_i \triangleright u_j) \cup R(u_i \triangleright u_k) &\rightarrow w' \in \Phi(\alpha) \\ \text{iff } \forall w', (w, w') \in R((u_i \triangleright u_j) \& (u_i \triangleright u_k)) &\rightarrow w' \in \Phi(\alpha) \\ \text{iff } w \in \Phi(\text{OB}_{(u_i \triangleright u_j) \& (u_i \triangleright u_k)} \alpha) \end{aligned}$$

Thus,  $\models_w^{\mathcal{M}} \text{OB}_{(u_i \triangleright u_j) \& (u_i \triangleright u_k)} \alpha$ . Hence, the axiom is sound.

### 5 Policy Enforcement

Enforcement of policies in the security domains are done by two subsystems. *Obligation enforcement* subsystem which is used to enforce the actions which must be done in a specific situation. *Access control* subsystem which is used for controlling subjects' access requests.

#### 5.1 Access Control

Access control in individual domains is easily done based on the security policy rules specified by their authorities. However, for the shared domains, policy enforcement

strategy might be different based on the agreement made between the rightful authorities. In previous sections, cooperative administration is modeled by the concept of composite authority. Hence, for access control, we just need to infer implicit policy rules composed by composite authorities in the shared domains. For example, if an authority  $u_i$  makes agreement with  $u_j$  on having collaborative administration strategy in their shared domain, we must infer implicit policy rules composed by collaborative authority  $u_i \& u_j$ .

The access decision making functions are as follow. In these functions,  $u \in AU$ ,  $s \in S$ ,  $o \in O$ , and  $a \in A$ .

$$\begin{aligned} \text{BADF}(u, s, o, a) &= \begin{cases} \text{Deny} & , \text{ if } \text{KB} \vdash \text{IM}_u \text{do}(s, o, a) \\ \text{Grant} & , \text{ if } \text{KB} \vdash \text{PE}_u \text{do}(s, o, a) \\ \text{Don'tCare} & , \text{ otherwise} \end{cases} \\ \text{FADF}(u, s, o, a) &= \begin{cases} \text{Deny} & , \text{ if } [\text{BADF}(u, s, o, a) = \text{Deny}] \\ & \text{ or } [\text{BADF}(u, s, o, a) = \text{Don'tCare}] \\ & \wedge \text{DefSt} = \text{IM}] \\ \text{Grant} & , \text{ otherwise} \end{cases} \end{aligned}$$

BADF (Basic Access Decision Function) goes through the existing policy rules for permissible or impermissible ones and FADF (Final Access Decision Function) makes the final decision. In the definition of FADF, DefSt returns to the default access right which might be set to one of IM, or PE deontic statuses. Thus, if there is no policy rule for a request, the default strategy determines the final decision for the requested access. It is worthwhile to note that in case of existing contradictory policies (from different authorities on the same resource), we may not be able to infer an access decision. In this case, DefSt solves our problem and resolves the conflicts by enforcing the default decision.

#### 5.2 Obligation Enforcement

The issues related to the inference of obligation policies are similar to the inference of authorization ones. We follow the same approach for having cooperative administration of security obligations here. However, enforcing obligations is different from the authorizations and requires its enforcement mechanisms and services apart from the access control services.

Monitoring and enforcing obligations (or its restricted type, provisions) is one of the open problems in security management. Since, we concentrated on the specification and inference of security policies including obligation policies in this paper, we do not scrutiny the details of obligation enforcement in this paper. Some approaches for monitoring and enforcement of obligations and provisions are addressed in [7, 16, 17].

## 6 Case Study

In the MIT Oxygen project [1], a *collaborative meeting region* is defined as an area with a set of devices for meeting. This region has a set of trust and authorization rules that specify what happens during a meeting. For security management of collaborative region in Oxygen, we suggest applying our proposed model.

In a collaborative meeting room, all meeting members (who are participating in a meeting) are authorities of the meeting room (with all resources available there). Each meeting member has his/her own security policy rules. In our case, Bob and Alice are meeting members with the following security policy rules. We suppose that the meeting room has a security agent that we call it MSA in short. MSA is another authority of the room. We will see the role of MSA in this case later.

**Alice's Security Policy Rules:** Alice likes to delegate the administration to the meeting room's security agent (MSA) by transferring her security policy rules to it. She does not allow printing the confidential documents (in her domain) in any case. She also gives the read-only permission on customers' information to a meeting member when the location of meeting is outside their company. The logical representation of Alice's security policy rules are as follow. Note that in the following policy rules, each statement placed in the parentheses in the left side of a rule, is a proposition.

[AP1] (Alice's location is meeting room)  $\wedge$  (time is meeting time)  $\rightarrow$   $\text{OB}_{\text{Alice}}$  **do**(AliceSecAgent, MeetSecPolicies, transferTo(MSA))

[AP2]  $\text{True} \rightarrow \text{IM}_{\text{Alice}}$  **do**(Any, ConfDocs, print)

[AP3]  $\neg$  (requester's location is company)  $\wedge$  (location is meeting room)  $\rightarrow$   $\text{PE}_{\text{Alice}}$  **do**(MeetMember, CustInfo, read)

**Bob's Security Policy Rules:** Bob similar to Alice likes to delegate the administration to the meeting room's security agent (MSA). He does not allow anybody who is outside the company to write or update customers' information.

[BP1] (Bob's location is meeting room)  $\wedge$  (time is meeting time)  $\rightarrow$   $\text{OB}_{\text{Alice}}$  **do**(BobSecAgent, MeetSecPolicies, transferTo(MSA))

[BP2]  $\text{True} \rightarrow \text{PE}_{\text{Bob}}$  **do**(MeetMember, CustInfo, read)

[BP3]  $\neg$  (requester's location is company)  $\rightarrow$   $\text{IM}_{\text{Bob}}$  **do**(Any, CustInfo, write)

By entering Alice and Bob into the meeting room, following their first obligation policy, their agent (which is installed on their PDAs) must send all the security policies to the meeting security agent (MSA). MSA establishes its

security policies based on the received security policies as follows. In this way, MSA obligates every obligation policy specified by Alice or Bob and makes permissible every authorization policy specified by them.

[MP1]  $\text{True} \rightarrow \text{OB}_{\text{MSA}}(\text{IM}_{\text{Alice}} \text{ do(Any, ConfDocs, print)})$

[MP2]  $\neg$  (requester's location is company)  $\wedge$  (location is meeting room)  $\rightarrow$   $\text{PE}_{\text{MSA}}(\text{PE}_{\text{Alice}} \text{ do(MeetMember, CustInfo, read)})$

[MP3]  $\text{True} \rightarrow \text{PE}_{\text{MSA}}(\text{PE}_{\text{Bob}} \text{ do(MeetMember, CustInfo, read)})$

[MP4]  $\neg$  (requester's location is company)  $\rightarrow$   $\text{OB}_{\text{MSA}}(\text{IM}_{\text{Bob}} \text{ do(Any, CustInfo, write)})$

We set the security enforcement system for the collaborative meeting room to enforce the security policies based on collaborative administration of MSA on behalf of each meeting member. Formally, the desired composite authority for our case is (MSA  $\triangleright$  Alice)  $\&$  (MSA  $\triangleright$  Bob).

Suppose that in the meeting of Alice and Bob, Alice request to update a customer information through her PDA device. By her request, she sends a certificate that she is a meeting member. The security enforcement system calls FADF for checking the read and write access of Alice (as a meeting member) to customers information (CustInfo) as follows. Note that update operation is interpreted to read and write operations.

FADF((MSA  $\triangleright$  Alice)  $\&$  (MSA  $\triangleright$  Bob), MeetMember, CustInfo, read)  
FADF((MSA  $\triangleright$  Alice)  $\&$  (MSA  $\triangleright$  Bob), MeetMember, CustInfo, write)

Following MP2, and MP3 rules, BADF infers the following statement for read operation, and so returns *Grant*.

$\text{PE}_{(\text{MSA} \triangleright \text{Alice}) \& (\text{MSA} \triangleright \text{Bob})} \text{ do(MeetMember, CustInfo, read)}$

However, for write operation, since, it cannot infer neither PE nor IM, returns *Don'tCare*. Therefore, in this situation, FADF grants read operation and denies write operation following the default strategy for access control (suppose DefSt=IM).

## 7 Conclusions

In this paper, we proposed a logical security model for pervasive computing environments based on MASL logical security policy language. A pervasive computing was taken as a multi-security-domain environment in the proposed model, and three styles of cooperative administration were proposed for shared domains; namely collaborative, disjunctive, and delegative administration. Following each cooperative administration style, a set of logical axiom were presented for cooperative policy derivation.

In future steps of our research we are about to take the logical model of domains into account. In this paper we left this concept informally and just supposed that each authority is responsible of one or more domains.

## Abstract

*Existing search engines like Google, Yahoo!, Live etc. are not yet capable to answer queries that require deep semantic understanding of the query or the document. Instead, it is preferable to find and ask someone who has related expertise or experience on a topic and thus Web-based online communities have become important places for people to seek and share expertise. We need to gather the data that describes these online communities. But extracting, aggregating and analyzing data from these communities for finding experts on a single framework is a challenging task. Also there is no universal standard data structure for the outline of user participation in these communities. In this paper, we present a Grid-enabled framework of expertise search (GREFES) engine which utilizes online communities as sources for experts on various topics. This is a work in progress. We also propose an open data structure called SNML (Social Network Markup Language) to outline user participation in online communities. The architecture addresses major challenges in crawling of community data and query processing by utilizing Grid. An expert ranking algorithm is also discussed and evaluated.*

## 1 Introduction

Locating the expertise necessary to solve difficult problems is a social and collaborative problem. Recent advances in Web 2.0 [1] have enabled the proliferation of many online communities and interactive collaboration spaces like wikis, forums, blogs, scientific community and other social networking services which are gaining popularity and have become places for people to seek and share expertise [2].

Existing search engines like Google, yahoo etc. are not yet capable to answer queries that require deep semantic understanding of the query or the document [3]. Instead, it is preferable to find and ask someone who has related expertise or experience on a topic and these online communities are the places for people to seek advice or help. These online communities usually bound by shared professions, interest or products among their participants. The topics range from advice on medical treatment, programming, software, building a computer from scratch to repairing the kitchen sink. Our work seeks to create a next generation of expert finding searching framework based on these online communities.

But before such analysis can be done, we need to gather the data (questions and answers, social support or

discussion, comments or advice, content rating, social relations etc) that describes online communities. But their data representations are very different from general web pages. In online communities different users make use of different tools and social information is scattered. There are no standards for the outline of user participation. Also as these communities rarely interoperate, each is typically only aware of its own social data and cannot benefit from other communities data.

On the other hand, there are many challenges in crawling of online community data and query processing. The efficiency problem in query processing is due to the need to quickly evaluate a query over a rather large index in the presence of many user queries being submitted concurrently [4]. In case of Web crawling, efficiency problem is due to the large scale of the Web or online communities as well as the Web's constantly evolving nature, which require pages to be downloaded and indexed frequently [5]. Another problem in case of Web crawling is the freshness of the collection. Moreover, Web crawling needs a large amount of computational resources, high network bandwidth and a large amount of volatile memory to store and manage the data structures that grow quickly and continuously during the crawl [6]. Thus extracting, aggregating and analyzing data from these communities on a single framework is a challenging task.

In recent years, Grid computing has evolved to co-ordinate sharing of distributed and heterogeneous resources and to support a very powerful way of managing, processing and storing the huge amount of distributed data [7].

In this paper, we present a Grid-enabled framework of expertise search (GREFES) engine which is different from traditional ones in both design philosophy and functionality. This work is currently in progress. The framework collects, analyzes and aggregates data from different online communities or social networks available on the Web to find people with suitable expertise on various topics. A relevance ranked list of expertise results are returned by interpreting a search string and mapping it onto related keywords. The main contributions of this paper are as follows:

- A novel framework of expertise information retrieval that utilizes online virtual communities as sources of experts. It also addresses major challenges in crawling

and query processing in online communities by utilizing the computational power and high bandwidth inherently available in the Grid.

- An open data structure called SNML (Social Network Markup Language) to outline user participation in online communities.
- An expert ranking algorithm for finding experts from communities

The rest of the document is structured as follows: Section 2 briefly reviews related works. Section 3 presents the proposed Grid-enabled expert finding search engine architecture and its features. Section 4 depicts SNML and open APIs. Section 5 presents an expert ranking algorithm. Section 6 presents the evaluation of our ranking algorithm and Section 7 concludes the paper.

## 2 Related Work

### 2.1 Online Communities

Online communities are used for a variety of groups interacting via the Internet for social, professional, educational or other purposes. Examples are Flickr, Facebook, Del.icio.us, Myspace, Twitter and various forums, wikis etc. These communities do not always focused on social relationships. Instead it also reflects community member's shared interest.

In online communities, a user posts a topic or question and then some other user post replies to either participate in the discussion or to answer a question posed in the original post. The reason that users replies to a topic is usually because of an interest in the content of the topic rather than who started the thread. This also indicates that the replier has superior expertise on the subject than the asker. So there is a possibility to form an expertise network [8]

### 2.2 Expert Search

Expert finding systems have been explored in a series of studies including Krulwich and Burkey [26], and McDonald and Ackerman [27] as well as the studies in Ackerman et al. [9]. Newer systems, which use a social network to help find people, have also been explored, most notably in Yenta [28] and Referral Web [10]. These systems attempt to leverage the social network within an organization or community to help find the appropriate others.

In most recent work [11], authors propose to find expert in an organization using social network. The social networks are built from two sources, from email and extracting co-occurrences of people from web pages. An expertise propagation algorithm is proposed based on social network.

Also in [12], authors proposes an expertise search system called Arnetminer which constructs a social network among researchers through their co-authorship,

and utilizes this network information as well as the individual profiles to facilitate expertise oriented search tasks. Our approach is different from above approaches as we are utilizing already existing online communities or social networks as sources of experts.

Online social communities are often huge and there is no standard data structure to outline user participation in these communities. Therefore, crawling these networks could be both challenging and interesting. There are few researches on the crawling of online social community data. Heer and Boyd [13] mentioned their use of a crawler to gather Friendster data for their Vizster social network visualization system, but they did not go into the details of the design and implementation of the crawler. Chau, Pandit et al [14] describes parallel crawlers for online social network utilizing a centralized queue. But all these are mostly centralized systems, not suitable for geographically distributed social network services. In [30] authors define a universal data interchange format called DyNetML to enable exchange of rich social network data and improve compatibility of analysis and visualization tools. Arikan and Erdogan [25] propose an open data structure called ULML (User Labor Markup Language) for retrieving the statistics of content (how many photos, friends, comments etc.) but not for actual content. We propose a universal data structure called SNML to outline user participation in online communities.

### 2.3 Grid Enabled Search Engines

The use of the grid for information retrieval is relatively new. To the best of our knowledge, GRACE (Grid Search and Categorization) [15] and SE4SEE (Search Engine for South-East Europe) [16] are the two attempts to develop grid-enabled search engines. But our work deals with finding people with expertise rather than documents from existing online communities using Grid technology.

## 3 Proposed Framework

### 3.1 Overview of the Architecture

The GREFES infrastructure is framed by the Open Grid Services Architecture (OGSA) framework and thus relies on Service Oriented Architecture (SOA) principles and second generation Web Service standards. As the underlying grid middleware is able to distribute the work evenly, load balancing is not an issue for the current system. The framework is shown in the figure 1. The terminology used to describe the system architecture is listed in table 1. A user can access our search web portal using a web browser from his/her desktop or mobile devices like laptop, mobile phone or PDA. In order to prevent the misuse of grid resources, the user needs to register their profiles to have a valid GREFES account, which is verified by the Grid security interface in the portal. The Web portal acts as a mediator between the user

and the Grid. It converts the user query into a Grid job and submits it through a Grid user interface node (GUI) to a Grid worker node (GWN). GWNs are responsible for executing the crawler, expert ranking and indexing tasks. The generated expert ranking results are stored in the distributed GWNs databases. Search and resource broker (SRB) is not only coordinates the jobs and handles their assignments, but also responsible for submits the search query to OGSA-DAI (Open Grid Service Architecture-Data Access and Integration) after getting appropriate content source from CSS (Content Source Selection) service. OGSA-DAI deliver the ranking results to web portal to satisfy user query.

We can see that our architecture has two parts: processing part (social network data extraction, expert ranking and indexing) and expert searching part. We will present them in detail in section 3.2 and section 3.3.

### 3.2 Processing Framework

The major components of processing parts are explained briefly as follows:

*Crawler* – Since GREFES framework deals with expertise search, which serves a large number of users each with specific, personal expert needs, here a crawler is used to collect SNML files (described detail in section 4) which contain user activities (log data – comments or advice) data, profile data (may include expertise areas) and relation data from online communities. Furthermore, in order to be able to adapt to the heterogeneous nature of the Grid infrastructure, a platform independent crawler should be preferred which is capable of executing on different architectures, thus preventing the recompilation overhead and compatibility issues. Usually many crawler threads execute concurrently on GWNs in order to overlap network operations with CPU processing, thus increasing the throughput. The crawlers in Grid worker nodes retrieve community data in a breadth-first fashion.

The crawlers in Grid worker nodes retrieve community data in a breadth-first fashion. A queue data structure is used to store the list of pending users which had been seen but not crawled. Initially, a seed set of users was inserted into the queue. Then at each step, the first entry of the queue is popped, all information for that user was crawled, and every user who had left (but was not yet seen) was enqueued. Once all of the user's information was crawled, the user was marked as visited, and stored in a separate queue.

*Expert Ranking Service* – The main goal of our search engine is to find suitable experts on a given topic. So after collecting SNML files of users through crawlers from different communities, ERS service is used to find users knowledge or expert areas (If not mentioned by users) and also used to calculate their expert ranking values on these areas using a ranking algorithm. Finally, a relevance

ranked list of experts is presented to the user from different communities with similar topic. If ranking values are same for experts on a topic from different communities, community rank value is used for final ranking of experts. The community which has more members will be ranked high. We will explain more detail about the expert ranking algorithms in section 5.

*Search and Resource Broker (SRB)* – It coordinates and schedules the jobs on worker nodes and also responsible to send search query to OGSA-DAI by contacting content source selection (CSS) service.

*Indexer* – Expert ranking results are indexed by indexers and stored in the distributed worker nodes databases. It helps to quickly find suitable expertise on various topics and thus reduce query response time.

*Monitoring and Event Notification (MTEN) Service* – It monitors distributed worker nodes as well as notify them if any profile update is available in the online communities. Then resource broker schedules worker nodes to execute crawlers.

The processing work flow as shown in figure 1 is explained step by step as follows:

*Step 1 – Resource broker submits and coordinates the jobs of distributed worker nodes. A worker node runs multiple crawler threads concurrently for collecting social network data from online communities.*

**Table 1: List of commonly used terms**

Terminology	Description
Crawlers	Locating, fetching, and storing the content residing within the online communities
Indexers	The expert data is transformed to expert indexes by indexers
Grid Worker Node (GWN)	Distributed computing resource which executes crawling, expert ranking and indexing tasks
SNML	An open data structure to outline user participation in online communities
Expert Ranking Service (ERS)	Ranking experts on various topics based on a ranking algorithm
Monitoring and Event Notification	MTEN monitors Grid worker nodes and notify them if any profile changes in online communities
Web Portal	Web interface for searching expert
GSI security	Grid security interface to validate registered user
OGSA-DAI	Connect to distributed databases and deliver results to the web portal
Grid User Interface	Through this interface, Grid jobs are submitted to search and resource broker
Search and Resource Broker (SRB)	Coordinates the jobs and handles their assignments to worker nodes. Also sends search query to CSS service
Content Source Selection (CSS)	Generates and maintains content source descriptions and optimizes the distribution of queries by selecting suitable sources
Mashup Service	Integrates services like Google map to display

Fig. 1: The Next Generation Expert Finding Search Engine Framework on Grid

Step 2 – After collecting and processing SN data, expert ranking tasks are performed in the worker nodes using our ranking algorithm to find experts on various topics in different online communities.

Step 3 – Then the indexers in the worker nodes create expert indexes for efficient query and store them in worker node databases.

Step 4 – If any profile changes in online communities, MTEN service notifies worker nodes which then updates the expert ranking results.

### 3.3 Searching Framework

This framework provides a relevance-ranked list of experts to user on a topic. The major components of this framework are explained as follows:

**Web Portal** – It is the only interaction point between the user and the GREFES back-end and thus a major component of our architecture. Users register their profiles as well as submit their queries through the portal. Queries are submitted as a Grid job through Grid user interface (GUI). The portal has to be user-friendly, even though it requires a more complex interface than classic search engines due to the application's added capabilities like mashup services (i.e. Google map etc.).

**Content Source Selection (CSS) Service** – It generates and maintains expert content source descriptions which include partial content indices, summative content indices, or result traces from training or past queries. It uses CORI [17] selection algorithm (the standard collection selection

mechanism) and Language Modeling techniques [18] to find appropriate expert index collections. Thus it optimizes the distribution of queries by selecting target expert index sources which are relevant to a given query.

**OGSA-DAI** – Open Grid Service Architecture-Data Access and Integration [19] is an extensible framework for data access and integration. It provides three basic activities- querying data, transforming data, and delivering the results using ftp, e-mail, and push services. In our architecture, OGSA-DAI is used to query expert indexes from distributed worker nodes databases and deliver the query results to the web portal.

The workflow of the expert search process is shown in figure 2 and is explained step by step as follows;

The first stage of the process is the warm up sequences denoted in the figure 2 as steps (1)-(6) and steps (7) – (13) denote the querying sequence

Step 1: The SRB contacts the CSS to initialize the service of collecting expert index descriptions

Step 2: The CSS contacts the OGSA-DAI to acquire descriptions of each expert index.

Step 3: The OGSA-DAI requests the description from the expert index

Step 4 and 5: The expert index provides the collection statistics in a pre-defined format to the CSS through OGSA-DAI.

Step 6: Steps (2)-(5) are repeated for each index, until all the expert indexes are described, and the warm up of the CSS is completed.

Step 7: A query is submitted to the SRB through the web portal.

Step 8: The query is sent to the CSS for selection of the set of expert indexes.

**Fig. 2: Sequence diagram of the search process**

Step 9: The CSS returns a ranked list of expert indexes. This may be the top  $n$  indexes which are most likely to satisfy the query, or all those indexes above a certain threshold. These criteria can be defined when performing the selection.

Step 10 and 11: The selected indexes are then contacted through OGSA-DAI and queried for finding relevant experts on a topic. This process is performed concurrently for efficiency (via threading).

Step 12 and 13: The expert ranking result sets, produced by each index from distributed worker node's databases, are merged and final ranking results of experts are delivered to the web portal through OGSA-DAI.

### 3.4 Architectural Features

The distinguishing features of proposed framework are as follows:

- 1) Utilizing online Web communities as sources of expert
- 2) The computational burden of Web crawling and indexing is alleviated by the utilization of resources available in the Grid.
- 3) Queries are run against multiple distributed collections of data sources in parallel with a likelihood of possessing relevant sources, thus eliminating the need of searching other unnecessary collections.
- 4) Rather than seeking sub-second response times over billions of documents, as monolithic search engines

do, our system seeks such performance over far smaller collections. This will enable more complex query processing.

- 5) Because of their smaller size and locality to a particular collection source, the distributed collections can be updated more quickly, thus eliminating the delay among harvest runs exhibited by search engines.

### 4 SNML Data Format

SNML is an open data structure protocol based on XML that can be generated by the service provider and is followed by our framework. Crawlers collect SNML documents which describes community data in a universal format. SNML document contains community information, user's participation information like his/her experiences, expertise areas, various activities, relations etc. SNML consist of four sections: as shown in figure 3 and describes briefly as follows:

**Fig. 3: SNML Data structure with four sections**

**<Community>**: The community a user is belongs to. It consists of community type and community profile. Community type describes type of media example blog, wikis, forum etc. and community profile describes the community activities or services.

**<Profile>**: Consists of basic profile and extensible profile. Basic profile includes personal information like name, age, expertise area, phone, address etc. Extensible profile depends on different social network or communities. For example Facebook's profile data which includes other information than basic.

**<Relation>**: Consists of depth and connected user profiles to the current user. It may include no. of friends connected to the user, their profile etc.

**<Activities>**: Consists of activity name and media URI (Universal Resource Identifier). It includes user comments, posts etc.

The SNML data format is shown in figure 4.

```
<? xml version="1.0"?>
<SNML xmlns="urn:GIR:2008:08-SNML-NS"
 xmlns:SNML="urn:GIR:2008:08-SNML-NS">
 <community mimeType="text/plain">
 <type/>
 <profile/>
 </community>
 <profile mimeType="text/plain">
 <basic>
 <name/>
 <expertise area>
 <item/>
 <descriptor/>
 </expertise area>
 <age/>
 <address/>
 <phone/>
 </basic>
 <extension>
 <!-- extensible profile -->
 </extension>
 </profile>
 <relation mimeType="text/plain">
 <depth/>
 <profile>
 <!-- user profile based on profile in SNML -->
 </profile>
 </relation>
 <activities mimeType="text/plain">
 <name/>
 <uri/>
 </activities>
</SNML>
```

**Fig. 4: SNML Data Format Structure**

## 5 Expert Ranking Algorithm

Most current systems use modern information retrieval techniques to discover expertise from implicit or secondary electronic resources. Campbell et al. [20] and Dom et al. [21] used graph-based ranking algorithms in addition to content analysis to rank users' expertise levels. However, there is a weakness in these studies. The size of their networks is very small and does not reflect the characteristics of realistic social networks.

Yu and Singh's referral system [22] explicitly argues for a specific expertise-finding algorithm. In their experiment, they use the similarity between a query vector and a neighbor's expertise vector, plus some consideration of its historical referring performance, as the criteria for picking the next agent in a referral graph. However, the query vector and expertise vector in their experiment are manually coded; and each is a combination of preset

topics from a taxonomy. This approach is not practical in real world scenarios:

Adamic et al's best connected search (BCS) algorithm [23], which makes use of the skewed degree distribution of many networks, can also be used to find experts. However, Adamic et al. also found that the BCS algorithm is not always efficient in all networks.

Here we need to find experts in online communities. We also use graph-based algorithm. The task of determining expert is naturally decomposed into two stages.

1. Discovering and identifying possible knowledge areas.
2. Measuring the person's competency in these areas compare to others that is finding his/her expertise ranking.

We represent the profile of a person  $pr$  as a vector of  $n$  values, where the  $i$ th element of the vector corresponds to the knowledge area  $ka_i$ , and  $score(pr, ka_i)$  reflects the individual's knowledge in the given area. To find the knowledge areas of a candidate, we use keyword similarity of candidates and knowledge areas as described in [31]. After parsing the questions, answers, comments or activities, we can extract the top 20 keywords using the TF-IDF weighting formula [29]. Let  $KW(d)$  be the set of keywords that are extracted from profile document  $d$ .

We can obtain the set of keywords of a knowledge area  $ka$  by looking at a query-biased subset of documents  $D_{ka}$ , using the top  $n$  documents retrieved using  $ka$  as the query and the W3C corpus as the document collection. Then we use all keywords from these documents to form a list of keywords of the given area. Formally:

$$KW_{ka} = \bigcup_{d \in D_{ka}} KW(d) \dots\dots\dots (1)$$

Similarly, we can obtain keywords of individuals, by taking keywords of profile documents that they are associated with:  $KW_{pr} = \bigcup_{d \in D, A(d, pr)=1} KW(d) \dots\dots\dots (2)$

Having the set of keywords both for knowledge areas and for candidates in hand, we estimate the profile scores with the ratio of co-occurring keywords:

$$score(pr, ka) = \frac{|KW_{ka} \cap KW_{pr}|}{|KW_{ka}|} \dots\dots\dots (3)$$

After determining his knowledge areas based on the highest score, we now need to calculate his expertise ranking on this area.

Online communities can be shown as a post-reply network as shown in figure 5. In this figure, we map a replying relationship into a directed graph. On the left we have a bipartite graph of users (circles) and the discussion threads (squares) they participated in. This is transformed to a directed graph where an edge is drawn to the user making the initial post (the dashed edge) from everyone who replied to him. From figure 5, a user's expertise may be found by counting the number of questions he/she answered. We call it the "AnswerNum" measure. There is a potential problem in counting the number of answers one posted. A user who answers 100 newbies' questions will be ranked as equally expert as another user who answers

100 advanced users' questions. Obviously the latter usually has greater expertise than the former. We propose to generate a measure that not only considers how many other people one helped, but also whom he/she helped. We call it  $Exp_{rank}$ . From figure 5, we can see that if C is able to answer A's question, and B is able to answer C's question, B's expertise rank should be boosted not just because they were able to answer a question, but because they were able to answer a question of someone who herself had some expertise.

**Fig. 5: Post-reply network**

This is similar to PageRank. In a sense,  $Exp_{rank}$  propagates expertise scores through the question answer network. So the proposed  $Exp_{rank}$  algorithm is described as follows:

Suppose User B has answered 50 questions and helped users  $U_1 \dots U_n$ . Then  $Exp_{rank}(B)$  is calculated as follows:

$$Exp_{rank}(B) = (1-d) * NA(B) + d * \sum_{i=1}^n NA(U_i) / H(U_i) \dots (4)$$

where  $NA(B)$  = no. of replies or answers of user B,  
 $NA(U_i)$  = no. of answers of user  $U_i$ ,  $i=1..n$   
 $H(U_i)$  = no. of users helping  $U_i$  and the parameter  $d$  is a damping factor which can be set between 0 and 1. The damping factor allows the random walker to 'escape' cycles by jumping to a random point in the network rather than following links a fraction  $(1-d)$  of the time.

## 6 Evaluation of the Expert Ranking Algorithm

For the evaluation of the ranking algorithm, we collected the data from a Korean Social network website called "www.rukie.com". This site mainly focuses on different programming issues and user asks questions and some people answer them. Since there was no explicit user-supplied expertise ranking data in this site, we needed to use human raters to generate a "Standard" for comparison. Because it was not possible for us to rate a large number of these users, we randomly selected 130 users from the network for use as a comparison sample. By omitting those users posting fewer than 10 times, we ensured that the sampled users had generated enough Forum content for a reviewer to evaluate their expertise levels. Raters

must read from ten to hundreds of messages posted by a user to evaluate his/her expertise level. It is also difficult to compare two users when they both have posted many messages but have not replied to each other. Based on our observation of the forum and the results of a pilot rating set, we decided to categorize the users into 3 expertise levels like professional programmers, Learners (who knows some basics) and newbies.

We found two raters who are programming experts to rate the 130 users' expertise. We use Kendall's Tau correlation measure in our evaluation [32]. Kendall's Tau gives equal weight to any interchange of equal distance, no matter where it occurs. For instance, an interchange between rank 1 and 2 will be just as bad as interchange between rank 100 and rank 101. The Kendall's Tau distance between the two human raters was 0.752 for the 130 users. Therefore, we may expect that any automated algorithm would at best achieve around a 0.752 correlation with the human raters. For each of these users, in the data analysis below, we summed the ratings from the two raters together as the standard human rating (HR). Figure 6 shows the Kendall's Tau statistical correlations between various algorithms and the human ratings of the 130 users. From the figure, one can see that our  $Exp_{rank}$  algorithm performs well than other existing ones.

**Fig. 6: The performance of various algorithms in Kendall's Tau statistical metric**

## 7 Conclusion and Future Work

No prior work done in the expertise search domain has considered Grid-based search engine to utilize web communities as sources of experts. Many of them find experts in an organization or in a social community or build social networks from emails or web pages to find relevant experts on a topic. So in this paper, we have presented a novel framework of expertise information retrieval on Grid utilizing online web communities. The system returns a relevance ranked list of experts by

interpreting a search string (topic) and mapping it onto related keywords. We have proposed an open data structure called SNML for sharing community data efficiently and effectively. Also we have presented an expert ranking algorithm and evaluated its performance. Currently this work is in progress. In future, we will analytically evaluate the performance of our architecture with other distributed information retrieval system.

# Disassembling SLAs for Follow-Up Processes in an SOA System

## Abstract

This work presents a novel scheme for Service Level Agreements (SLAs) in a service-oriented architecture (SOA). An SLA is a contract that guarantees quality of service (QoS) between service providers and consumers. An SLA can be split into several parts for an SOA system which is consisting of different services. A split SLA is used to guarantee quality of services for one of services in an SOA system. However, these contract rules do not regulate follow-up process in services. SLA violations may occur consequently. For instance, interactions between services are not encrypted because the encryption parameter isn't included in the split SLA contract. Confidential data would be transmitted through unsafe channels. There would be a security issue of SLA Management for follow-up processes in an SOA system. The novel scheme in this work addresses these problems. Using SLAs management proposed in this work can identify the services that consumer needs and split the contracts for follow-up services. SLAs are not only guaranteed between service providers and consumers but also assured in follow-up processes. The proposed method improves the security and completeness of SLA using in an SOA system.

**Keywords** : Service Level Agreement, Service-oriented architecture

## 1. Introduction

An increasing number of business applications are currently deployed with network topology. To fulfill the requirements of customers all over the world, companies need a

mechanism with increased efficiency for software development. Therefore, Service Oriented Architecture (SOA) was proposed. SOA could easily integrate different business processes for one specific purpose. Services programmed in different languages are deployed on the web and served for different user requests. Additionally, every web service is specific to one purpose and has no common interface for communication. Entire system must be redesigned to fit new goals when the purpose differs. SOA, which is a low-cost and time-saving method for building services, is loosely coupled between web services. The services in an SOA system are already tested and verified. They use the same interface to interact with each other. Even when some services are replaced, the system will be online within a short time.

When a service is fully developed, the relationship between service consumers and providers must be stipulated. SLAs as contracts between service providers and consumers are proposed. An SLA uses formal terms to define the responsibilities of service providers and service consumers. Such contracts also outline penalties for service providers who do not reach the level of quality defined in the contract. Service quality must be measured and monitored to ensure it meets parameters defined in an SLA. Once violations occur, service providers have to adjust system resources to meet parameters in the contract.

An SLA in an SOA system only exists between service consumers and providers. However, there is not any limitations existing in follow-up processes and potential agreement violations may occur.

---

Figure1. Potential violation in SOA system

The following example is utilized to describe the insufficiencies of an SLA in an SOA system. The service consumer requests information from service A for a financial process (Fig. 1). First, SLA management component negotiates with the consumer. Results of negotiation are then stored in databases. Second, the service consumer starts transferring confidential data which are already encrypted to Service A and SLA management component monitors the connection to prevent violations. Financial process procedures include multiple services such as stocks or fund applications in banks or companies. Additionally, user information must be transmitted to other organizations. Service A must send requests to servers B and C for other financial services. These requests include personal information such as credit card ID, which are not encrypted and violate SLA. SLA manager will not detect violations between service A and services B or C. Thus, this work presents a novel split SLA for services for follow-up processes in an SOA system. Figure 2 shows this scheme. SLA was split for different services relative to request and these services must meet the requirements of split SLAs. Split contracts inherit encryption from upstream contracts. Transmission of data between services is safer than traditional systems.

The reminder of this paper is organized as follows. Section 2 presents literature reviews. Section 3 describes the proposed system architecture. Section 4 characterizes the message flow in the proposed scheme. Section 5 provides a scenario that corresponds to a real case. Section 6 is the conclusion.

Figure2. Split SLA for preventing violation

## 2. Relative Work

Business processes can be quantified and described using XML-based language [1, 5]. The SLA language for dynamic electrical businesses [2] is collected and analyzed the requirement of SLAs. The SLA language must support a variety of parameters and obligations. Parameters can not be ambiguous for monitors and all parameters can be split. It also addressed the structure and policies for SLA language. In the proposed scheme, parameters in an SLA between consumers and providers are formatted to prevent ambiguous explanations arising from different platforms. Splitting an SLA is what primarily discussed in this paper. An SLA is a contract that defines resource allocations between users and service providers. Violations are detected when resources are insufficient. The Web Service Level Agreement (WSLA) framework [1] was proposed for monitoring SLAs. A WSLA provides a flexible language that supports various SLAs and monitored by the third party. The WSLA was developed for contracts between service consumers and providers. The WSLA has two parts: a script language that describes the SLA which is based on XML schema; and, an execution architecture that includes service monitoring. When the WSLA is applied to an SOA system [6, 7, 8, 9, 10], communication between services can not fulfill contractual agreements between users and service providers. Service management always uses related services to complete a complex job. Third-party monitoring only supervises the interactions between users and service providers. Follow-up processes of services could transmit

data without constraints and cause security problems.

Service oriented architectures have been recently applied to business systems. Stakeholder-driven service [3] was proposed to develop dynamic software system. Stakeholder-driven service provides a life-cycle for developing software and more flexible schema that replaces services dynamically. This work provides a better mechanism to develop software than existing structure. However, managing Stakeholder-driven model can also result in violation when consumers can be replaced. The proposed scheme also solves these problems. Integrating an SLA with an SOA system [4] generates some problems. The system utilizes different software to provide integrated service for users. Services are working concurrently and may change command value in database. A contract can be utilized to limit communication between services.

Figure 2. Split SLA for preventing violation

### 3. System Architecture

This section describes all components in the proposed system. Figure 3 presents the system architecture. A conventional SLA can be split and parts of contract can be sent to other services; however, split contract can not guarantee follow-up services. The proposed architecture guarantees that the SLA will be followed. The capabilities of components are discussed in detail as follows.

#### 3.1 Service consumer

Users or services who request service from service provider are so called service consumers.

#### 3.2 Service controller

The service controller is responsible for searching, monitoring and managing resources or services for service consumers. Service controller can be divided to two parts.

Figure 3. System architecture

#### 3.2.1 SLA management

The SLA manager is in charge of negotiating with consumers, analyzing SLAs, splitting contracts and monitoring requested services.

##### 3.2.1.1 Negotiation

The component is responsible for providing contract content to service consumers. Various service consumers need the same service, but they offer different definitions for service-level objects. Parameters in an SLA contract typically vary and may be ambiguous. Negotiation is used to define appropriate parameters for follow-up services.

When receiving requests, the SLA manager must negotiate with consumers. The contract is in XML-based language. The contract defines communication protocol and other quality values for service consumer.

##### 3.2.1.2 Inheritance analysis engine

This component computes the relations among parameters in a contract. A contract may be split for requesting other services in an SOA system. Every service provider only receives parts of a contract and guarantees partial obligations. However, some characteristics of the original contract have to be extended to split contracts. Otherwise, violations will occur. This

component is used to calculate relationships among parameters and determine which arguments must be inherited. For example, encrypted data from consumers are decrypted according to the key stored in an SLA. The data are then split and transmitted to different services providers in plain code as the key was not inherited. The proposed scheme provides for inheritance of original and split SLAs. This component prevents conditions that violate the SLA.

### 3.2.1.3 Disassembler

When a service consumer signs the SLA, the contract will be analyzed. If only one service is needed, a complete contract will be transmitted; otherwise, the disassembler analyzes and splits requests. Parameters in an SLA are functional and can be split. When splitting a contract, inheritance relationships are computed by inheritance analysis engine. According to computational results, the disassemblers use independent parameters and inherited parameters to build new service SLAs.

Figure 4. relations of disassemble SLA

For example, a consumer request could involve numerous services. Disassembling and inheritance analysis compute a request that includes three services and relationship among parameters. Figure 4 shows the relationships between split SLAs and parameters. Independent parameters are only restricted for one specific service, not for any services. All of the SLAs must include inherited parameters to prevent violations. Partially inherited parameters, which exist in some services, use the same data from consumers and must follow the related rules.

### 3.2.1.4 Monitor

Monitor maps service level objects to resources correctly for detecting violations. All services are measured by an SLA monitor. Resource information is collected periodically to prevent violations. When violations are detected, the monitor notifies SLA manager and

service consumers. The SLA manager then adjusts resources allocations in compliance with contract rules. A service consumer can charge compensation from service provider according to the record of violations.

### 3.2.1.5 Storage

The SLA storage stores all agreements, including complete and split contracts, in the database. A complete SLA is referred to users and service providers for the purpose of maintaining the overall agreement. A Split SLA is referred to service manager and service providers for the purpose of handling partial rules.

## 3.3 Service management

This module manages all of the services. As a bridge to other components, Service management could coordinate negotiations between consumers and SLA managers and allocate resources to services.

### 3.3.1 Service dispatch

According to different services, requests from service consumers are analyzed and split. Based on analytical results, a dispatcher looks up a service provider and locates corresponding services. The service dispatcher forwards split SLAs and requests the required services. When violations occur, the SLA monitor will allocate resource using this component.

### 3.3.2 Service merger

The service provider returns computed results which are responded from different services to consumers. The service manager must merge these results and forward this data to consumers. The merging component assesses the completeness of results since consumers request the whole one service but not three-quarters or half service. Merging component would guarantee the integrity of service responses.

### 3.3.3 Request receiver

All users and service provider requests are received by this component. When service response results sent to consumers, request receiver component would work as an interface for consumers.

## 3.4 Service provider

The Universal Description, Discovery, and Integration (UDDI) provides an index of services for service management. All service providers must register in the UDDI. Service managers will search for the UDDI when a

service request is received and split.

### 3.5 Resource

System resources include CPU, memory, bandwidth and encryption key. These resources require flexible definitions for different requests form numerous platforms. All resources and related parameters are used to provide services.

Figure 5. Message Sequence

#### 4. Diagram of message flow

This section presents an overview of the message sequence when a consumer sends a request to a service provider. Figure 5 shows this procedure.

1. Request: Initially, service consumers connect to the service management and send a request to request receiver. The request receiver provides an interface for receiving different requests from consumers and sending responses.
2. Forward: The request receiver send a request to SLA manager who starts negotiating with consumer.
3. Negotiation: The SLA manager provides a contract to service consumer. According to requests, all relative parameters are used as contract content

in SLA negotiation. This stage will be pending until the consumer responds.

4. Reply: If a service consumer disagrees with the contract, the process is interrupted; otherwise, the contract is approved and stored in a database.
5. Notify: The SLA manager notifies the service manager that the agreement has been approved. According to the decomposed SLA received from the SLA manager, the service manager finds the required services.
6. Searching: The service manager finds the required services using the UDDI component and starts communicating with them.
7. Index reply: The UDDI provides an index of services for the service manager. The service manager dispatches split requests to the corresponding services.
8. Split SLA: The SLA manager computes the inheritance of services and splits the contract for specific services. These split contracts and inherited parameters are combined into different SLAs and stored in a database. The SLA manager then sends these new contracts to the corresponding services.
9. Data: The data from consumer in runtime are transmitted to the service manager. The request receiver remains the interface for consumers.
10. Dispatch data: According to the initial request, data are divided and dispatched to the corresponding services listed in the SOA system.
11. Monitor violation: The SLA manager monitors connections between services. Once the violation occurs, the monitor will notify consumer and the SLA manager to revise resources allocations.

#### 5. Scenario

This scenario applies the scheme to financial services. The number of electronic business services on Internet today is increasing. Service consumers, like the users, want to trade via the Internet trading and perform account transfers. First, users must transmit bank account and stock information to service controller. The request is then analyzed to determine which services are needed. At the same time, the service controller negotiates an agreement with

users. This agreement includes authentication, encryption, bandwidth usage, transfer limits, and stock trading limits. In this case, the service provider finds the Internet trading service offered by the investment company and Internet banking service which needs the account information and a password. The service controller obtains the information of services and split the SLA for these services. The decomposed SLA also inherits the necessary limitations from the original contract. Individual contracts are then transmitted to different services and connections are monitored. The user sends account numbers and passwords to the service controller and divided information into two parts. One part of information is stock investment service, and the other is for banking company. However, stock investment company also requires banking service to charge, it becomes a service consumer in the system. The connection between the stock investment company and bank must follow the split SLA stored at stock investment company. Under this scheme, communication in follow-up process totally complies with the contract.

Figure 6 Process of financial service

## 6. Conclusion

The proposed scheme for SLAs uses more resources than the traditional structure. This is unavoidable since additional processes are necessary to monitor the same parameter in numerous services. Furthermore, the additional processes are needed to monitor communications between services in the SOA system. Contract rules are extended in the follow-up processes to prevent potential violation which isn't completely guaranteed in traditional SLAs architecture.

This work presented a novel scheme for SLAs in an SOA system. The security issue of services in an SOA system and follow-up processes is ensured. Services involved will comply with relevant contract rules and improve the accuracy of an SLA.

### Abstract

With the advent of semantic technology, access control cannot be done in a safe way unless the access decision takes into account the semantic relationships among the entities in a semantic-aware environment. The SBAC model (Semantic Based Access Control model) considers this issue in its decision making process. However, time plays a crucial role in new computing environments, which is not supported in SBAC. In this paper, we propose the Temporal Semantic Based Access Control (TSBAC) model, as an extension of SBAC, which enhances the specification of user-defined authorization rules by constraining time interval and temporal expression over users' history of accesses. TSBAC uses logical time, rather than to real time, in its authorization rules. A formal semantics for temporal authorizations is provided and conflicting situations (due to the semantic relations of the SBAC model and a sub-interval relation between authorizations) are investigated and resolved in our proposed model. An architecture for the access control system based on TSBAC is presented.

### 1. Introduction

An important requirement of any information management system is to protect data and resources against unauthorized disclosure (confidentiality) and unauthorized or improper modifications (integrity), while at the same time ensuring their availability to legitimate users (no denials-of-service). Therefore, enforcing protection requires that every access to a system and its resources be controlled and all and only authorized accesses can take place [1]. The development of an access control system requires the definition of the regulations according to which access is to be controlled and their implementation as functions executable by a computer system.

An important requirement, common to many applications, is related to the temporal dimension of access permissions. In these systems, permissions are granted based on previous authorizations given to the users of the system or denied in specific time points (in the past). Another critical requirement is the possibility of expressing the semantic relationships that usually exist

among different authorization elements, i.e. subjects, objects, and actions. To overcome this challenge, our model is constructed based on the SBAC model (Semantic Based Access Control model) [2, 3] which is a semantic-based access control model. SBAC authorizes users based on the credentials they offer when requesting an access right. Ontologies are used for modeling entities along with their semantic interrelations in three domains of access control, namely subjects domain, objects domain, and actions domain. To facilitate the propagation of policies in these three domains, different semantic interrelations can be reduced to the subsumption relation.

In this paper we unify the two concepts mentioned above; that is, we use the SBAC model (as the base model), and associate a temporal expression with each authorization. Thus, in this paper we employ logical time operators to specify historical constraints over the elements of the history base in authorization rules. Furthermore, a time interval bounds the scope of applicability of the temporal authorization rules, and usage of elements of history (e.g., [1, 2, 20] shows that the authorization is valid for time interval starting at '1' and ending at '20', and history elements with the time stamp greater than 2 are taken into account). Thus, the main feature provided by our model is the possibility of specifying authorization rules which express temporal dependencies among access events in the past (stored in a *history base* in the form of  $done(t, s, o, a)$  and  $denied(t, s, o, a)$ )

The rest of this paper is structured as follows: Section 2 discusses the related work in this topic. Section 3 gives a brief introduction of the SBAC model and describes the model of time used throughout our work. In section 4, we represent our authorization rules in detail, offer their formal semantics, and conflict resolution in access decision point. Section 5 gives an architecture for the access control system based on the proposed model. In Section 6 an implementation of the basic components of the model using CLIPS is presented. In section 7, a case study in a banking environment is described. A qualitative and quantitative evaluation of the model is discussed in section 8. Finally, Section 9 concludes the paper and gives some future works on the topic.

## 2. Related Work

Access control systems for protecting web resources along with credential based approaches for authenticating users have been studied in recent years. With the advent of Semantic Web, new security challenges were imposed to security systems. Bonatti *et al.* [4] have discussed open issues in the area of policy specification for Semantic Web community such as important requirements for access control policies. Developing security annotations to describe security requirements and capabilities of web service providers and requesting agents have been addressed by Rabitti *et al.* [5]. Qin and Atluri [6] proposed a concept level access control model that considers some semantic relationships in the level of concepts in objects domain. SBAC which is the basis of our model, is proposed by Javanmardi *et al.* [2, 3], and is based on the OWL ontology language and considers the semantic relationships in the domains of subjects, objects, and actions to make decision about an access request.

The first security policy based on the history of events was introduced as Chinese Wall Security Policy (CWSP) [7]. The objective of CWSP is to prevent information flows which cause conflict of interest for individual consultants. Execution history also plays a role in Schneider's security automata [8] and in the Deeds system of Edjlali [9]. However, such works focus on collecting a selective history of sensitive access requests and use this information to constrain further access requests; for instance, network access may be explicitly forbidden after reading certain files. Another approach that considers the history of control transfers, rather than a history of sensitive requests, is presented by Abadi and Fournet [10].

In a basic authorization model, an authorization is modeled by a triple  $(s, o, \pm a)$ , interpreted as "subject  $s$  is (not) authorized to exercise access right  $a$  on object  $o$ ". Recently, several extensions to this basic authorization model have been suggested. One of them is the temporal extension, which increases the expressive power of the basic authorization model [11-15]. In the model proposed by Bertino *et al.* [11], an authorization is specified as  $(time, auth)$ , where  $time = (t_b, t_e)$  is the time interval in which the authorization  $auth = (s, o, m, pn, g)$  is valid. In  $auth$ ,  $s$  represents the subject,  $o$  the object, and  $m$  the privilege,  $pn$  is a binary parameter indicating whether an authorization is negative or positive, and  $g$  represents the grantor of the authorization. This model also allows operations *WHENEVER*, *ASLONGAS*, *WHENEVERNOT*, and *UNLESS* on authorizations. For example, *WHENEVER* can be used to express that a subject  $s_i$  can gain privilege on object  $o$  whenever another subject  $s_j$  has the same privilege on  $o$ . Later Bertino *et al.* [14] extended the temporal authorization model to support periodic authorizations. They completed their research in [16] by presenting a powerful authorization mechanism that

provides support for: (1) periodic authorizations (both positive and negative), that is, authorizations that hold only in specific periods of time; (2) user-defined deductive temporal rules, by which new authorizations can be derived from those explicitly specified; (3) a hierarchical organization of subjects and objects, supporting a more adequate representation of their semantics. From the authorizations explicitly specified, additional authorizations are automatically derived by the system based on the defined hierarchies.

## 3. Preliminaries

In this section we give a brief introduction to the SBAC model, proposed by Javanmardi *et al.* [2, 3], and introduce the model of time used throughout our work.

### 3.1 Introduction to SBAC

Fundamentally, SBAC consists of three basic components: Ontology Base, Authorization Base, and Operations. Ontology Base is a set of ontologies: Subjects–Ontology (SO), Objects–Ontology (OO), and Actions–Ontology (AO). By modeling the access control domains using ontologies, SBAC aims at considering semantic relationships in different levels of ontology to perform inferences to make decision about an access request. Authorization Base is a set of authorization rules in the form of  $(s, o, \pm a)$  in which  $s$  is an entity in SO,  $o$  is an entity defined in OO, and  $a$  is an action defined in AO. In the other words, a rule determines whether a subject which presents a credential  $s$  can have the access right  $a$  on object  $o$  or not.

The main feature of the model is reduction of semantic relationships in ontologies to subsumption relation. Given two concepts  $C$  and  $D$  and a knowledge base  $\Sigma$ ,  $C < D$  denotes that  $D$  subsumes  $C$  in  $\Sigma$ . This reasoning based on subsumption represents that  $D$  (the subsumer) is more general than  $C$  (the subsumee).

### 3.2 Modeling of Time

We assume that the system is composed of a single process, and we timestamp each event with a counter based clock. The clock ticks every time an event occurs.

## 4. SBAC with Logical Time Constraints

In some applications, only the logical sequence of events is of considerable importance, or due to the system specifications, time stamping of events with real time is impossible. Thus, in these situations, we use logical time instead of real time and timestamp events using the logical time scheme introduced in section 3.2.

**Definition (Temporal Authorization Rule)** A temporal authorization rule is a triple  $([t_{sv}, t_{sh}, t_f], (s, o, \pm a), F)$ , where  $t_{sv}, t_{sh}, t_f \in LogicalTime$ , and  $t_{sv}, t_{sh} \leq t_f$ . In this notation,  $[t_{sv}, t_{sh}, t_f]$  represents the authorization  $(s, o, \pm a)$  validation time interval, and formula  $F$  is a temporal constraint which is formally defined in Table 1.

**Table 1. Definition of temporal predicate  $F$**

$A ::= done(s, o, a)   denied(s, o, a)  $ $\neg done(s, o, a)   \neg denied(s, o, a)$
$E ::= prev(A)   past\#(A)   H(A)   sb\#(A, A)  $ $ab(A, A)   ss(A)   during(A, A)$
$F ::= true   false   E   \neg E   E \wedge E   E \vee E   E \rightarrow E   E \leftrightarrow E$

The temporal authorization rule  $([t_{sv}, t_{sh}, t_f], (s, o, \pm a), F)$  states that subject presenting credential  $s$  is allowed (or not allowed) to exercise access  $a$  on object  $o$ , in the time interval  $[t_{sv}, t_f]$  if formula  $F$  is evaluated to true by the access events occurred in the time interval  $[t_{sh}, t_f]$ .

**Definition (Temporal Authorization Base)** A temporal authorization base (TAB) is a set of temporal authorization rules in the form of  $([t_{sv}, t_{sh}, t_f], (s, o, \pm a), F)$ .

**Definition (History Base)** A History Base is a set of authorizations with timestamp, in the form of  $done(t, s, o, a)$  that means access  $a$  has been granted to subject presenting credential  $s$  on object  $o$  at logical time  $t$ , and  $denied(t, s, o, a)$  that means the system has denied access  $a$  on object  $o$  at logical time  $t$  requested by subject presenting credential  $s$ .

#### 4.1 Informal Meaning of Temporal Authorization Rules

The intuitive meaning of (logical time) temporal authorization rules is as follows (in these statements *auth* is used instead of  $(s, o, \pm a)$ ):

- $([t_{sv}, t_{sh}, t_f], auth, prev(A))$ : Authorization *auth* is valid at the time of request  $(t)$ ,  $t_{sv} \leq t \leq t_f$ , if  $A$  is evaluated to true at the time  $(t - 1)$ , and  $t - 1 \geq t_{sh}$ .
- $([t_{sv}, t_{sh}, t_f], auth, past\#(A))$ : Authorization *auth* is valid at the time of request  $(t)$ ,  $t_{sv} \leq t \leq t_f$ , if  $A$  is evaluated to true  $\#$  of times in the time interval  $[t_{sh}, t]$  in the history base.
- $([t_{sv}, t_{sh}, t_f], auth, H(A))$ : Authorization *auth* is valid at the time of request  $(t)$ ,  $t_{sv} \leq t \leq t_f$ , if  $A$  is evaluated to true at all time-points in the time interval  $[t_{sh}, t]$  in the history base.
- $([t_{sv}, t_{sh}, t_f], auth, sb\#(A_1, A_2))$ : Authorization *auth* is valid at the time of request  $(t)$ ,  $t_{sv} \leq t \leq t_f$ , if  $A_1$  is evaluated to true  $\#$  of times before the last occurrence of  $A_2$  in the time interval  $[t_{sh}, t]$ .
- $([t_{sv}, t_{sh}, t_f], auth, ab(A_1, A_2))$ : Authorization *auth* is valid at the time of request  $(t)$ ,  $t_{sv} \leq t \leq t_f$ , if  $A_1$  is evaluated to true at  $t'$  ( $t_{sv} \leq t' \leq t$ ), and there exist a time-point  $t''$  ( $t' \leq t'' \leq t$ ), in which  $A_2$  is evaluated to true.

- $([t_{sv}, t_{sh}, t_f], auth, ss(A_1, A_2))$ : Authorization *auth* is valid at the time of request  $(t)$ ,  $t_{sv} \leq t \leq t_f$ , if  $A_1$  is always evaluated to true, from the first occurrence of  $A_2$  in the time interval  $[t_{sh}, t]$  till  $t$ .
- $([t_{sv}, t_{sh}, t_f], auth, during(A_1, A_2))$ : Authorization *auth* is valid at the time of request  $(t)$ ,  $t_{sv} \leq t \leq t_f$ , if  $A_1$  is not true before the first, or after the last time-point in which  $A_2$  is true in the time interval  $[t_{sh}, t]$ .

#### 4.2 Comparison with Linear Time Temporal Logic Operators

As mentioned in previous sections, TSBAC is an access control model that makes its access control decision based on the temporal relation between users' access events in the history. Due to this requirement, we considered a modified set of operators of the Propositional Linear Temporal Logic (Future and Past version) [17]. In addition, some of the operators were added due to the requirements of real environments where the access control system based on the model is applicable. In the following, an overall comparison of the operators of TSBAC and LTL is presented. The newly added operators are described next.

The basic temporal operators of this system are '*Fp*' (sometime *p* or eventually *p*), '*Gp*' (always *p* or henceforth *p*), '*Xp*' (next time *p*), '*p U q*' (*p* until *q*), and the modality '*p B q*' (*p* precedes *q*).

'*Prev*' in TSBAC is the past time equivalent of '*X*' in LTL (or *X<sup>-</sup>*), '*H*' is the past time equivalent of '*G*' (or *G<sup>-</sup>*), '*sb#*' is the past time equivalent of '*B*' which takes into account the number of instants in which the first operand ( $A_1$ ) is evaluated to true. In some situations we need to identify the situation in which an event ( $A_1$ ) has been repeated in all timepoints in the past. Thus, the operator '*ab*' seems necessary. '*ss*' is the '*Since*' operator but with a minor modification; in addition to being a past time equivalent, it is required that the first operand ( $A_1$ ) holds from the moment that  $A_2$  is evaluated to true.

In order to describe a situation in which an event occurred only between the first and last occurrence of another event, during operator seems necessary. '*past#*' is the modified version of '*prev*' which makes its decision based on the desired number of its operand evaluated to true.

For the purpose of increasing the expressiveness of the model, the propositional logic combination of the predicates generated so far was taken into account to create a temporal expression. In this manner, we have a fully functional expressive set of operators that could be used to express different temporal relations between the elements of a history of accesses.

### 4.3 Formal Semantics of Logical Time Authorization Rules

To formalize the semantics of temporal authorization rules, we first define an evaluation function  $\Phi$ . This function evaluates the predicate  $F$  of temporal authorization rules at a logical time point  $t$ , and based on the elements stored in *History Base*. The semantics of such an evaluation is given in first order logic and is reported in Table 2.

**Table 2. Formal semantics of the  $\Phi$  evaluation function**

$\Phi_t(t_{sh}, done(s, o, a))$ $= \begin{cases} true, & t \geq t_{sh} \wedge done(t, s, o, a) \in HB \\ false, & t \leq t_{sh} \vee done(t, s, o, a) \notin HB \end{cases}$ $\Phi_t(t_{sh}, denied(s, o, a))$ $= \begin{cases} true, & t \geq t_{sh} \wedge denied(t, s, o, a) \in HB \\ false, & t \leq t_{sh} \vee denied(t, s, o, a) \notin HB \end{cases}$ $\Phi_t(t_{sh}, \neg done(s, o, a))$ $= \begin{cases} true, & \nexists t, t \geq t_{sh}, done(t, s, o, a) \in HB \\ false, & \exists t, t \geq t_{sh}, done(t, s, o, a) \in HB \end{cases}$ $\Phi_t(t_{sh}, \neg denied(s, o, a))$ $= \begin{cases} true, & \nexists t, t \geq t_{sh}, denied(t, s, o, a) \in HB \\ false, & \exists t, t \geq t_{sh}, denied(t, s, o, a) \in HB \end{cases}$ $\Phi_t(t_{sh}, prev(A)) = \Phi_{t-1}(t_{sh}, A)$ $\Phi_t(t_{sh}, past\#(A)) = \exists t_1, \dots, t_{\#} \cdot \bigwedge_{k=1}^{\#} \Phi_{t_k}(t_{sh}, A)$ $\Phi_t(t_{sh}, H(A)) = \forall t_i, t_{sh} \leq t_i \leq t, \Phi_{t_i}(t_{sh}, A)$ $\Phi_t(t_{sh}, sb\#(A_1, A_2)) = \exists t_{22}, t_{sh} \leq t_{22} \leq t, \exists t_1, \dots, t_{\#}$ $\leq t_{22} \cdot \Phi_{t_{22}}(t_{sh}, A_2) \wedge \bigwedge_{k=1}^{\#} \Phi_{t_k}(t_{sh}, A_1)$ $\Phi_t(t_{sh}, ab(A_1, A_2)) = (\exists t_1, t_{sh} \leq t_1 \leq t \cdot \Phi_{t_1}(t_{sh}, A_1))$ $\rightarrow (\exists t_2, t_1 \leq t_2 \leq t \cdot \Phi_{t_2}(t_{sh}, A_2))$ $\Phi_t(t_{sh}, ss(A_1, A_2)) = \forall t_2, t_{sh} \leq t_2$ $\leq t, (\Phi_{t_2}(t_{sh}, A_2)$ $\rightarrow (\forall t_i, t_2 \leq t_i \leq t \rightarrow \Phi_{t_i}(t_{sh}, A_1)))$
------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

$\Phi_t(t_{sh}, during(A_1, A_2))$ $= \left( \left( \left( \exists t_{min}, t_{sh} \leq t_{min} \right. \right. \right.$ $\leq t \wedge \Phi_{t_{min}}(t_{sh}, A_2)$ $\wedge \left( \nexists t_x, t_{sh} \leq t_x \right.$ $\leq t_{min} \wedge \Phi_{t_x}(t_{sh}, A_2) \left. \left. \right) \right)$ $\wedge \left( \left( \exists t_{max}, t_{sh} \leq t_{max} \right. \right.$ $\leq t \wedge \Phi_{t_{max}}(t_{sh}, A_2)$ $\wedge \left( \nexists t_y, t_{max} \leq t_y \right.$ $\leq t \wedge \Phi_{t_y}(t_{sh}, A_2) \left. \left. \right) \right)$ $\rightarrow (\forall t_1, t_1 \leq t$ $\rightarrow (\Phi_{t_1}(t_{sh}, A_1) \rightarrow t_{min} \leq t_1 \leq t_{max}))$ $\Phi_t(t_{sh}, \neg E) = \Phi_t(t_{sh}, E)$ $\Phi_t(t_{sh}, E_1 \wedge E_2) = \Phi_t(t_{sh}, E_1) \wedge \Phi_t(t_{sh}, E_2)$ $\Phi_t(t_{sh}, E_1 \vee E_2) = \Phi_t(t_{sh}, E_1) \vee \Phi_t(t_{sh}, E_2)$ $\Phi_t(t_{sh}, \neg E) = \neg \Phi_t(t_{sh}, E)$ $\Phi_t(t_{sh}, E_1 \wedge E_2) = \Phi_t(t_{sh}, E_1) \wedge \Phi_t(t_{sh}, E_2)$ $\Phi_t(t_{sh}, E_1 \vee E_2) = \Phi_t(t_{sh}, E_1) \vee \Phi_t(t_{sh}, E_2)$ $\Phi_t(t_{sh}, E_1 \rightarrow E_2) = \Phi_t(t_{sh}, E_1) \wedge \neg \Phi_t(t_{sh}, E_2)$ $\Phi_t(t_{sh}, E_1 \leftrightarrow E_2) = (\Phi_t(t_{sh}, E_1) \rightarrow \Phi_t(t_{sh}, E_2))$ $\wedge (\Phi_t(t_{sh}, E_2) \rightarrow \Phi_t(t_{sh}, E_1))$
-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

By the definition of the evaluation function  $\Phi$  and by the assumption described above, the semantics of authorization rules are presented in Table 3. In the following,  $grant(t, (s, o, a))$  denotes subject presenting credential  $s$  is granted to exercise action  $a$  on object  $o$ , and analogously,  $deny(t, (s, o, a))$  denotes the access request of subject having credential  $s$  for exercising an access  $a$  on object  $o$  is denied.

**Table 3. Semantics of logical time authorization rules**

$([t_s, t_f], (s, o, +a), F)$ $\Leftrightarrow \forall t (t_{sv}, t_{sh} \leq t \leq t_f \wedge \Phi_t(t_{sh}, F))$ $\rightarrow grant(t, (s, o, a))$ $([t_s, t_f], (s, o, -a), F)$ $\Leftrightarrow \forall t (t_{sv}, t_{sh} \leq t \leq t_f \wedge \Phi_t(t_{sh}, F))$ $\rightarrow deny(t, (s, o, a))$
------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

### 4.4 Access Control

The centric security mechanism in each system is an access control system. Upon receiving an access request in such a system, we need to make a decision whether to grant the requested access or deny it. Following the proposed model of temporal authorization in the previous sections, upon receiving an access request  $(s_r, o_r, a_r)$  at

time  $t$ , the access control system performs the following steps:

1. Determine the explicit and implicit valid authorization rules in TAB at time  $t$  (following the definition of valid authorization rules), satisfying the following conditions:
  - $t_s \leq t \leq \min(t_f, t_d)$ ,  $t_d$  is the time of deletion of a specific authorization rule.
  - Temporal predicate  $F$  is evaluated to true at time  $t$  (based on  $\varphi_t$  evaluation function).
2. Extract the set of valid authorization rules such as  $([t_{sv}, t_{sh}, t_f], (s, o, \pm a), F)$  which match the access request. These authorization rules must satisfy, at least, one of the following conditions:
  - $s = s_r, o = o_r, a = a_r$
  - Following the propagation rules of the SBAC model, in the case of a positive action ( $+a$ ), we have  $s_r < s, o_r < o, a_r < a$ , and in the case of a negative action ( $-a$ ), we have  $s_r < s, o_r < o, a < a_r$ .
3. If there exist just positive valid authorization rule(s) such as  $([t_{sv}, t_{sh}, t_f], (s, o, +a), F)$  in MVA, grant the requested access.
4. If there exist just negative valid authorization rule(s) such as  $([t_{sv}, t_{sh}, t_f], (s, o, -a), F)$  in MVA, deny the access request.
5. If there exist both positive and negative authorization rules in MVA, resolve the conflict and follow the result.
6. If there exists no valid authorization rule, which matches the requested access, follow the default access policy.
7. Store  $done(t, s_r, o_r, a_r)$  in case of the requested access is granted and  $denied(t, s_r, o_r, a_r)$  in case of the access request is denied.

#### 4.5 Conflict Detection and Resolution

A conflict occurs when two or more access policies cannot be applied in the same time. In access control, due to modal conflict between *matched valid authorizations*, we need a conflict resolution strategy.

##### 4.5.1 Conflict Occurrence

In TSBAC, conflict occurs due to the semantic relations between the entities (in the domains of subjects, objects, or actions) and applying the inference rules of SBAC, or due to the sub-interval relationship between temporal authorization rules of TSBAC.

- *Conflict due to the semantic relations between the entities*: as mentioned before, in the domains of subjects and objects, subsumee has all the privileges (positive and negative) of subsumer, but, in the domain of actions, positive access rights is propagated from subsumer to subsumee, while negative access rights is propagated in the opposite direction (that is from subsumee to subsumer). These semantic relationships and propagation of negative and positive authorizations between entities may result in conflicting situations.

##### 4.5.2 Conflict Resolution

In access control, due to modal conflicts between valid matched authorization rules (in set MVA), it is required to have a conflict resolution strategy to resolve conflicts. The conflict might be a result of semantic relationships between the entities (i.e. subjects, objects, and actions) and applying the inference rules of SBAC model, or the sub-interval relation between authorizations (i.e.  $[t_{sv2}, t_{f2}]$  is a sub-interval of  $[t_{sv1}, t_{f1}]$ ).

TSBAC supports three predefined strategies for conflict resolution; negative authorization rule takes precedence (NTP) strategy, positive authorization rule takes precedence (PTP) strategy, and most specific rule takes precedence. Similar to the default access policy, the conflict resolution strategy is determined by the administrator.

## 5. Architecture

In order to guarantee the applicability of the model and usefulness in semantic based and temporal environments, an architecture for the access control system based on the proposed model is presented.

Figure 1. An architecture for the access control system based on TSBAC model

## 6. Implementing TSBAC using CLIPS

In order to make inference by CLIPS engine, we must introduce TSBAC to the CLIPS inference engine. This procedure can be summarized into these steps:

- Expressing description logics axioms.
- Expressing subjects ontology, objects ontology, and actions ontology.
- Expressing fix facts of the model.
- Expressing inference rules of SBAC.
- Feeding history base to the inference engine.
- Expressing temporal authorization rules.
- Applying access control and conflict resolution.

The description and details of the implementation could be found in the following URL:

<http://ce.sharif.edu/~noorollahi/Downloads.html>

## 7. Case Study

The required information for applying access control is as follows: two subjects, that is,  $s_1$  and  $s_2$  exist in the environment, and objects ontology and actions ontology can be seen in Figure 2.

Figure 2. Objects and actions ontology in the sample banking environment

Sample temporal authorization rules are as follows:

$$\begin{aligned}
 R_1: & \left( [10, \infty], (s_1, LongTermDeposit_1, +InterestWithdraw), \right. \\
 & \left. H(\neg done(s_1, LongTermDeposit_1, Withdraw)) \right) \\
 R_2: & \left( [0, \infty], (s_1, CurrentAccount_1, -Withdraw), \right. \\
 & \left. sb0(done(all, CurrentAccount_1, Settlement), true) \right) \\
 R_3: & \left( [10, \infty], (s_1, CurrentAccount_1, +GetCheque), \right. \\
 & \left. ss(done(s_1, CurrentAccount_1, GetCheque), \neg denied(all, CurrentAccount_1, pass), 1) \right)
 \end{aligned}$$

$$R_4: \left( \begin{array}{l} [120, \infty], (s_2, \text{SpecialDeposit}_2, +\text{GetLoan}), \\ ss \left( \begin{array}{l} \text{done}(s_2, \text{SpecialDeposit}_2, \text{PrePayment}), \\ \text{done}(s_2, \text{SpecialDeposit}_2, \text{Payment}), 30 \end{array} \right) \wedge \\ \text{past120}(\text{done}(s_2, \text{SpecialDeposit}_2, \text{Payment})) \end{array} \right)$$

The elements of history base are as follows:

- 1:  $\text{done}(20, s_1, \text{LongTermDeposit}_1, \text{Withdraw})$
  - 2:  $\text{done}(30, s_1, \text{LongTermDeposit}_1, \text{Withdraw})$
  - 3:  $\text{done}(25, s_1, \text{CurrentAccount}_1, \text{Settlement})$
  - 4:  $\text{done}(35, s_1, \text{CurrentAccount}_1, \text{Settlement})$
  - 5:  $\text{denied}(50, s_2, \text{CurrentAccount}_1, \text{Pass})$
  - 6:  $\text{done}(51, s_2, \text{CurrentAccount}_1, \text{Pass})$
  - 7:  $\text{done}(130, s_2, \text{SpecialDeposit}_2, \text{PrePayment})$
  - 8:  $\text{done}(140, s_2, \text{SpecialDeposit}_2, \text{Payment})$
  - 9:  $\text{done}(150, s_2, \text{SpecialDeposit}_2, \text{Payment})$
  - 10:  $\text{done}(160, s_2, \text{SpecialDeposit}_2, \text{Payment})$
  - 11:  $\text{done}(170, \text{SpecialDeposit}_2, \text{Payment})$
- **First Access Scenario:** Suppose that request  $\text{req}_1 = (s_1, \text{LongTermDeposit}_1, \text{InterestWithdraw})$  is initiated at the time  $t_{\text{req}} = 40$ . Regarding  $R_1$  and elements #1 and #2 of History Base, the temporal predicate is evaluated to false, and this access request ( $\text{req}_1$ ) is denied (in the case of a closed access policy, or granted in the case of an open access policy). Finally,  $\text{denied}(40, s_1, \text{LongTermDeposit}_1, \text{InterestWithdraw})$  is added to History Base.
  - **Second Access Scenario:** Suppose that request  $\text{req}_2 = (s_1, \text{CurrentAccount}_1, \text{Withdraw})$  is initiated at the time  $t_{\text{req}} = 75$ . Regarding  $R_2$  and elements #3 and #4 of History Base, no negative authorization is issued for this request. Therefore, in case of an open access policy, the authorization is granted and  $\text{done}(75, s_1, \text{CurrentAccount}_1, \text{Withdraw})$  is added to History Base, but in case of a negative access policy, the authorization is denied and  $\text{denied}(75, s_1, \text{CurrentAccount}_1, \text{Withdraw})$  is added to History Base.
  - **Third Access Scenario:** Suppose that request  $\text{req}_3 = (s_1, \text{CurrentAccount}_1, \text{GetCheque})$  is initiated at the time of  $t_{\text{req}} = 100$ . Regarding  $R_3$  and element #5 that exists in History Base, this access request is denied and  $\text{denied}(100, s_1, \text{CurrentAccount}_1, \text{GetCheque})$  is added to History Base.
  - **Fourth Access Scenario:** Suppose that request  $\text{req}_4 = (s_2, \text{SpecialDeposit}_2, \text{GetLoan})$  is initiated at the time  $t_{\text{req}} = 200$ . Regarding  $R_4$  and elements #7...#11 exist in History Base, in spite of existence of element #7 (prepayment) and elements #8 through #11 (monthly settlement),

this access request is denied (because the number of monthly payments is less than 120) ,and  $\text{denied}(200, s_2, \text{SpecialDeposit}_2, \text{GetLoan})$  is added to History Base.

## 8. Discussion and Evaluation

The best way to evaluate an access control model is to qualitatively evaluate it against the security requirements of the environment. Moreover, we can take some quantitative criteria into account, but this consideration is only possible if an implementation of an access control system based on the proposed model exists.

### 8.1 Qualitative Evaluation of TSBAC Model

In this section we evaluate TSBAC regarding requirements of semantic-aware environments.

- **Conditional Authorization:** With the existence of temporal operators, TSBAC supports this type of authorization. In this model, due to wide spectrum of temporal operators, and using first order logic operators for combining temporal expressions, conditional authorization is provided, on the basis of existence or non-existence of specific authorizations in the past.
- **Conflict Detection and Resolution:** Conflict occurrence may be a result of semantic relationships between authorizations, or, sub-interval relations between validity constraint intervals. TSBAC detects these conflicts, and resolves them. Different conflict resolution policies include: denials take precedence, positives take precedence, and most specific takes precedence.
- **Supporting History-based Information:** The main feature of TSBAC is that authorizing an access request is done based on granted or denied access requests (done and denied access requests, which are stored in History Base), or, access requests that have not been done or have not been denied in the system (which can be inferred from History Base). These elements could be combined with temporal operators, or first order logics operators to compose temporal expressions.

### 8.2 Quantitative Evaluation of TSBAC

Due to the existence of an implementation for TSBAC, quantitative evaluation of the model is possible. The time and space complexity of the system based on the logical time operators of the model is as follows.

- **Time Complexity:** Since every access request is validated at the time of the request, and the process of authorization is based upon searching History Base and evaluating the temporal predicate, due to vast amount of elements of History Base and temporal predicate complexity,

access control in TSBAC is time consuming. In order to clarify the subjects mentioned above, we give a brief complexity analysis on *logical time* operators (in case of existence of  $n$  elements in History Base) of the proposed model.

$$\begin{aligned} \text{complexity}(\text{prev}) &= n \\ \text{complexity}(H) &= (t - t_s) \times n \\ \text{complexity}(\text{past}\#) &= \# \times n \\ \text{complexity}(\text{sb}\#) &= (\# + 1) n \\ \text{complexity}(\text{ab}) &= n \\ \text{complexity}(\text{ss}) &\leq (t - t_s) \times n \\ \text{complexity}(\text{during}) &= n \end{aligned}$$

- *Space Complexity:* All of the access requests (granted or denied) are stored in History Base. Storing all the requested accesses in the system, gradually, requires a huge amount of storage space. In case of a vast amount of history elements, and thus, incapability of keeping all these elements on volatile storage, time complexity of access control process is amplified too.

## 9. Conclusion

In this paper, an extension of the Semantic Based Access Control model (SBAC), in order to enhance its capabilities by taking the history of accesses of the system into account was proposed. The proposed model (named TSBAC) uses the same semantic relationships of SBAC, and moreover, it is capable of using temporal relations between the access events occurred in the past (composed as a temporal expression) in specifying authorization rules. In this model, a dynamic aspect are also given to the authorizations by attaching a time interval to each of the authorizations that restricts the validity period of them. These authorization rules (which are composed of base authorization of SBAC, validity time interval, and temporal expression over the history of users' accesses in the system), provides the ability to derive new authorizations based on the occurrence (or not occurrence) of other accesses in the past.

The formal semantics of our authorization rules, plus the access control and conflict resolution procedures were proposed. An architecture for an access control system based on TSBAC was presented. Finally, a banking environment was modeled using TSBAC as a case study.

A generalized history-based access control model that could be applied to other access control policies (such as RBAC) is one of our important future works that will be done.

## Abstract

*The goal of this work is to design a new adaptive routing technique for ad hoc wireless networks. This paper proposed the basic design of the algorithm that works based on the principle of Ant Colony Optimization (ACO). This is a probabilistic adaptive technique that changes its routes with the change of network topology over the period of time by learning its environment. It identifies appropriate paths with the feedback of previously travelled packets and maintains routing table accordingly. A self-made simulator implemented on C++ is used to evaluate performance of this algorithm on the basis of diverse adaptive issues such as Change of Probability, Growth of Pheromone Intensity, Randomness of the Selection and Packet sending rate through different paths.*

**Keywords:** Ant Colony Optimization, Ad hoc Network, Adaptive System, Routing Protocol

## 1. Introduction

Mobile ad hoc network (MANET) started to become popular during mid 90's [1]. In between 1994 and 2004, hundreds of routing protocols came though most of them failed to survive due to their weak proactive nature [2, 3, 4]. During this period four Ad hoc routing protocols became extremely popular. In 1994 Charles E. Perkins proposed his first routing protocol *Dynamic Destination Sequenced Distance Vector (DSDV)* [5]. Two years later in 1996, David B. Johnson proposed his famous Ad hoc routing protocol *Dynamic Source Routing (DSR)* [9,10,11]. In 2002 Niklas Beijar proposed another protocol, *Zone Routing Protocol (ZRP)* [12] though it maintains few restrictions and also lacks in its generalized nature. During this period Perkins was working in Norka Research Centre and developing a new routing protocol and finally in July 2003 his most famous and most commonly used routing protocol *Ad hoc On-demand Distance Vector (AODV)* [6] routing protocol got accepted as Request For Comments (RFC) [7].

Since then DSR and AODV have been dominating ad hoc arena with promising success.

Though DSR and AODV are the most popular routing protocols of current time, they are not perfect yet. Biggest drawback of DSR is its packet overhead as it has to send large control information with the packet. On the other hand, AODV broadcasts huge control data (RREQ packet) to its neighbouring router while establishing a route which increases its bandwidth overhead. Since then a number of approaches has been tried to either improve their performances or implement parallel routing protocols.

## 2. Related study

Due to the NP complex nature of ad hoc routing problem, it is pretty hard to get a perfect solution or even a better solution without increasing the bandwidth or packet overhead. All those problems led the researchers to work with Adaptive protocols for ad hoc routing. In 2001 a routing protocol came named Adaptive Distance Vector Routing [14]. In the same year Adaptive Demand Driven Multicast [15] routing came. There was another algorithm named Fuzzy Sighted Link State Algorithm [15]. In July 2006 M. Roberts Masillamani proposed a GA based routing protocol for conventional distance vector routing and they are currently working to convert this protocol to a GA based adaptive AODV [16].

## 3. Ant Colony Optimization

Ant Colony Optimization (ACO) [17, 18] is an adaptive technique to find partial solutions for the problems where identifying exact solution is either difficult or impossible [19, 20]. ACO is proposed by Dr. Marco Dorigo in 1992 and inspired by the behaviour of ants in finding paths from the colony to food. In 1997, Dr. Marco Dorigo in his work *Ant Colony System: A comparative learning approach to the Travelling Salesman Problem* [21] hinted that network routing can be implemented based on Ant

Algorithm. Very next year he published another research work [22] where he discussed that packets and ants are typically identical for an adaptive system and routing algorithm can be formed or improved based on ant algorithm. In 1999, in another paper, *Ant Algorithm for Discrete Optimization* [31] he proposed the same idea. Despite the fact that he always recommended his algorithm to be used in computer networks, neither he nor other researchers showed enough interest in this regard.

#### 4. Design

ACO is a generalized adaptive technique [27, 28, 29, 30] like Fuzzy Logic [25, 26], Genetic Algorithm [16] or Simulated Annealing [24]. It has different phases such as Initialization, Probability Calculation, Selection, Pheromone Deposition, Pheromone Evaporation etc. which are problem dependent [31]. Each of those phases needs to be designed based on the problem demand and nature. Rest of the part of this section will talk about the design issue of those phases for the proposed routing technique.

##### 4.1 Initialization

ACO is a meta-heuristic method that requires to be initialized at the beginning of the procedure [23]. Conventionally in ACO, all the ant tracks (here routing paths) are initialized with numerical value *zero* because it is assumed that initially there is no pheromone on the tracks. But proposed algorithm initializes its paths in a different way; with numerical value of *one* instead of zero. The rational behind this modification is quite straightforward – in this algorithm a non-zero value of intensity represents a connection which means pheromone intensity also indicates connectivity of nodes and paths having zero intensity indicate there is no connection between two particular nodes.

**Figure 1:** A network topology with a stable pheromone intensity of the paths.

**Figure 2:** Changed topology when a new router G joined the network.

In Figure 1, a stable network topology has been shown where pheromone intensities of the paths are  $I_{AB}$ ,  $I_{CD}$ ,  $I_{DB}$ ,  $I_{DF}$  and  $I_{DE}$ . Let us assume that a new node G has just joined the network (shown in Figure 2), hence creates three new paths GB, GF and GE. Conventional approach of ACO would initialize these three paths with zero intensity as those new paths have not been travelled by any ant (packet) yet. But, as per our proposed algorithm initialization will be done with one in order to indicate that there is a path available between B and G, F and G and E and G.

##### 4.2 Probability Calculation

Probability calculation is one of the most important issues for any adaptive algorithm and success of the proposed technique is highly influenced by the proper calculation of the path probability as while sending a packet from one node to another node, which path should get selected is determined by this probability. Proposed technique calculates this parameter based on the pheromone intensity of different paths. Probability of a path is defined as,

$$P_i = \frac{I_i}{I_t}$$

**Equation 1:** Path probability

Here,

$P_i$  is the probability of a particular path  $i$  connected with the respective node.

$I_i$  is the intensity of a particular path  $i$  connected with the respective node.

$I_t$  is the summation of intensity of all paths connected with the respective node.

##### 4.3 Selection

Selection is done by single spin roulette wheel method. Space allocation for each path on the wheel is proportional to its probability. Say for example, there are three paths A, B, and C connected with a router having probability  $P_A=0.50$ ,  $P_B=0.25$  and  $P_C=0.25$ . Arrangement on the wheel for this particular case is shown in Figure 3.

**Figure 3:** Roulette Wheel arrangement for PA=0.50, PB=0.25 and PC=0.25.

Another important issue in selection is generation of pseudo random number as weakness of random number generation may create initial fluctuation problem [31]. In real life, most of the built-in random number generator functions return close value if they have been called with in a short duration of time (such a 1 millisecond) as they take current time in second as seeds. A method for well distributed random number generator has been proposed with this algorithm. A C++ code segment has been given bellow. This function takes a *value* as a parameter and returns a well distributed random number in between *zero* and *value*.

#### Random Number Generator Function

```
Int random(int highest)
{
 srand((unsigned)time(0));
 int random_integer;
 int lowest=0;
 int range=(highest-lowest)+1;
 random_integer = lowest
 +int(range*rand()/(RAND_MAX
 + 1.0));
 return random_integer;
}
```

#### 4.4 Pheromone Deposition

In this proposed algorithm, pheromone deposition is done by the *backward* packets. After a successful delivery, each packet increases the intensity of each path that it has travelled to deliver the packet based on the following formula.

$$I_{new} = I_{old} + \frac{Q}{Lenth\_Ratio}$$

**Equation 2:** Pheromone Deposition Formula

Here,  $Q$  is a unit quantity of pheromone to be deposited. But, all the paths wont get the full portion of  $Q$  rather deposition of  $Q$  will be inversely proportional to the travelled Path.

Here **Length Ratio** varies from node to node. For each node on the path it is measured as the path length between the source and the calculated node.

In this technique, backward packet will deposit more pheromone on the shorter path compare to the longer path while coming back from the destination. As the probability calculation is dependent of the pheromone density which ultimately increases the chance of best path to be selected.

A pictorial example is shown here to describe the above literature. Consider the following network topology shown in Figure 4 and 5. In Figure 4, it shows that A has made a successful delivery of a packet to C. During this travel, this packet marked the paths that it has travelled.

**Figure 4:** A is sending a packet to C.

**Figure 5:** Intensity of the paths is being changed by the backward packet.

Let us consider  $Q = 10$ . Based on the Equation 2 pheromone of each track will be updated as follows:

$$\begin{aligned} I_{AB(new)} &= 10 + (10 / 3) = 13 \\ I_{DB(new)} &= 87 + (10 / 2) = 92 \\ I_{CD(new)} &= 20 + (10 / 1) = 30 \end{aligned}$$

Figure 5 shows backward packet sent by C to A. This backward packet will increase the intensity of the paths (underlined) that it has travelled while coming from A to C.

#### 4.5 Pheromone Evaporation

Pheromone evaporation is another issue in ACO. It decreases pheromone from less travel paths. In this algorithm pheromone evaporation is done based on a parameter called *evaporation parameter*,  $\lambda$ . Value of  $\lambda$  depends on the traffic density of the network. If Intensity of any path at a junction crosses the value of  $\lambda$ , intensity for all the paths of that junction will be changed as follows:

$$I_{i(new)} = \frac{I_{i(old)}}{GCD(I_{1(old)}, I_{2(old)}, \dots, I_{k(old)})}$$

**Equation 3:** Pheromone Evaporation Formula

Here,

$I_{i(new)}$  is the Intensity of  $i$  path after the evaporation.

$I_{i(old)}$  is the Intensity of  $i$  path before the evaporation.

$k$  is the number of connected paths with that router.

## 5. Operation

A routing technique has to perform three basic operations, namely *Route Establish*, *Route Discovery* and *Route Maintenance* [13]. Nature and performance of a routing algorithm is determined on how does it deal with these three tasks. Followings are the brief operational summary of the proposed technique.

### 5.1 Route establish

Route establishment is a prime and foremost task for any routing procedure. In our proposed technique, at the beginning of the network or when a new node enters into the network, it finds its neighbouring node and initializes local intensity value of the corresponding paths with unit value (i.e. 1). Initially it also assumes that all the nodes of the network are reachable through any of those paths. It maintains a vector table like distance vector routing where it puts the intensity of different paths. This table is arranged in the conventional form of “*from A to B via C*” [13]. But instead of distance value, it holds intensity of a particular link. As time passes, gradually best outgoing link for a particular node becomes stable in the intensity table.

### 5.2 Route discovery

This routing technique does not send any route request packet like AODV or any service discovery like DSR. Still it maintains a reactive on demand nature. Before sending any packet to a particular destination, it finds the path based on a probabilistic selection mentioned earlier in

section 3. Path having been travelled most to reach a destination will get higher priority in the selection. This route discovery is an adaptive method based on Ant Colony Optimization and it becomes stable eventually by learning the environment.

### 5.3 Route maintenance

Proposed technique maintains its route in an adaptive manner. When a node gets down from the network, no packet can successfully be delivered through the path that goes over that particular node. As a result pheromones of that path will be evaporated and other paths will start to get the priority in selection. If the down node gets back to the network then this path will be established again otherwise due to periodical pheromone evaporation this path will become a dead link.

## 6. Result and Evaluation

A self made simulator implemented on C++ is used to evaluate performance and behaviour of the proposed technique. This simulation mainly concentrates in measuring and evaluating adaptive natures of the algorithm. A 50 node scenario is considered taking two nodes as source and destination where three different and complex paths are available to reach the destination from the source node. Among the paths, *Path 2* is the best one while *Path 3* and *Path 1* are the second and third best respectively. We measured following four issues to evaluate our proposed technique:

1. Change of Probability
2. Growth of Pheromone Intensity
3. Randomness of the Selection
4. Packet Sending Performance

### 6.1 Change of Probability

Change of probability is measured over the period of 900 packet send time from the source node to the destination. Initially when the very first packet was sent, the probability of each path was equal, i.e. 0.33. As time increased, gradually best path was established and the worst two got almost down. Figure 8.1 shows change of probability of different paths within an interval of 100 packet send period.

### 6.2 Growth of Pheromone Intensity

In this part of the evaluation once again 900 packets were sent and within an interval of each 100 packet send time measurement was taken. Initially pheromone intensity of all three paths was 1. Figure 8.2 shows change of intensity due to pheromone deposition on the experimental

paths. Result clearly shows that best path got more pheromone deposition and its intensity increased. Intensity of other two paths was increasing with an extremely slow rate.

**Figure 6:** Change of Probability in the test topology

**Figure 7:** Growth of Pheromone Intensity

### 6.3 Randomness of the Selection

Randomness of the selection has been measured by this experiment maintaining the same network topology over five different runs. Figure 8.3 shows the result where it is clearly noticeable that the variation is very marginal in different runs.

**Figure 8:** Randomness of the Selection

### 6.4 Packet Sending Performance

In this final evaluation total number of packet sent through each path is measured for the same topology over the period of 100 packet sent time. Figure 8.4 shows, as time increased, Path 2 (best

path) got selected more frequently for sending packets from the source node to the destination.

**Figure 9:** Packet Sending Performance

## 7. Conclusion and Future Work

An ant navigation based adaptive routing technique is proposed and evaluated in this paper and we are confident that it will work effectively in the real ad hoc network scenario. This work mainly concentrates on designing different adaptive parameters of the technique rather than concentrating in the network layer issues. Our future objective is to implement this algorithm using OPNET [32] for mobile ad hoc network and compare its performances with AODV and DSR.

Concordia University  
Montreal, Quebec, Canada  
{mah\_r, aagarwal, a\_alsar}@ece.concordia.ca

## Abstract

*To utilize the available frequency channel space in wireless mesh networks (WMNs), recent work has significantly been focusing on the channel assignment in multi-interface and multi-channel wireless mesh network. This paper presents our design of a distributed channel assignment algorithm that assigns channels based on capacity of the channels. It is shown that the performance of the network is significantly improved when interference and capacity are considered to choose a channel. Simulation results show that our channel assignment algorithm performs better than a similar channel assignment algorithm which is distributed and based only on interference.*

## 1. Introduction

Wireless Mesh Network (WMN) is the next generation wireless internet paradigm that is under progress for commercial deployment. The performance of the entire system of wireless mesh networks is influenced by the radio resource management (routing, transmission power, channel assignment). Power constraints and mobility issues are not the major concern for such networks in current research. Although significant progress has been achieved during the last decade, it still requires more work to achieve higher performance.

Recent research has shown that each node in a wireless mesh network greatly enhances the performance of wireless mesh networks by using multiple radios [1]. A typical wireless mesh network requires a common channel between two nodes to communicate. Deployment of multi radio introduces the availability of having multiple channels to improve the system throughput of WMNs. Use of multiple channels is introduced to avoid the interference in adjacent access points in a network. Proper channel assignment algorithms are therefore required to utilize multiple channels efficiently.

Previous work done in [1] shows that 802.11a offers twelve and 802.11b offers three non overlapping channels. Although multiple channels and multiple interfaces are used to improve the throughput of the network, inappropriate channel assignment will cause the throughput reduction [2]. Thus, a

channel assignment algorithm plays as one of the most important roles for the performance of such networks. In this paper we aim to design a channel assignment algorithm for multi-channel wireless mesh networks that enhances the network performance with better throughput and reduced delay.

The rest of the paper is organized as follows. Section II presents the review of the previous work in channel assignment for wireless mesh network. Section III motivates the benefits of having multiple interfaces and multiple channels. Fundamental issues for channel assignment and different kinds of channel assignment strategies are shown in Section IV. Section V describes our algorithm and evaluates the performance result of our algorithm. Section VI concludes the paper.

## 2. Related Work

Several mechanisms have been proposed in [1-8] for channel assignment in wireless mesh network. These are different in behavior and have focused in separate issues in wireless mesh network. The main purpose of most of these researches is to find optimality for packet transmission and to enable multiple packet transmission with better throughput in the network. These are mainly categorized into two different kinds of algorithms: centralized and distributed.

A centralized algorithm has the ability to process and assign channels to different nodes based on the information stored in a central entity. All nodes send their channel information (interference level, default channels available and channels already assigned) to the central entity which assigns channels for nodes based on this information. As a consequence, more bandwidth is consumed. The main drawback of this approach is the complete failure of the network in a situation where the channel assignment server would fail.

Distributed algorithms have the advantage of having a better ability to cope with failures (fault-tolerance). A distributed algorithm must have the ability to be self stabilizing when used for routing purposes, for example, no matter what the initial configuration is, the algorithm will eventually achieve its intended purpose. In the distributed assignment scheme, each node collects information from his neighbors only to

select the channels and consequently not consume large bandwidth. This kind of approach is scalable but it has the limitation of increased computing power in each node of the network.

In [1] a hybrid channel assignment is proposed where each node of the network is assigned as one fixed and one dynamic channel. It has shown that using this mechanism, nodes can both transmit and receive data simultaneously. The fixed channels in the interface are only used to receive the data and the switchable one chooses a channel according to the demand to transmit the data to other nodes. However, no mechanism is shown in this research to choose the proper channel when it is communicating to other nodes to improve the performance of the network.

The algorithm proposed in [2] is mainly focused on the multicast mechanism in wireless mesh network. Using a centralized approach, this algorithm improves the system throughput by allowing simultaneous close-by transmissions with multi-channel and multi-interference. It assigns all the available channels to interface. The channel assignment and routing is optimized according to the change of topology and node failure. Thus, it does not assure the stability of the network.

The algorithm presented in [3] provides a mechanism to recognize the node failure and to restore the connectivity. It reduces the number of hop count in the network and also decreases the interference between the nodes by considering node levels. It uses a randomized channel assignment in a distributed manner and maintains the network connectivity.

A breadth search based centralized channel assignment was proposed in [4], which mainly focuses on the interference level and better throughput of the network. It uses a default channel for transmission and has a link redirection protocol to improve the stability of the network. However, it does not consider the routing issues.

In [5], the proposed algorithm for channel assignment can minimize the overall interference of a multi-hop wireless mesh network. The result shows that this algorithm preserves connectivity and the interference level decreases with the increase of radios. Routing and stability issues are however not considered in this algorithm.

The channel assignment algorithm described in [6] considers link bandwidth and channel diversity to transmit a packet from source to destination. Although it works better in shortest path, it gives 35% more improvement than any other algorithms for a path that has more than 5 hops.

In [7], the goal of the channel assignment algorithm is to improve the throughput. It does not deal with the interference avoidance. This algorithm is used to assign channels to the network interfaces such that the resulting available bandwidth on these interfaces is at least equal to their expected traffic load. It is measured by calculating the expected bandwidth needed for traffic to each pair of node. Connectivity of the network is not considered in this algorithm.

In [8], a distributed channel assignment algorithm was proposed that has self-stabilizing mechanism which assigns channels to multi-radio nodes in wireless mesh networks

based on the interference of the channels with the neighboring nodes. The scheme is stable to a desirable channel configuration that strikes a good balance between network connectivity and channel diversity, and that routing protocols can exploit to provide better end-to-end system performance. The design considers several constraints present in current 802.11 devices, and its distributed nature ensures it is sufficiently light-weight to be executed on large scale mesh networks. However, issues such as channel capacity and switching delay were not considered here.

We have chosen the algorithm described in [8] to compare the proposed algorithm. In [8], even though the channel assignment mechanism is done in the real test bed, we have chosen almost the similar environment in our simulation. The mechanism shown in [8] focuses to utilize the 802.11 channels within the mesh routers [8]. Unlike the other channel assignment algorithms described previously, it considered the real wireless mesh network environment with 14 nodes. It emphasizes only on the channel assignment issue for wireless mesh network. We are dealing with multi-channel issues for the wireless nodes which were also a key concern for this algorithm. The distributed nature of this channel assignment enhances major improvement by balancing between connectivity and stability of the network and thus assures end to end quality of the network [8].

### 3. Motivation

In this section, we first describe the wireless mesh network architecture. Thereafter we show the motivation to have a proper channel assignment in wireless mesh networks.

#### 3.1 Network Architecture

**Figure 1. Wireless Mesh Network architecture**

Wireless mesh networks provide users with more services when compared to other wireless network types. The network contains two types of nodes: mesh routers and mesh clients [10, 11]. Conventional users can connect to mesh network through mesh routers if their system have a wireless network interface, otherwise they can connect via Ethernet links. Mesh router can have multiple wireless interfaces built on either the same or different wireless access technologies.

As a result, many wireless networks with different technologies can be integrated through mesh routers. WMNs network architecture can be classified into three groups [11, 12]:

**Mesh Gateway:** Mesh gateway act as the backbone of the network. It has necessary functions for mesh networking. They can be connected to other networks through gateways or bridges.

**Mesh Router:** Mesh routers perform routing and configuration functions as the access point. Because they provide extra functions, end user devices need more resources to establish a connection with them. Mesh routers are considered to have less mobility or no mobility at all than clients. It is considered to be immobile or with small mobility.

**Mesh Client:** Mesh clients are the end users of mesh network. They can connect both with the gateway and access point routers. Mesh clients are considered to be mobile.

### 3.2. Benefits of having Multi-Interface

From [1], we found that the previous works in wireless mesh network used single interface. It is because the networks were maintained by single channel for all the nodes. Multi-interface is beneficial when the network is having multi-channel for the nodes. As mentioned in Section I , wireless mesh networks nodes need to be in the same channel to establish a connection between them. If we use a single interface for the nodes then it has to use a channel to send or receive a packet from other node. While it is in communication with another node no other node can communicate with that specific node. As a result, when a single interface is used, packets might have to wait to use that specific node or to find an alternative route which will also have to provide a common channel. This increases end to end delay for the network if different hops are not in the common channel. Another important benefit that multi-interface provides is to transmit and receive data simultaneously. If a node has multi-interfaces working in multi-channels, both interfaces can transmit and receive data simultaneously. This doubles the maximum throughput in a multi-hop route [1].

### 3.3. Necessity of Multi-Channel

The deployment of multi-channel in wireless mesh network makes the whole network very flexible. Multi-channel makes the network robust, since it increases the optimality of the route in the network. The connectivity might not affect the whole network performance if the nodes have multi-channel to use in their interfaces. Also, from the previous section we get the understanding that to run simultaneous communication for multi-interface we need multi-channel to avoid interference. In a single channel environment, if most of the nodes have the same channel then interference will result in reduction of the total throughput. Multi-channel gives the flexibility of selecting routes that uses different channels. Thus, having these benefits really made the difference from a single channel network.

### 3.4. Need for Proper Channel Assignment

Channel assignment determines the connectivity between radios since two radios can communicate with each other only when they are on a common channel, and therefore it determines the network topology. As we know, the routing decisions are made based on the network topology. Thus, channel assignment has a direct impact on routing. Channel assignment should be dynamically adjusted according to the traffic status, which is determined by a routing algorithm. Therefore, channel assignment and routing are tightly coupled with each other.

Channel assignment also puts an impact on the connectivity of the network. The concept of channel assignment is not constant and hence it depends on the network classification. Different channel assignment schemes were proposed for Single Radio networks and Multi-Radio Networks; so, the connectivity changes accordingly. It improves the channel diversity for the nodes in a wireless network which in the long run enhances the quality of the network.

The use of single channel in wireless mesh network cannot fully use the aggregate bandwidth available in the network. Using multi channel avoids this problem and gives a better performance for the network. The purpose of channel assignment in a multi channel wireless mesh network is to assign channels efficiently so that the total interference of each link is reduced, thus resulting in an improvement of the total throughput. As more interfaces within the range are available and use same channel within the interference range, the bandwidth available per interface will surely decrease. Therefore, a proper channel assignment algorithm is needed to balance the network connectivity and improve the aggregate bandwidth. The delay for each link will also depend on the channels used for each node. With a proper channel assignment the delay can also be reduced.

## 4. Channel Assignment in WMNs

In this section we provide the fundamental issues for channel assignment, different channel assignment strategies and our algorithm for channel assignment in wireless mesh networks. Several key performance issues such as: interference, connectivity, stability and routing; are considered in our research to find a proper channel assignment algorithm in wireless mesh networks. Using a proper channel assignment and maintaining these constraints constraints, a good quality of service of a network can be guaranteed.

### 4.1. Fundamental Issues for Channel Assignment

Several channels are employed to establish the communication with the other nodes. Numerous issues are considered to assign the channels. These issues set the performance of the network. Using a proper channel assignment and maintaining these constraints, a good quality

of a network can be guaranteed. The issues that we consider in this paper are described as follows:

**Interference:** The main obstacle to achieve high capacity wireless mesh networks is interference between the mesh links. This is the major factor that degrades the performance of the network. The throughput of the network has a direct relationship with the interference among the links. Due to interference, the quality can change arbitrarily with any change in the routing pattern. As such, these measurements have limited predictive value because they cannot tell whether re-routing existing flows would result in better network throughput or which path is best for a new flow. Mesh networks however operate in the unlicensed bands and have no particular claim to the spectrum they use. They must share frequencies not just with other wireless LANs but with a broad range of products, from cordless phones, microwave ovens to wireless video surveillance cameras. In addition, physical objects like buildings, mountains and bridges, pose major problems for wireless transmissions. Interference can be classified in two categories: co-channel interference and adjacent channel interference.

**Connectivity:** A network is said to be connected, if for every pair of nodes there exists a path between them; otherwise it is disconnected. Connectivity is a fundamental property of wireless mesh networks. Unlike cellular networks, a multi-hop wireless mesh networks has a decentralized approach to establish a connection between links which is more sophisticated. To achieve a connected network, a wireless multi-hop path must exist from each node to each other node. Each single node contributes to the connectivity of the entire network. If a node fails, the connectivity might be changed. The probability for a network to be connected depends on the density of nodes and their transmission ranges. However, the connectivity is not the same for single-channel and multi-channel networks. Based on this, channel assignment can change the topology of the wireless mesh networks. There is a trade-off relationship between connectivity and interference. The more radios are assigned to the same channel, the more connectivity is achieved and more interference is induced.

**Stability:** Stability plays a very important role in the successful deployment of any wireless network. It may be regarded as one of the most important aspects, since a network does not exist without a connection. If a network technology offers a secure routing mechanism along with stable connection among the various participants, the network is anticipated to be a stable one. To maintain stability, a channel assignment is done in such a way that the channels in the interfaces of the nodes do not change back and forth among several choices. When two nodes discover that a channel is under-utilized, they might simultaneously switch to this channel and both begin the transmission on it, and then switch back upon discovering this channel is overloaded.

**Routing:** The topology of the network changes accordingly to the route taken for that network. For wireless mesh networks, the basic factor of making a routing decision is done on channel assignment. If the channels assigned for the nodes in the network are changed, the routing will also be changed,

thus the network topology changes. Even though wireless routers are typically stationary in this kind of network, routes in this network are expected to be unstable. Because of issues like multi-path fading effects, external interference and weather conditions, wireless links vary widely in their qualities. Link interference can lead to variations in the quality of mesh routes, which can result in route change. So, routing is a very important issue to be considered in a channel assignment. For an example, channel assignment schemes in [1] for multi-radio mesh networks assign channels to frequently diversifying routes in the mesh. If routes are expected to change, the mesh radios should also be re-assigning channels in order to ensure optimal network performance.

## 4.2. Channel Assignment Strategies in Interfaces

Channel assignment in multi-interfaces can be classified into three different kinds. These are static or fixed, dynamic, and hybrid channel assignment.

**Static Channel Assignment:** In static channel assignment, each interface of the nodes is assigned a channel permanently or for a long period of time. Such assignments are relatively simple but cannot adapt to the capacity changes. Different channels can be assigned for adjacent links but channel must be assigned to the links with a certain distance. This is the easiest one among all the strategies, but provides the worst channel utilization. It also cannot adapt to different traffic load in different links.

**Dynamic Channel Assignment:** In dynamic assignment, channels are assigned for different nodes for a small period of time. The advantage of this kind of strategy is to have the ability of switching one interface to any channel, thereby having the choice to use many channels in very few interfaces. It has some drawback too. It gives worse performance than static channel assignment under heavy traffic loads.

**Hybrid Channel Assignment:** Hybrid channel assignment is the combination of both static and dynamic channel assignment. It divides the number of channels into two groups, one of which is used for fixed allocation while the other is used to keep the channels to be shared by all the nodes. It needs fewer interfaces than dynamic channel assignment and can also be used with channel reassignment strategy.

Switching the channels between the interfaces has a close relationship with the performance of the network. Multi-interfaces need a proper mechanism to switch the channels properly among the interface to reduce switching delay.

## 5. Capacity based Channel Assignment

In this section, we describe a new distributed channel assignment algorithm. We consider interference and capacity ratio to choose the best channel among all the available channels. To calculate the interference of a channel we have chosen the mechanism shown in [8]. Each node selects a

channel that has less interference with neighbors. Section IV discussed how interference enhances the channel assignment and the performance of the network. We consider the least interference and the highest capacity of a channel to assign channels for a node to improve the performance of the network in terms of throughput and delay.

Capacity of a channel can be defined as the highest upper bound on the amount of information that can be reliably transmitted over a communication channel. In other words, capacity of a channel will decide how fast a node can send or receive information. Every channel has separate capacity and it can vary depending on the frequency spectrum. In our algorithm, each node selects a channel by executing the algorithm shown below.

---

#### *Channel Selection ( node i)*

---

*Input*

*i: node i*

*S<sub>k</sub>: set of channels for node k*

*S<sub>i</sub>: set of candidate channels*

*I: interference for a channel*

*C<sub>i</sub>: the capacity of channel i*

*begin procedure*

*for each i ∈ S<sub>i</sub>*

$$I_i = \sum_{k \in S_k} I(i, k)$$

$$R_i = \frac{C_i}{I_i}$$

*End for*

*Selected \_ Channel = Max(R<sub>i</sub>)*

*end procedure*

---

Each node selects a channel that has less interference and maximum capacity. The cost function to measure the interference,  $f(a, b) \geq 0$ , provides a measure of the spectral overlapping level between channels a and b [8]. The interference cost function in [8] is defined in such a way that  $f(a, b) \geq 0$  and  $f(a, b) = f(b, a)$ , where two channels are justified as non interference channels when the value of the function is 0 [8]. Each node computes the interference between the candidate channel and neighboring channels. From the result observed in [8], which considers only the interference to assign the channel among the nodes, we figured out that considering interference-capacity ratio would

generate noteworthy improvement. The algorithm in [8] chooses a channel based on the least interference. A node selects a channel that has the minimum sum of the interference cost for the set of nodes within the interference range [8]. Considering capacity as a key parameter, we have chosen the maximum value that we can measure after finding the interference capacity ratio for every single channel. Capacity for the channels is taken as a random value since our focus was not to justify the amount of capacity for the channels. Thus, for each node the channels are assigned from the channel list in a way that it gives the best throughput and fast transmission of data from source to destination.

We have already discussed the advantage of multi-interface in wireless mesh networks. The multi channel assigned for all the nodes can be distributed using the algorithm. The interfaces are assigned a channel which is the same channel for the interface used in the destined node. This improves the performance even better if the other interface of the node is used only to transmit and receive the data [7]. Moreover, it assures network connectivity even if any other node enters into the network. That means, this protects the end to end communication from topology changes. In [8], the algorithm likely assigns different channels to the non neighboring nodes. In our proposed algorithm, since the channels are not assigned only based on interference, the information of non neighboring nodes does not make an important impact.

However, network parameters such as link delay, link bandwidth, switching delay and congestions are not the motivation of this paper. These parameters are needed to be considered for an improved routing protocol. The objective of the proposed algorithm was focused to show how an improved channel assignment can enhance the total performance of WMNs. Improving routing protocol was out of our scope for this paper. Several important issues for WMNs environment are considered to evaluate the performance of the channel assignment algorithm. The effects of these issues are discussed in the next section.

## **5.1 Performance Evaluation and Result**

In this section, we show the methodology we used for the simulation and also evaluate the performance of the network. In the result, we have showed the performance of the network in terms of throughput and delay.

## **5.2. Simulation and Methodology**

In our work we used Sinalgo simulation framework that is used for testing and validating network algorithms and abstracts from the underlying layers. Sinalgo focuses on the verification of network algorithms. To justify the performance of the algorithms, we implement both of the algorithms under similar simulation environment. The algorithms are implemented in the same topologies considering a wireless mesh network environment. We have considered a 14 nodes topology. These nodes are considered to have two interfaces and to ensure the performance of the result a random number

of messages are chosen from end to end. The network parameters chosen for evaluating the algorithms and the methodology of the simulation are shown below.

PARAMETER	COMMENT
Number of Nodes	14
Total Number of Channels	30
Number of Channels per Node	3-10
Distribution Model	Random
Mobility	Considered
Connection Type	TCP
Message Type	Data Packet

Table 1. Network Parameters

**Spectrum of interference:** Spectrum of interference for the simulation is implemented as a bi-dimensional array. The values used in the array represent the distances between any two channels. This distance is uniformly distributed. The spectrum is initialized at initialization of simulator and it does not change while the simulator is running. Total thirty channels are considered in the spectrum.

**Channel Assignment:** The nodes are created randomly. This is handled by “Sinalgo” framework. When a node is created the channels are taken randomly from the spectrum of interference. The number of channels for each node is randomly generated as well and each node can have 3 to 10 channels.

**Connectivity:** We implemented our connectivity, based on the commune nodes between channels. If there are commune nodes an edge will be drawn, so the nodes are connected and routing is possible. We have tested the performance of the network when there are any node failure or topology changes. Since the channels are uniformly distributed always two nodes should have commune channels.

**Routing:** Various routing protocols have been already experimented in wireless mesh networks. As per [1], the most common routing protocols such as DSR and AODV selects shortest path to reach the destination. But since the available channels in wireless mesh networks cannot be properly used by the shortest path route, it is not suitable for multi-channel, multi-interference wireless mesh network. It also does not consider the impact of switching channels in a dynamic channel assignment.

Our channel assignment algorithm is not tied to any routing algorithm. Our focus was to improve the throughput by selecting the proper channels for different nodes. The exact set of paths between a communicating node pair is chosen randomly based on the interference and capacity ratio. Our focus was to evaluate the performance of the network for different random routes. For evaluation purposes, we have considered different topologies to measure the performance of the algorithm. Each node maintains a routing table. When a

node (source) wants to send a message to other node (destination), the source node sends a flooding message to the other nodes in neighborhood and waits for an acknowledgement. When the acknowledgement arrives to the source, the destination, the next hop to destination and the number of hops to destination is stored in the routing table.

**Throughput Calculation:** When a node is created, a random number of messages are created and sent to a random number of chosen neighbors. The neighbors are chosen randomly. When the messages arrive to destination, they are stored in a hash table. After all messages arrive the throughput of all messages is summarized and calculated.

**Network Topologies:** The simulation done for analyzing the performance of our algorithm is free from the size, number of hops and change of the topology of the network. We have done the simulation for ten different topologies.

### 5.3. Evaluation Results

The following figures show the result found from the simulation. The solid line (CBCA) in the graph is used to show the result for our algorithm and the dotted line (IBCA) is for the channel assignment algorithm used in [8].

Figure 2. Comparison of throughput

Figure 2 shows the throughput of the two algorithms. The x-axis in the figure represents the throughput in kbps, and the y-axis indicates the number of packets in each run. The performance gain by our mechanism is clear. For instance, at 3750 messages, the throughput of our algorithm reaches 119250.0 kbps, while the best of the [8] achieves no more than 71250.0 kbps.

Figure 3 compares cumulative distribution of the throughput of two algorithms. The results show that our algorithm outperforms the algorithm in [8]. The x-axis in the figure represents the throughput in kbps, and the y-axis indicates the cumulative distribution function of the throughput.

**Figure 3. Comparison of cumulative distribution**

It can be clearly seen that our algorithm has less probability to achieve low throughput. The simulator was run ten times. No run achieved a throughput of less than 1500 Kbps in our scheme whereas the algorithm in [8] shows the cumulative distribution of 0.2 for the same throughput. Moreover, 3 runs of our algorithm achieved throughput around 6000 kbps. Therefore considering channel capacity increases the throughput.

**Figure 4. Comparison of delay**

By reducing the interference and choosing the channel that has the maximum ability to transmit data we compare the delay of the two algorithms in Figure 4. When the load (number of packets in the system) is small, the difference in delay is small because the load is not sufficient to cause congestion in the network. However, by increasing the load (1500, 2250, 3000 and 3750) we see the difference in delay is increasing. Our algorithm reduces the delay because it

chooses the channels that has less interference and has ability to transfer more data, which means less delay.

**Figure 5. Comparison of throughput in different topologies**

The locations of nodes are changed each time the simulator is run, generating different topology for each run. We run the experiments over 10 different topologies. The result in Figure 5 shows that even in this case our algorithm outperforms the one in [8]. The x-axis in the figure represents the topology index, and the y-axis indicates the throughput in kbps.

From the results, it can be clearly seen that the algorithm based on the capacity has better performance for different cases. As a result we can propose that considering capacity along with interference surely improves the performance of the network.

## 6. Conclusion

In this paper, we have proposed an algorithm to assign channels in wireless mesh networks. We have showed by simulation that considering channel capacity in decision function improves the throughput significantly. Other factors can be considered for improving the quality of the network too. These factors include: routing, link delay, switching delay, channel error rate, path loss, etc. The results show that the delay with our algorithm is also less than the algorithm proposed in [8]. It assigns the best channel from interference capacity ratio. The results also show that for different topologies, our algorithm performs better. As a consequence, considering capacity to channel assignment makes a difference. In the future we will focus on issues such as routing and switching delay that can enhance the performance of the network with channel assignment.

### Abstract

*Delay/Disruption Tolerant Networking (DTN) architecture adopts the concept of intermittent networks that may suffer frequent disconnections, with the possibility of never having end-to-end connectivity between the source and destination over a given period of time. Therefore, the design of protocols for those networks becomes a unique challenge. Routing in DTNs is one of the key components and remains open for discussion. In this paper we treat the routing for anycast delivery that is useful in situations where a host, applications or users wish to locate a host which supports a particular service. However, if several servers support the service, any of these servers can be used. Then we implement a routing algorithm using genetic algorithm (GA), because the route and destination decision influence many parameters simultaneously. Our simulation results have shown that the routing using GA performs better than the shortest path algorithm.*

### 1. Introduction

In the last few years, Delay/Disruption Tolerant Networking (DTN) has grown as a research area that is focused on addressing the communication requirements specific to challenged networks. These networks are characterized by frequent disconnection and long duration partition, with the possibility of never having end-to-end connectivity between the source and destination over a given period of time.

RFC 4838 [1] defines an end-to-end message-oriented overlay, called the bundle layer, located between the transport (or other) and application layers of the networks on which it is hosted (see Figure 1).

The protocol's data units passed between entities participating are called bundles (the format of a bundle is described in RFC 5050 [2]).

Routing in DTNs [3,4] is one of the key components and remains open for discussion in the DTN architecture (the architecture for interoperability between and among challenged networks is proposed by Fall [5]). In store-carry-forward routing, a next hop may not be immediately available for the current node to forward the data (bundle). The node will need to buffer the data until the node gets an opportunity to forward the data and must be capable of buffering the data for a considerable duration.

Many of the principles of DTN architecture are reviewed by Fall and Farrel [6], being highlighted design decisions that have persevered through repeated analyses.

In this paper we treat the routing for anycast delivery: a host transmits a datagram to an anycast address and the internetwork is responsible for delivery of the datagram to at least one, and preferably one, of the members in an anycast destination group. There are various applications of anycast in DTN such as resource discovery (people may want to find a determined service without knowing their accurate locations), long distance education (e.g. provides asynchronous Internet access to schools in remote villages with bus and/or motorbike acting as ferries), battle fields (a soldier may want convey the surrounding information to any one of the command centers), and many other applications.

Figure 1. Bundle layer

Due to large transfer delays in DTNs, group membership may change during a message transfer. Under these situations, it is necessary to define the intended receivers of a message. We treat the anycast semantic models that allow users to explicitly specify the intended receivers of a message in section 3.2.

In unicast area in DTNs, many works were found, however, in this case, the destination is determined when the message is generated, while in anycast, the destination can be any one of a node group. Thus, during the routing, both the route for a destination group member and the destination of the anycast message can change dynamically according to the movement of mobile devices and semantic model.

Route and destination decision will influence many parameters simultaneously (like delay, delivery probability). The Genetic Algorithm (GA) has ability to manipulate them. GAs are appropriate when there is no single value to be minimized or maximized, but having multiple objectives.

Moreover, GA can provide adaptive route with optimized delivery probability and delay to deal with directed multi-graph (we talk about DTN graph in section 3.1). In this paper, we applied GA to search routes that optimize the routing objectives.

The rest of the paper is organized as follows: Section 2 describes the related work while Section 3 introduces the anycast in DTNs. We present the routing using GA in the Section 4. Section 5 describes the simulation and performance evaluation and, finally, in Section 6 we conclude the study and present future works.

## 2. Related work

There is a rich literature on anycast routing in the Internet and mobile ad hoc networks (MANET). More specifically, anycast routing using GA in MANETs has been studied quite extensively [7,8], but routing in DTN is different and more challenging due to the frequent partitions and long end-to-end delay.

Abdulla and Simon [9] analyze the multicasting in DTNs, using several multicast routing schemes, incorporating some previous ideas in core-based routing and DTN unicasting, as well as gossiping and epidemic approaches. It is important to note that when the multicast service is used, mobile nodes responsible for assisting in the delivery of messages (when we refer to messages, is the same that bundle), store the messages until it is confirmed that all members of the destination group already have received. In our anycast case, mobile nodes responsible for bringing the message to a member of the anycast group need to

store them until delivery to only one member of the anycast group, which leads to a substantial saving in storage of mobile devices that relayed the messages to a destination group.

Gong et al [10] analyze the anycast semantic for DTN and presented a metric named EMDDA (Expected Multi-Destination Delay for Anycast). The authors assumed that nodes in the network were stationary. The connectivity among the nodes was the mobile devices that act as carrier to deliver messages for the nodes. Also the moving patterns of these mobile carries can be obtained. We used some ideas from [10], but this work is based on estimation, i.e., the intermediate nodes decide whether to store the packet and wait for a better chance, or decide to which nodes to forward. The routing performed by Gong et al [10] is categorized as a stochastic routing protocol. Our routing can be considered deterministic. In a tutorial article [11], is described a simple combinatorial reference model that captures most characteristics of time-varying networks.

In [12], is proposed a new adaptive anycasting approach for mobile nodes where the link availability is opportunistic and the approach is adaptive in nature by communicating with the underlying network for getting the current topological information.

Despite [10] use three anycast semantic models that allow the source explicitly specify the destination of a message through the CM (Current Membership), TIM (Time Interval Membership) and TPM (Temporal Point Membership) models, the network traffic during the selection of routing is not considered. Our anycast routing scheme incorporate both node storage constraint and network traffic dynamics.

## 3. Anycast in DTNs

One of the challenges in designing an anycast routing protocols is to maintain the group membership efficiently. Due to the long delivery delay in DTNs, group membership may already change during the delivery of a message. This leads to the necessity to define new anycast semantic models for DTN.

Moreover, many times the mobile nodes that perform the transport of the messages have limited storage capacity, requiring an efficient anycast routing that does not forward the messages randomly in the networks, avoiding buffer overflows.

### 3.1. Network model

We consider that the topology of the network may be known ahead of time, categorized as deterministic

case by Zhang [3], i.e., the future movement and connections are completely known.

The DTN graph is a directed multi-graph, in which more than one edge (also called link) may exist between a pair of nodes. Furthermore, the link capacities (storage capacity, propagation delay and departure time) are time-dependent.

An edge in a DTN graph is showed in Figure 2. An edge between node  $u$  and  $v$  means that there exist some mobile devices moving from the initial node  $u$  (source) to the terminal node  $v$  (destination). The storage capacity ( $c(u,v)$ ) on all nodes and the mobile devices is limited. We assumed that every mobile device that moves between the same initial node,  $u$ , and terminal node,  $v$ , has the same moving speed, thus having the same moving delay,  $d(u,v)$ , from the source to the destination. The departure time  $w(u,v)$  of mobile devices on each edge is represented by randomly generated numbers with Poisson distribution.  $b(u)$  and  $b(v)$  are the storage capacity of node  $u$  and  $v$ , respectively.

**Figure 2. An edge in a DTN graph**

We assume nodes in the network are stationary and generate messages. On the other hand, mobile devices do not generate messages themselves. They move from one node to another.

### 3.2. Anycast semantics

In [10] the anycast semantics for DTN are analyzed. It is described that the intended receiver should be clearly defined for a message as group membership changes when nodes join and leave the group. It is showed three anycast semantic models that allow message senders to explicitly specify the intended receivers of a message:

- Current Membership Model (CM): the receiver of the message should be destination group member at the time of message delivery;
- Temporal Interval Membership Model (TIM): a message includes a temporal interval that specifies the period during which the intended receiver must be a member of destination group member;
- Temporal Point Membership Model (TPM): its intended receiver at least should be a member of destination group at some time during membership interval.

In our anycast routing we define the intended receiver when the message is generated. Thus, when the messages arrive to one of these receivers, independently if the receiver is located in the initial group, this will be a valid receptor. This is a particular case of the TIM model, whereas that the temporal interval is the instant of the message generation.

## 4. Routing using genetic algorithms

Genetic algorithms are defined as search algorithms based on the mechanics of natural selection and natural genetics [13]. They combine survival of the fittest among string structures (in our case, routes) with a structured yet randomized information exchange to form a search algorithm. While randomized, genetic algorithms are no random walk. They efficiently exploit historical information to speculate on new search points with expected improved performance.

Before examining the mechanics and the power of a simple genetic algorithm, we must be clearer about our goals when we say we want to optimize a function or a process.

In order to use GA for route decision, in every generation, the GA keeps a population of routes created using randomly selected possible paths (our chromosome) and allows filter routes to combine and produce offspring with new characteristics, which may replace low fitness old routes. Fitness function is a particular type of objective function that quantifies the optimality of a solution.

Diversity in the individual population is highly desirable in order to have a set of alternative routes. The GAs copy routes with some bias toward the best, mate and partially swap (sub) individuals, and mutate occasional possible paths for good measure.

We set the crossover probability to 0.8 and the mutation probability to 0.1. Jong's study [14] suggested the use of a high crossover probability and a low mutation probability (inversely proportional to the population size). We consider values a little higher than the suggested by Jong [14] to increase the diversity in the individual population. The population has 50 individuals. Our GA is controlled by the number of generations.

We applied GA to search the route and consequently the destination that better serve the routing objective (enhance some metric). An example of population representation and crossover is showed in Figure 3. CR1 and CR2 represent the population before the crossover and P1 and P2 the individuals generated. Each number in the each square represent a node, and

each square represent a possible route between the source and destination.

To reduce the time that the GA takes to converge we evaluate and compare the GA when we consider the route obtained by shortest path algorithm as input. Moreover, we test selecting routes with short hops, rejecting the routes with large hops. The results of the two techniques are showed in session 5.

Figure 3. Crossover example

## 5. Simulation and performance evaluation

Routing algorithms in the constructed space-time graph can be developed using shortest path algorithm. For example, Dijkstra's algorithm was adapted to compute the shortest path by Jain, Fall and Patra [4].

We use simulation to compare the performance of the GA-based anycast routing algorithm and the shortest path algorithm modified (the cost function considered was the number of hop) under different environments.

### 5.1. Modeling and simulation

Knowledge oracles are able to answer questions we task of them about the DTN. Accordingly [4], our routing algorithm has a partial knowledge (more practical assumption from an implementation perspective than complete or zero knowledge): our algorithm use information about node and edge queuing, store capacity, moving delay, and departure time of the mobile devices. Those informations are used to compute the route and define the destination.

In our simulation, we employ Waxman Network Topology Generator [15] to generate a random graph of 40 nodes. In the Waxman generator, the nodes follow a Poisson process in the plane and edge density can be controlled. The probability to have an edge between  $u$  and  $v$  is given by

$$P(u,v) = \alpha \cdot e^{-d/(\beta \cdot L)} \quad (1)$$

where  $\alpha > 0$ ,  $\beta \leq 1$ ,  $d$  is the distance from  $u$  to  $v$ , and  $L$  is the maximum distance between any two nodes. We

set  $\lambda$  to 0.6 (intensity of the Poisson process),  $\alpha$  to 0.4 (small values of  $\alpha$  increase the density of short edges relative to longer ones),  $\beta$  to 0.2 (small values of  $\beta$  result in graphs with lower edge densities).

To simulate the behaviors of DTNs, we assume the communication between nodes is carried out by mobile devices. For each edge generated by Waxman generator, we replace it with a mobile device acting as ferry (a set of special mobile nodes that exploits device mobility are utilized to enable or improve communication). We use the statistic toolbox `poissrnd` to generate random numbers from the Poisson distribution to represent the leaving time ( $w(u,v)$ ) of mobile devices on each edge with mean interval time selected randomly from 600 to 6000 seconds. The moving delay ( $d(u,v)$ ) on each edge is a number selected randomly between 60 and 600 seconds, which is multiplied by the distance between the nodes. We assume that the storage capacities ( $c(u,v)$ ) of each mobile device can vary from 300 to 800 messages, and the storage capacities of each node may vary from 600 to 1000 messages (we showed an example of edge between node  $u$  and  $v$  in Figure 2).

We enumerate the nodes in the area 1300 m x 1300 m (see Figure 4). For each anycast session (we consider only anycast traffic in our simulations) we generate a random number between 2 and 5 to represent the number of possible destinations. We randomly pick a node as the anycast source. The first destination member is selected randomly from the possible nodes except the source node. The rest of destination group is the node in sequence if this node is different from source node until completes the number of desired destinations. The messages to send to the destination group for each source can vary between 200 to 500 messages. We generate random numbers from the Poisson distribution between 0.04 and 0.06 to represent the inter-arrival times (messages generated per second). The table 1 has an example of initial traffic for four sessions.

A message is split only at source and different parts (fragments) are routed along same paths. To compare the algorithms we collected statistics about delivery probability (total number of unique anycast bundles received by any anycast group member to the total number of bundles transmitted by the anycast source) and delay (weighted mean of delay, the weighs are the number of bundles relayed).

### 5.2. Simulation experiments

First we simulate a network with only 4 anycast sessions (to facilitate the demonstration of the

algorithms functioning), however the simulation and results with more anycast sessions is presented in the next session. In this case, the simulation is controlled by the number of generations (50). The initial traffic is showed in Table 1. Figure 4 presents the considered network topology.

Figure 5 shows that the GA (best individual – GA best) achieve the same delivery probability that the shortest path algorithm (100%), but got a delay a little lesser. The main contribution is this, with GA we can choose a minimum delivery probability (in the example we used 80%) and the algorithm will search the route (optimal or very good) that satisfying the probability and has the lesser delay.

**Table 1. Initial traffic**

	Session 1	Session 2	Session 3	Session 4
Source	40	33	1	20
Destination Group	[30; 31]	[8; 9; 10; 11]	[20; 21; 22]	[15; 16; 17]
Messages to sent	290	400	340	460
Beginning of the session (s)	1400	2700	3900	7000

**Figure 4. Network topology used in example**

**Figure 5. Delay vs. delivery probability**

Analyzing the Tables 2 and 3 we can conclude that the reason for the GA (best route) achieve a delay lesser than the shortest path algorithm is that the route in session 1 and 3, relayed the messages through node 22 (can be a bottleneck). Moreover, the second best route obtained by GA (GA 2), generated a delay larger and a delivery probability lesser than others results showed in the tables, possibly because the route in session 5 performs several hops.

**Table 2. Performance metric comparison**

Results	Total Delay	Route Session 1	Route Session 2	Route Session 3	Route Session 4
Shortest Path	9.651 s	40-27-22-10-36-31	33-20-24-11	1-38-7-22	20-15
GA best route	9.456 s	40-27-7-38-1-13-36-31	33-20-24-11	1-38-7-27-22	20-15
GA 2	10.19 s	40-27-72-38-1-30	33-20-23-9	1-13-15-20	20-24-19-36-13-15

**Table 3. Messages delivered per session**

Results	Deliv. Prob.	Session 1: 290	Session 2: 400	Session 3: 340	Session 4: 460
Shortest Path	1.0000	290	400	340	460
GA best route	1.0000	290	400	340	460
GA 2	0.9463	290	400	340	380

Looking at Figure 5 and Table 2, we can see that if we carried out a crossover between the first (GA best route – CR1) and second (GA 2 – CR2) GA individual, in session 4, we could get a lesser delay (P2) than the results showed in Figure 5 (see Figure 3).

**Figure 6. Best individual evolution**

To see the evolution in every generation of GA, we maintain the best individual and plot in Figure 6. It is

important to note the decrease in the delivery probability in generation 22. This can be easily justified looking at the delay graph, by the fact that our GA, seek the route that has the shortest delay among those that have a probability above the allowed. The best individual is found in generation 23.

### 5.3. Performance evaluation

For performance evaluation, we implemented the proposed algorithms for anycasting under different traffics and number of generations. The GAs take a variable time to produce an optimal or near optimal route depending on the number of sessions and generations used. With 4 anycast sessions the algorithm takes 0.5 seconds per generation. When we have 10 anycast sessions takes 1.5 seconds per generation. If the number of sessions is 20, GA takes 3.2 seconds per generation.

First, we simulated a DTN with 4 anycast sessions. Figure 7 shows that in all cases the GA obtains a delay lesser or equal than the shortest path algorithm and a delivery probability above 80%. The GA converges quickly and has better performance than shortest path because with 4 anycast sessions the diversity of the problem is small.

The difference between Normal GA and SP Input GA is that the second algorithm has the shortest path route as input. We computed the number of average generations to find the best individual. Although this number can change due the randomly of GA, the SP Input GA finds good routes in less generations (18) than Normal GA (27).

Figure 7. Four sessions result

Figure 8. Ten sessions result

Figure 8 shows a simulation with 10 anycast sessions. The algorithm needs a larger number of generations for convergence due to the increase of the complexity. Only with more than 200 generations the GA achieved a better performance than shortest path and again the SP Input GA converge to good routes faster than Normal GA. It is important to note that for 250 and 300 generations the shortest path does not achieve the delivery probability of 80%. However, GA found routes with delivery probability higher than 80%.

Figure 9 shows simulation results with 20 anycast sessions. The GA failed to converge and the shortest path found results better or equal than GA. This can be explaining by the fact that the GA increases the number of generations necessary to converge when the diversity of problem is large. After that, we present a technique to resolve this in the next session.

Figure 9. Twenty sessions result

### 5.4. Improving the convergence

To improve the convergence we modified the way that the GA chooses the routes to form the population, because if the GA takes a long time to converge, it could become unfeasible. We viewed that when the numbers of sessions is increased, the algorithm complexity increases too. Then, if the number of session is large, we avoid hold individuals (routes) with a large number of hops, because this routes, normally leads to long delays.

Figure 10. Performance using Normal GA

The improvement can be viewed in Figures 10 and 11. We simulated a DTN with 20 anycast sessions and 300 generations. We can see that the shortest path does not achieve the minimum delivery probability of 80%, although the shortest path has a lesser number of hops than the routes found by the GA. However, the two best individuals found with GA have a delivery probability above the 80%. Again the SP Input GA found the best individual (in generation 59) more quickly than Normal GA (in generation 201).

Figure 11. Performance using SP Input GA

## 6. Conclusions and future works

In this paper, we presented a GA-based anycast routing algorithm. Here we are considering a deterministic network with partial knowledge (information) about the network. Moreover, our GA incorporates node storage constraint and permits search a route with the lesser delay between the routes that have a delivery probability above a minimum that can be chosen.

Our simulation results show that GA can reduce the average delay compared to shortest path algorithm. Depending on the traffic, we can employ different strategies to improve the GA performance. For example, when the number of sessions is large, we can efficiently choose the routes to reduce the time to GA convergence.

Otherwise, when we increase a lot the number of sessions and the traffic, the performance of GA is reduced. As future works, we intend to develop different techniques to the GA converge faster and analyze the algorithms performance under different network scenarios.

### Abstract

*Designing efficient, cost-effective routing solutions for the infrastructure-less MANETs remains a daunting task till date. A proven optimization technique, the Ant colony optimization has been used in this paper to find the optimum in terms of the shortest route in a MANET. Special attention has been given to the load balancing and congestion control in the network. The simulated performance graphs show an improved congestion control for the proposed routing protocol.*

### 1. Introduction

The mobile ad hoc network (MANET) is an autonomous system of mobile routers (and associated hosts) connected by wireless links – the union of which form an arbitrary graph. The routers are free to move randomly and organize themselves arbitrarily; thus, the network topology may change rapidly and unpredictably. Such a network may operate in a standalone fashion, or may be connected to the larger Internet. Routing in adhoc network is very difficult and challenging. ACO algorithms have been employed to solve numerous problems in ad hoc networks. The swarm intelligent mechanisms present in natural ant colonies are used by a powerful class of optimizing algorithms that was derived from the behavior of natural ant colonies. Dorigo *et al* first combined ACO with source routing to produce AntNet, Schoonderwoerd *et al* combined ACO with distance vector routing to produce Ant-Based Control and various other authors produced ACO-based routing algorithms with the focus on different factors such as Quality-of-Service and clustering of large networks. Ants consistently achieve remarkable feats of cooperation, coordination and construction [2]. Of particular interest to this work is how ants can find shortest routes between their nest and food sources. To study this phenomenon, Deneubourg

*et. al.*, set up the binary bridge experiment. In the binary bridge experiment a food source and a nest of ants are separated by a bridge with two branches, one being longer than the other. Ants deposit a substance called pheromone on the ground as they walk. Other ants can smell this pheromone, and their path-taking decisions are influenced by the pheromone. When subsequent ants sense this trail of pheromone, they will follow the trail with a probability that is proportional to the concentration of pheromone – the higher the concentration, the larger the probability that subsequent ants will follow this trail. The pheromone evaporates at an exponential rate, which means that the strength of pheromone encountered by another ant is a function of the original pheromone strength and the time since the trail was laid.

### 2. The State of the Art Scenario

In flat (or non clustered) networks the nodes are not clustered into any form of hierarchical structure, all nodes are homogeneous in terms of network responsibility and packet handling. The first protocols to use ACO used basic source routing or distance vector algorithms where the traditional routing tables were replaced with pheromone tables, while more advanced protocols also incorporated ad hoc characteristics such as mobility and congestion into the pheromone mechanism.

SACO [2] aimed to solve the problem of finding shortest path between two nodes on a MANET. A number of ants are placed on the source node of the network. Each ant incrementally constructs a path to the destination node during each iteration of the algorithm. The next hop node is chosen on the basis of highest pheromone concentration. At each node ant uses the following probability to select the next node. The pheromone deposition in an ACO based system can be influenced by heuristic information. However, SACO

does not take into consideration the effects of load and congestion of the network.

Antnet [3] describes the application of ACO to dynamic routing in packet-switched networks. This is the first application where ACO is used for routing with a source routing mechanism, i.e. the entire route of the packet is listed in the header of the packet. Each node  $s$  in the network periodically generates an artificial ant (called a forward ant) with a randomly selected destination node  $d$  to observe the trip time from source node  $s$  to destination node  $d$ . The forward ant uses the current routing tables to find a path to node  $d$ , and records the route taken. When the forward time, taking the same path as the forward ant in the opposite direction. Each node has its own routing table [4]. Although AntNet forwards data packets using distance-vector principles, route discovery and maintenance are done using source routing. AntNet consequently suffers similar bandwidth and hop-count drawbacks encountered in Dynamic Source Routing (DSR). This translates to very limited scalability, and the results could be checked on networks of only 36 nodes.

ARA [7] is an ACO-based routing scheme using distance vector routing. Route discovery is done by broadcasting Forward Ants (FANT). The FANT sets up a pheromone trail pointing back to the source node as it is broadcast through the network. When a route is found to the destination node, a Backward Ant (BANT) is created. The BANT follows the pheromone trail created by the FANT back to the source node, and sets up a pheromone trail pointing to the destination node. The amount of pheromone deposited by FANT and BANT packets is a function of the length of the route associated with the pheromone. Once the route is established, packet transmission starts. The data packets also reinforce the pheromone trails pointing to the source and destination nodes. In the case of a route failure, the intermediate node attempts to send the packet over an alternative link. If no alternative link is found, the packet is returned to the previous up-stream node, which also tries to send the packet over an alternative link. If the packet is returned in this way to the source node, a new route discovery sequence is initiated using backtracking [7]. ARA implements the packet sequencing mechanism to prevent packet loops. However, in AODV each RREQ packet is also given a RREQ-sequence number to ensure that destinations only respond to a RREQ once. Contradictory to AODV, however, in ARA, destinations respond to multiple FANT packets received from the same node, thus supporting multipath routing [1].

MACO [9] concentrates on load balancing of the network. It uses more than one colony of ants to search for optimal path, and each colony of ants deposits a different type of pheromone of a different color. Although ants in each colony respond to pheromone from its own colony, MACO is augmented with a repulsion mechanism that prevents ants from different colonies to choose same optimal path. The degrees of attraction and repulsion determined by two weighting parameters, combined into a probability function which is used into VWP network. Different sets of mobile agents corresponding to a pheromone table of each colony are used. By adopting the MACO approach, it may be possible to reduce the likelihood that all mobile agents Establish connection using only the optimal path [9]. The advantage of using MACO in circuit switched routing is that it is more likely to establish connections through multiple paths. It helps to balance the load but does not increase routing overhead. MACO can establish connection through multiple paths while traditional ACO is most likely to establish connection through the optimal path.

### 3. The Proposed LCRACO Algorithm

A new routing methodology named Load and Congestion Controlled Routing based on Ant Colony Optimization Algorithm (LCRACO) has been proposed here, giving special attention to load balancing and congestion control of the network. This algorithm uses more than one colony of ants to search for the optimal path. The next hop is chosen based on the highest concentration of pheromone. Connection is established on a multipath basis to balance the load in the network.

#### 3.1 Assumption

We make a couple of important assumptions before we propose the new routing algorithm.

1. There are two colony of ants. Symbol 0 indicates red colony and 1 indicates blue colony. Initially there are two array. One is blue pheromone array and another one is red pheromone array. Two arrays give the information of amount of pheromone between two nodes, which are initialized as follows:

For red pheromone array: [000...0]

For blue pheromone array: [111...1]

2. All the possible routes are needed to reach the destination node are already known by the source node and all the details of next hop node in each route are stored in routing table.

In this algorithm at particular time a source node wants to send m no of messages to a destination node.

### 3.2 Definitions

- Cost Table – Consists of the cost of reaching nodes (next hop). This consist of a set of tuples:  $\{S_{ip}, N_{ip}, C_{sn}\}$ , where,  
 $S_{ip}$  - Source node address,  
 $N_{ip}$  - Neighbor node address  
 $C_{sn}$  - Cost on the path is a derived entity and is a function of time interval of sending “HELLO” message by node  $s$  and receipt of an “ACK” message from node  $n$ .
- The HELLO message:  $S_{ip} D_{ip} N_{ip} S_{t1}$ , where  $D_{ip}$  is the Destination node and  $S_{t1}$  is the start time 1
- The ACK message :  $S_{ip} N_{ip} D_{ip} S_{t1} S_{t2}$ , where  $S_{t2}$  = Start time 2
- Routing Table: It consists of information about the next hop node on the path to particular destination node. Thus the routing table vector is— $S_{ip} N_{ip} D_{ip}$
- Red pheromone array gives the information about the amount of red pheromone deposited by red ants between source and all possible next hop node to reach the destination node. Blue pheromone array gives the information about the amount of blue pheromone deposited by blue ants between source and all possible next hop node to reach the destination node. The structure of the red pheromone array is  $[\delta r_1 \delta r_2 \delta r_3 \dots \delta r_n]$ . The structure of the blue pheromone array is  $[\delta b_1 \delta b_2 \delta b_3 \dots \delta b_n]$ .  
Here,  $\delta r_i$ ,  $\delta b_i$  represent the pheromone value deposited on the way from the source node to  $i$ th node from the next hop list of the routing table. The pheromone value is modified using the eqn. (3), (4) and (5). For evaporation of pheromone, equation (7), (8) is used.

Probability calculation for ant of red colony:

$$P_{kn}^d(t) = \{\delta r_{kn}(t) / \sum_{x \in N_k(t)} \delta r_{kx}(t)\} \quad \dots (1),$$

where  $t$  = Time index

$P_{kn}^d(t)$  = The probability that an ant at node  $k$  at time  $t$  traveling to node  $d$  will select node  $n, 1 \leq p \leq 0$

$\delta r_{kn}(t)$  = The red pheromone level at node  $k$  at time  $t$  associated with using node  $n$  as a next hop node

$N_k(t)$  = The set of feasible node connected to node  $k$  at time  $t$ .

Probability calculation for ant of blue colony:

$$P_{kn}^d(t) = \{\delta b_{kn}(t) / \sum_{x \in N_k(t)} \delta b_{kx}(t)\} \quad \dots (2),$$

where  $t$  = Time index

$P_{kn}^d(t)$  = The probability that an ant at node  $k$  at time  $t$  traveling to node  $d$  will select node  $n, 1 \leq p \leq 0$

$\delta b_{kn}(t)$  = The blue pheromone level at node  $k$  at time  $t$  associated with using node  $n$  as a next hop node.

$N_k(t)$  = The set of feasible node connected to node  $k$  at time  $t$ . Each ant deposits certain amount of pheromone. The amount of pheromone deposited is proportional to the quality of the route selected by the ant.

Updation of red and blue pheromone matrix:

$$\delta r_{kn}(t+1) = \delta r_{kn}(t) + q_r \quad \dots (3)$$

$$\delta b_{kn}(t+1) = \delta b_{kn}(t) + q_b \quad \dots (4)$$

where  $q_{ri}$  is the inverse of the cost function between source and destination node,

$$\text{i.e., } q_r = 1/c_{kn} \quad \dots (5)$$

$C_{kn}$  is the cost function, which gives the average time required to send message between source node  $k$  to next hop node  $n$ .

Evaporation of red and blue pheromone:

$$\delta r_{kn}(t+1) = \delta r_{kn}(t) - \mu * c_{kn} \quad \dots (7)$$

$$\delta b_{kn}(t+1) = \delta b_{kn}(t) - \mu * c_{kn} \quad \dots (8)$$

$\mu$  = evaporation constant. value of it is 0.3

### 3.3. Proposed Algorithm

Step1: Each node in the network sends “HELLO” message to all possible next hop node after certain time interval to reach the destination node and each next hop node sends “ACK” message. According to the total time required to receive “ACK” message, source node calculates the cost on the path of all possible next hop node and stores it into the cost table.

The source node sends “HELLO” message after fixed time interval to check cost table.

- Let start time  $t_1$  (when “HELLO” message is sent) and the neighbor node receives the message at time  $t_2$ . So total time required to send “HELLO” message is  $T_1 = t_2 - t_1$
- If start time  $t_2$  when “ACK” message is sent by the neighbor node and source node receives the message at time  $t_3$ . So total time required to send “ACK” message is  $T_2 = t_3 - t_2$
- Total time  $T = (T_1 + T_2) / 2$
- Update  $C_{sn}$  with  $T_x$   $k$ , where  $k$  is the cost per unit time.

Step2: Step 1 is descriptive-, whereas step 2 is

For each (Sip)

a) {Construction of ant}

for each ant  $k=1$  to  $m$

Generate an alternate sequence of 0 and 1 and stores it in  $v$ .

begin {Probability calculation }

b) If  $v$  is 0 then

i) Each node calculates the concentration of red pheromone for all it's next hop node to reach particular destination node using the equation (1).

ii) The ant chooses next hop node in which concentration of red pheromone is highest.

iii) Red pheromone array is updated.

else

i) Each node calculates concentration of blue pheromone for all it's next hop node to reach particular destination node using equation (2).

ii) The ant chooses next hop node in which concentration of blue pheromone is highest.

iii) Update blue pheromone array.

End {Probability calculation }

Step 3: Evaporation of red pheromone is done by the equation (7) and the same for blue is done by using equation (8).

Step 4: The process continues till all the messages are reached to their destination node.

### 3.4. Illustration of Algorithm

Let's consider a network of four nodes. Suppose node A has to send four messages to node D.

Figure 1: A 4-node network

Thus, A broadcasts a HELLO message. All the neighbours of A, i.e., B and C accepts this message as they have D in their route table. B and C sends ACK message to the source node A. A derives the cost of the

routes from the time interval between broadcasting the HELLO message and receipt of ACK message. The routing table of A is :

	C	B
A	R=4	R=5

Then it finds probability of concentration of red pheromone in which path is highest. It is found that it is highest on the path AB. So A sends it's first packet on this path. Then A updates it's red pheromone table on this path. The red ant deposits red pheromone, the amount of which is equal to  $1/(\text{path length})$ . Now the updated red pheromone table becomes—

	C	B
A	R=4	$R=5+1/8=5.125$

Red Pheromone table

If  $v$  is 1 then it follows blue pheromone table and chooses the path on which concentration of blue pheromone is highest. The blue pheromone table is given below:

	C	B
A	B=6	B=4

Blue Pheromone table

At that moment ant chooses the path AC because concentration of blue pheromone is highest on this path and updates the blue pheromone table in same way as the red pheromone table.

	C	B
A	$B=6+1/9=6.111$	B=4

Blue Pheromone table

After certain time interval (after sending 3 messages) pheromone is evaporated. In this way the algorithm goes on and it controls congestion as well as load in the network.

#### 4. Performance analysis of LCRACO

The theoretical analysis of the algorithm helps us to notice the following points:

**Load Balancing:** Here more than one colony of ants are used to search for optimal path, and each colony of ants deposits a different type of pheromone by a different color and ants in each colony respond to pheromone from it's own colony. Thus the algorithm balances the load in the network load.

**Congestion Control:** Here one colony of ant chooses the path in which deposition of pheromone of that colony is highest and another colony of ant chooses the path in which deposition of pheromone of that colony is highest. The congestion in the network can thus be controlled to a large extent.

##### 4.1 The simulation results

###### 4.1.2 Variation of maximum probability value:

When a particular node wants to send set of packets, it chooses path alternately according to the concentration of red pheromone matrix and blue pheromone matrix. After selecting a particular path, the concentration of pheromone of that particular path is increased.

Figure 2: Pheromone level vs. Number of messages

The graph varies as maximum probability value of pheromone is changing. The variation of maximum probability value confirms that alternately the source node chooses the highest concentration of red and blue pheromone for sending each packet.

**4.1.2. Pheromone level variance:** The x axis of the graph in figure 4 shows the number of packets sent by a particular node and Y axis gives the performance of red

ant and blue ant.

The red curve indicates red pheromone level and blue curve shows the blue pheromone level. From this graph it can determine that for each message sent, there is a variance in pheromone level. Thus, the source node does not follow same path for sending all messages. In this way load as well as congestion in the network is controlled.

Figure 3: Pheromone Level for Two Ant colonies

Next, we studied the variance of packet delivery rate against the number of nodes. The X axis in figure 4 shows the number of packets sent by source node and the Y axis shows the delivery rate of each packet.

Figure 4: Delivery rate vs. Number of nodes

#### 5. Conclusion

A brief review of the well known methodologies in

this area shows that very little consideration had been given towards load balancing and congestion control of the network. This paper proposes a new routing methodology LCRACO based on the theory of ant colony optimization. Theoretical evaluation shows that this algorithm can take care of load balancing and congestion control. of the network. The algorithm will be useful in cases where the bandwidth of the packets sent by a node exceeds the bandwidth of the channel.

**Abstract** – IEEE 802.11 set of standards grew from a highly obscured and unsecured technology to a robust and reliable solution for many of us. Broad acceptance and relatively simple implementation also made 802.11 a perfect target for possible exploitation. Recently discovered wireless driver vulnerabilities exposed a new critical threat that legitimate users community is facing. What makes this vulnerability so dangerous to many of us is the fact that the actual exploitation cannot be prevented by commonly used tools such as firewalls, antivirus, and intrusion detection system's programs. Access to the victim's machine is gained through a flawed third-party wireless driver, giving full kernel level access rights to the attacker. While kernel-level exploitation domain covers everything running beneath the operating systems, this paper describes wireless device drivers vulnerability and proposes methods for vulnerability mitigations. This paper would assist IT professionals in evaluating, creating, and assessing security requirements associated with wireless networks connectivity.

*Index Terms* – 802.11, wireless driver, security, vulnerability

### 1.0 Introduction and a Brief History

Wireless technologies had their own share of success since the introduction of the first 802.11 legacy standard almost 10 years ago. Previously named as a wired networks killer technology, 802.11 had a very rough road in last a few years. Not many new technologies had so many admirers that turned back so fast because of the disastrous introduction and security issues of its earlier releases. Wireless networking in comparison to wired networks requires an additional set of requirements for companies and organizations on its implementation, maintenance and more importantly, on securing the boundaries of valuable resources and services.

Unsecured medium of communications and ubiquitousness of wireless-enabled clients provides great deal of opportunities for possible exploitations. The fact that the communication is going through the open airwaves accessible to anyone including unauthorized users poses the greatest risks to the networking processes. These risks are usually associated with loss of confidentiality and integrity and the threat of Denial of Service (DoS) attacks. All of the

exploits and vulnerabilities existing in regular land wired networks have presence in wireless settings. What makes the 802.11 technology special is the huge number of small portable devices holding sensitive information that can be compromised. Proper management and assessment of these resources requires an extra set of knowledge and effort from IT professionals in configuring and ongoing monitoring networks for anything unusual and suspicious as well as performing regular administrative duties such as backups, user management, and security assessments. The level of expertise of the tech support personal is very crucial as many of the commercially available products used in WLANs don't provide adequate protection, have weak default settings or poor software implementation.

### 2.0 Overview of Wireless Technology

Wireless technology is based on the usage of single carrier direct-sequence spread spectrum radio technology. When introduced in 1985, it was operating in an unlicensed spread spectrum, specifically designated by FCC for scientific, medical and other types of devices, such as some types of cordless phones and microwaves [1]. After the standardization of the wireless technologies under the umbrella of 802.11 standards, wireless technology was assigned to a limited spectrum in the 2450 MHz to 5800 MHz band range in United States. Use of other ranges of bands differs from country to country. In the pre and earlier implementations of the 802.11 standard, security was deliberately weak due to the export regulations of US government [2]. This was addressed in 2004 with the release of the 802.11i [3]. WEP and WAP because of their weak protection were superseded by WPA2 and use of AES block ciphers [4].

Below is a chronologically ordered list of modifications of 802.11 standards [5]:

- ◆ Pre 802.11 - 802.3 - released in 1980, and based on Xerox's PARC work in 1970s, it sets the standards for wired Ethernet networks. Defines the physical layer, and the media access control (MAC) sub layer of the data link layer;
- ◆ 802.11-1997 (802.11 legacy) - designed for 1 Mbps to 2 Mbps wireless transmissions;
- ◆ 802.11a - high-speed WLAN standard for the 5 GHz band and, supports 54 Mbps;

- ◆ 802.11b - operates in the 2.4 - 2.48 GHz band and supports 11 Mbps;
- ◆ 802.11g - operates in the 2.4 GHz waveband;
- ◆ 802.11n - significantly improves network throughput by adding multiple-input multiple-output (MIMO);
- ◆ 802.11y – adds operation in 3650 to 3700 MHz band by utilizing high power wireless technology equipment

Table 1 shows the main characteristics of 802.11 standards [5]:

Table 1: Characteristics of 802.11 standards

Protocol	Release Date	Op. Freq (GHz)	Throughput (Mbit/s)	Data Rate (Max) (Mbit/s)	Range (Indoor) in meter	Range (Outdoor) in meter
Legacy	1997	2.4	0.9	2	~20	~100
802.11a	1999	5	23	54	~35	~120
802.11b	1999	2.4	4.3	11	~38	~140
802.11g	2003	2.4	19	54	~38	~140
802.11n	2009 (est.)	2.4 - 5	74	24	~70	~250

## 2.1 Architecture

802.11 standards stipulate operation between wireless-enabled clients in two basic ways: an ad hoc or peer-to-peer communication, where clients use direct links to connect to each other, and infrastructure mode, where stationary Access Points (AP) hardware devices are used to provide gateway access services for wireless clients to access wired networks such as intranets or private LANs. The main structure components that can be found in any type of wireless networks are listed below [6]:

- ◆ Client - laptop or other mobile device with wireless enabled connectivity;
- ◆ Fixed wireless Access Point (AP) – hardware device that connects wireless communications, provides access to other networks (wired);
- ◆ Independent Basic Service Set (IBSS) – no APs are used, direct client to client networking communications
- ◆ Basic Service Set (BSS) - at least one AP is present and all of the communication is performed through that device.
- ◆ Extended Service Set (ESS) – multiple APs are connected to the same network segment through the router

Extended service set mode can be logically represented by collections of more than one BSS configured to use same

network, where clients can hop from one AP to another without losing connection to the network recourses. Configuration details of wireless clients and network depend on which mode is used.

## 2.2 Protocol

802.11 can be best described by using a seven layer Open Systems Interconnection (OSI) Basic Reference Model [7]. It operates on the lower two layers of this model and utilizes a Media Access Control (MAC) sub layer of the data-link layer and the physical layer. Logical Link Control (LLC) is another data link layer component of the OSI that is being used by 802.11 standards. Figures 1 and 2 represent layers responsible for wireless communications. The Media Access Control (MAC) layer known as CSMA/CA (Carrier Sense Multiple Access/Collision Avoidance) is the first of the OSI model layers that is being utilized by 802.11, where peer-to-peer connectivity does not require a server.

Figure 1 – OSI Basic Reference Model [6]

The 802.11 MAC frame consists of a MAC header, the frame body, and a Frame Check Sequence (FCS) as represented in an image below. The numbers in Figure 2 represent the number of bytes for each field.

Figure 2 – MAC frame [6]

The Frame Control Field provides much of the information related to the wireless driver vulnerabilities. 802.11 MAC FCF subfield's main purpose is to tell the system how to process the frames in wireless communications. Figure 3 shows the responsibilities of each Frame Control Field's subfield:

Figure 3 – Frame Control Field (FCF) [6]

Details and functionality of the FCF:

- ◆ Protocol Version provides protocol’s version type and used by client to determine if this version is supported;
- ◆ Type and Subtype field checks for the frame type (management, control, or data);
- ◆ To DS and From DS shows if the frame is coming or leaving from the distributed system;
- ◆ More Fragments indicates if more fragments of the frame will be received;
- ◆ Retry refers to the retransmitted frames;
- ◆ Power Management shows the status of the sending client (active vs. passive);
- ◆ More Data indicates that more data is coming;
- ◆ WEP shows if encryption and authentication are used in the frame;
- ◆ Order maintains the order of received frames.

Other parts of the MAC header contain information such as the address of source and destination, sequential number of each frame, actual data itself and the Frame Check Sequence algorithm for error prevention.

All of the existing flavors of 802.11 standards reside at the PHY sub layer. The physical layer of OSI model define a series of encoding and transmission schemes for wireless communications, such as the Frequency Hopping Spread Spectrum, Direct Sequence Spread Spectrum, and Orthogonal Frequency Division Multiplexing (OFDM) transmission schemes [8].

## 2.3 Wireless Communications

Wireless communication is established through the use of network frames defined by 802.11 standards. As described earlier, each frame’s fields contain information and describe the functions of that frame and thus can help classify frames into three categories: management, control, and data. Generally, in basic and/or extended service set mode, an access point device is broadcasting beacon management frames intended for any wireless clients. The clients are supposed to intercepts these frames and identify the correct AP and then join one of the available networks based on its setting. This process is a three stage communication where after identifying an AP, the client and the AP perform a mutual authentication by exchanging several management frames. At this point, the client is

already known to the AP, but does not yet have access to the network resources. Its status is “Authenticated and Unassociated.” The next stage of this process is “Authenticated and Associated,” where access is granted to the client. Most of the security risks arise before or during these processes and will be discussed in the next section.

## 3.0 Current Security Threats

In general, risks associated with wireless networks are the same as in the traditional wired networks environment, plus the new risks introduced by weaknesses in wireless protocols [12].

Jamming, deciphering and cryptanalysis, sniffing, injecting, masquerading, rogue access point insertion are the most common exploitation techniques found in wireless enabled environments today. Social engineering although not a unique wireless security problem, gets wider negative attention as well.

Great example of unacceptable negligence and inadequate qualification of IT people was biggest ever theft of personal data, T.J. MAX's failure to secure their wireless LAN [9] costing the company over a billion of US dollars. TJX was using WEP security algorithm on its network, nearly four years after it was proven to be insecure. Apparently the company was slow in implementing new standards. What's alarming that most of the other retail chains were you using WEP at that time and as a matter of fact some of them are still using it (Sears, Best Buy, Macys, etc.) [10]. It was recently reported that WEP 104-bit encryption can now be cracked in under a minute [11].

To mitigate all of these risks, all data and services involved in wireless networks should be evaluated and satisfy The Security Requirements Triad components of confidentiality, integrity and availability (CIA Triad) [13].

Continuous progress in developing more robust and secure operating systems in some way shifted the attention of hackers from finding the flaws in the operating systems to the less protected applications and in large numbers to the device drivers or wireless device drivers in particular.

## 4.0 Wireless Driver Vulnerabilities Overview

One of the most overlooked aspects of implementing secure wireless communication medium is the device driver’s vulnerabilities. Wireless driver exploitation falls into wider operation system’s kernel vulnerabilities domain and represents very fast growing and increasingly high risk trend in wireless security. The main reason for security professionals to be on alert is very high sophistication of the exploits.

Virtually all of the vulnerabilities are residing on a lower two levels of OSI model and are undetectable by the antivirus or intrusion detection systems. Historically, user written applications were separated from the operating systems Kernel, where device drivers reside. By exploiting the device, loaded into the memory, hackers receive unrestricted access to the whole system's resources. All of the existing OS as of today are at risk. Wide spread of the wireless technology with low default security settings and large number of old, legacy wireless clients creates a mess in situations where security needs to be tighten up to prevent unauthorized information access. Wireless drivers most often are exploited by using buffer overflow attack against particular fields of the MAC frames. One of the first known incidents that gained wide attention was Broadcom Wireless Device Driver vulnerability where SSID field was compromised.

### 4.1 Wireless Driver Exploits Details

Wireless security improved drastically in the last few years with many vendors and companies paying great deal of attention to producing solid secure products and implementing secure network environments. With introduction of more secure WPA/WPA2 encryption algorithms hackers are increasingly more often try to exploit client driver's vulnerabilities. Crafting malformed frames that trigger software vulnerabilities on a target machine was once very tedious work but with the introduction of the automated tools this will not be a problem in the near future. As described in "Wireless communication" section all clients go through a

three stage communication process before establishing connection to the network resources. More specifically, clients during first stage of that process perform mutual exchange of the requests in following order:

Figure 4 – Metasploit Framework web client interface

- ◆ Probe request;
- ◆ Probe response;
- ◆ Beacon;
- ◆ Authentication

```

Figure 5 – Exploit console, provided by Metasploit 3.1 [17]

Wireless discovery, whereas in passive or active mode, is done in a uniform way where clients are feeding probe requests to or listen to the beacon requests from AP or other wireless clients. In either way, network setting is embedded in the frames and broadcasted over the air. The nature of the wireless driver exploits is to produce wireless frames, very similar to the ones that are legit but containing slightly malformed subfield's data. Clients receiving malformed frames will behave differently due to the various network drivers' capabilities. Assuming the driver's weak code implementation is detected, and then the least risk scenario would be a temporary lockup of that driver network interface. The goal of the attacker would be not only to prevent clients from operations but to create a situation where detected driver vulnerability will allow intruders to gain an access to the victim's resources i.e. gain ring0 rights.

Ring0 or Kernel mode level access assumes that the code has full access to the operating systems resources and runs with supervisor mode [14] privileges. Weak driver's implementations would allow hackers to attain such rights through the process called fuzzing or automated driver's flaws testing. One of the available fuzzing tools is so called lorcon (loss of radio connectivity) [15] which inject 802.11 frames with malicious code that can be executed on client's machine.

Hello! This is an automatic message from the UWP campus network. It appears that your wireless driver is outdated. Your PC might be vulnerable to the remote exploits. You won't be able to access UWP resources until your PC is updated would you like to update your PC now?

Yes | No

Figure 6 – Example hot-spot default warning message

MAC layer frame's frame body subfield is a variable size field and is usually tested by supplying malformed data to it. The anticipated result of that activity is a code crash. While attack on this particular field is already known, other MAC frame fields can be compromised through more complicated fuzzing techniques. Results of successful fuzzing will expose client's vulnerability but the actual exploitation is not done yet. This is where the actual complication lies. The simple system or network interface denial of service also useful to some extent to intruders does not provide access to the victim's machine.

In order to fully exploit the wireless driver vulnerability capabilities, the buffer overflow technique is used to provide specifically constructed payload code that can be executed. This is when metasploit framework open source project comes into attention as a de facto standard framework with its capabilities to automate and produce highly sophisticated exploits tapping its Kernel mode flaws database. Figures 4 and 5 show how easy is the penetration of any system with outdated Broadcom wireless driver. Automated interface hides all the work producing valuable information in seconds.

Assuming, vulnerable target machine is identified by some tools such as fuzzing WiFIDEnum, network fingerprinting, or any other means of outdated wireless drivers detection, shell console window is launched, giving an attacker direct access to the victim's machine.

From here, attackers have the ability to issue commands and execute arbitrary code on victim's machine. As we can see, buffer overflow exploits, know for their high precision requirements, are even more complicated in terms of implementation in wireless driver's setting. Also automated tools as shown before exists, they are limited to the already precompiled sets of exposed vulnerabilities.

New exploits are just waiting to be found and with upcoming approval of 802.11n standard's complexity in driver's functionality, there is a huge area that is wide open for misuse. The skills level of the attacker has to be very high and this is why this type of exploits is still occurring very rarely. It also means that security professionals are suppose to be on constant alert, while continuing their education.

## 5.0 Mitigation

Today's arsenal of available prevention tools is very limited due to the nature of device driver exploits, it's highly advanced implementation status and similarities to kernel level root kits. They are almost impossible to detect using currently available security products and thus pose huge security risks to companies and regular end-users. While there is no single product available right now to detect, stop and prevent wireless drivers exploitation, complex multilayer approach should be taken by end users. Apparently, companies and other organizations would have different sets of objectives than the regular owners of wireless enabled devices. As the home end users are the ultimate consumers of the services provided by the third parties, main focus of the security burden should be placed on the wireless service providers. One biggest drawback of this and any other kinds of wireless medium common usage situations is the lack of regulations.

While this is the case, any size companies, providing wireless services should incorporate following techniques into their security requirements policies:

- ◆ Create an abstract set of security level risks associated with each wireless enabled end client based on its configuration, similar to the security clearance scheme of US government;
- ◆ Incorporate existing company-wise resources access group policies with created earlier security risks set
- ◆ Deploy proactive monitoring scheme to identify, notify, prevent, and upgrade wireless clients with inadequate device driver's software.
- ◆ Create an additional level of protection for hot-spots and any other mobile access point's installations by preventing access for any network clients with outdated device drivers.

In figure 6, UWP students trying to access intranet site with outdated device drivers are be warned of their high risk configurations and prevented from accessing any campus resources until the issue is resolved. In this scenario connection attempt also should be logged with any supporting information such as OS version, network card brand, driver's details, etc.

## 5.1 Available Tools

Exploitable conditions in a driver's code are usually detected using Black Box software testing methods. Most commonly used ones are fuzzing and driver fingerprinting where fuzzing mostly associated with discovering security flaws in the code. During the fuzzing process, as mentioned before, the wireless device is fed with random inputs. Inputs can be in a form of valid and/or malformed data. The goal is to make the driver fail, either by crashing the whole program or by misusing code assertions. Usually automated, fuzzing gives good return on the amount of time spent evaluating the code. As with any random data testing, it finds most obvious code bugs fairly fast. Another technique, wireless device driver fingerprinting, also not new, allows detection of the outdated drivers by sniffing the network traffic. Each wireless driver's type has its own network traffic pattern and can be used in detecting vulnerable clients.

An attacker's machine would passively listen in promiscuous mode to a wireless communication and accurately identifies wireless driver's type, version, and any other available information. Then this information would be matched against the precompiled database of vulnerable drivers. Such collections are freely available on the internet. As said before, there are numbers of fully automated software tools already available and no doubt more will be developed once more companies and organizations recognize the importance and seriousness of the wireless driver's vulnerabilities issue. Both fuzzing and fingerprinting techniques should be fully incorporated into proactive monitoring and prevention of possible exploitations by IT professionals.

## 6.0 Conclusion

There is a tremendous demand for more robust and secure wireless standards and availability of the relatively inexpensive wireless technologies. Constantly evolving technologies with their higher throughput rates and wider coverage areas makes network security professionals rethink how networks are designed, implemented, and secured. New 802.11n standards, along with increased performance gains, sets more complicated wireless drivers' requirements. There is a definite need for more comprehensive testing methods to discover flaws and vulnerabilities. Vendors should be responsible for providing timely updates and patched firmware to their hardware devices as well as users, who should be fully aware of the risks associated with using older products.

There is no magical ways to eliminate wireless driver vulnerabilities other than gradual replacement of legacy drivers on all wireless client machines, constant education of end users, monitoring and assessment of security policies.

**Abstract** — The availability of low-powered and cheap microprocessors, radio frequency integrated circuits and the development of new wireless communication techniques, make the wireless sensor networks (WSN) one of today's most promising technologies. Minimizing energy consumption and maximizing the lifetime of the networks are key requirements in the design of sensor network applications. Optimally designed medium access control (MAC) and routing protocols minimize energy consumption and prolong the network life. In this study, we have investigated an energy-efficient adaptive TDMA (EA-TDMA) protocol for railway applications that used in communication between sensor nodes and the cluster-head (CH) placed in a railway wagon. This protocol is suitable for medium traffic applications and reduces energy consumption by shortening the idle period when devices have no data to transmit. We have developed an analytical model for EA-TDMA and compared its performance with conventional TDMA and bit-map-assisted (BMA) protocols.

**Key Words** – Wireless sensor networking; railway wagons; energy-efficiency; MAC protocol.

## I. INTRODUCTION

Recent emergence of micro-electro-mechanical systems (MEMS) technology, wireless communications and integrated circuit design has enabled the development of low-cost, low-power, multipurpose sensor networks. This low-power sensor network can provide new monitoring and control capability in architectural infrastructure, vehicle infrastructure, including monitoring of railway signalling systems, and rail tunnel and track monitoring. Each sensor has wireless communication capability and some level of intelligence to collect data and route it to the sink node. This enhances operational efficiency. Sensor network applications require long lifetime, data accuracy, and energy efficiency. In a sensor node, power is required for data sensing, communication and data processing [1-3].

Energy efficiency is a major issue in designing an efficient WSN; the main sources of energy loss are:

- *Idle listening* occurs when a node is waiting to receive data from its neighbour nodes. A radio keeps their receiver open

all the time as it does not know when a message will arrive from its neighbours. So it is seen that nodes are kept in idle for most of the time.

- *Collision* occurs when two nodes want to send data at the same time and interfere each other. Collision can be removed in schedule-based MAC protocols however; it is a concern issue in contention-based protocol.

- *Overhearing* takes place when a node receives packets that are destined to other nodes i.e. receiver node is not the exact destination. It is a dominant factor in high traffic load situations.

- *Over-emitting* happens when a node sends packet to its destination but its destination is not ready to receive that message.

- *Control packet overhead* is the energy required to send, receive and transmit control packet [2-3].

Optimal design of MAC and routing protocol ensures power-efficient WSN applications that minimise power consumption and hence, maximise battery lifetime of the networks. Owing to their poor energy conservation, traditional MAC and routing protocols are not suitable for WSN applications [4].

In this paper, we have investigated an energy-efficient TDMA MAC protocol using clustering techniques to monitor vertical acceleration and lateral instability of railway wagons. This protocol reduces energy dissipation in sensor nodes while transmitting information between two nodes. In this protocol each node wakes up in its allocated time slot but, turns off its radio immediately if it has no data to transmit, otherwise it transmits its data to the CH. A mathematical model has been developed to evaluate the performance of this cluster-based EA-TDMA protocol. This paper is organised as follows. Section II represents the review of existing literatures. The architecture of proposed EA-TDMA protocol is discussed in Section III. Analytical Model of EA-TDMA, TDMA and BMA protocol is discussed in Section IV. Performance evaluation of the protocol is discussed in Section V. Section VI concludes the paper with future direction.

## II. LITERATURE REVIEW

An efficient use of MAC and routing protocols plays a key role in achieving energy-efficient WSN applications. The major requirements of a MAC protocol are: energy-efficiency, scalability, latency, fairness and bandwidth

utilisation. MAC protocols generally focus on two different areas: contention based or random-access methods and schedule-based or fixed-assignment channel access methods.

Contention-based protocols are scalable and adaptable to node density or traffic load variations. However this scheme has a major limitation relating to an enormous amount of energy wasted due to collisions, overhearing and idle listening [4]. Overcoming these drawbacks are a primary concern of MAC protocol design and a few approaches that reduces these key problems have been introduced, such as S-MAC, T-MAC [4-6].

S-MAC [4] is a contention-based synchronous protocol, designed to reduce energy consumption from the sources of energy loss: *idle listening*, *collision*, *overhearing* and *control overhead*. Periodic sleep, virtual clustering and adaptive listening techniques are used in this protocol to achieve low power duty cycle that reduces energy consumption significantly. It uses virtual carrier sense techniques to reduce collision avoidance and in-channel signalling to implement overhearing avoidance. S-MAC fragments the long message into many small parts and transmits them in burst to reduce contention and communication overhead. An evaluation with the Mote developed by the UCB proved that S-MAC works 2-6 times more energy efficient than the IEEE 802.11 MAC. Simulation results show that power efficiency achieved with this protocol as it reduces collision and overhearing. As only active part of the frame is used for communication S-MAC reduces overall throughput. However, it has synchronization overhead of sending and receiving SYNC packets. It has high message latency and not suitable for a network with heavy traffic [4 - 5].

All messages are transmit in a burst of variable length in T-MAC protocol to reduce idle listening significantly. Nodes are periodically wakes up to transmit data and go to sleep again when there is no event for a specific time period. A node will be on active status until it is busy with listening and transmitting message and after waiting a period of  $T_A$  as idle it turns to sleep mode. It enhances the poor results of the S-MAC protocol under variable condition. Active period  $T_A$  is adjusted dynamically and data transmission occurs during the start of active period. Virtual clustering mechanism is used to synchronize node schedule. A back-off algorithm is used to reduce the collisions in high load and minimize latency during minimum load condition. The future-request-to-send (FRTS) mechanism is introduced to overcome early sleep problems. Determination of active period  $T_A$  is a complex work and sometime sending node may go to sleep even if the receiving node is alive. To overcome early sleeping problem FRTS and data-send (DS) packets are used which increases power dissipation [6].

Time-division multiple access (TDMA) is a scheduled-based MAC protocol in which the channel is divided into several time slots. Each node is assigned a time slot. The node wakes and transmits data only in their allocated slots and remains in sleep mode at other times [2-4, 13].

Fig. 1: Single round for TDMA and BMA protocol [8].

Conventional TDMA MAC protocols are used to prevent collisions by fixing individual time slots for each node. It also reduces energy consumption as all nodes are in sleep condition except for the transmitting nodes. Hence, TDMA protocol is a suitable choice for sensor networks. However, this protocol is suitable for a network with heavy traffic load. Usually in sensor networks there are fewer nodes in a cluster which have no data to transmit to the CH in their allocated time slots. Nodes with empty buffers still turn on their radio during their scheduled time and hence dissipate some of their remaining energy. The CH has to keep its radio on all the time in readiness to collect data from the nodes it serves. Hence, the CH does not use its energy efficiently as it wastes energy in its idle time. The energy-efficient TDMA (E-TDMA) reduces energy consumption due to idle listening. Sensor nodes keep their radios off when there is no data to transmit. However, CH has to keep on the radio during all the timeslots and hence waste energy [2-4, 8]. Fig. 1 illustrated a single round for TDMA protocol.

Low-energy adaptive clustering hierarchy (LEACH) [7] combines cluster-based routing and MAC protocol. This protocol architecture for wireless micro sensor networks achieves low energy dissipation and latency without sacrificing application-specific quality. The key design goals of LEACH are: adaptive cluster formation, energy-efficient TDMA MAC, application specific data processing. Nodes in a WSN organise themselves into local clusters with one node acting as the CH. Overall throughput of the network increases as latency is reduced and system life increases. Collision and interference are overcome by using TDMA and CDMA protocol respectively. Data aggregation mechanisms reduce the amount of data that must be transmitted to a BS, hence, reduces energy consumption. Strengths and weaknesses of highlighted MAC protocols are illustrated in Table-I.

TABLE - I: Comparison of MAC protocols

Article	Rationale	Strengths	Weaknesses
S-MAC [4, 5]	Techniques used in S-MACs are: nodes periodically listen and sleep, virtual clustering and adaptive listening.	Synchronization overhead decreases due to adaptive listening techniques. Energy consumption reduces by sleep scheduling	As sleep, listen periods are constant, may decrease the efficiency of the protocol. Increases latency because an event may occur during sleep time.
T-MAC [6]	Introduces an adaptive duty cycle and reduces energy loss by shortening the awake period during idle condition.	It enhances the poor results of the S-MAC protocol under variable traffic load by dynamic listen period. T-MAC can change the network condition.	High latency and overhead associated with synchronization and introduces early sleeping problem.
TDMA [2, 4]	Channel is divided into several time slots and one time slots is assigned to each node. Nodes awake and transmit data in their allocated slots.	Prevent collisions by fixing individual time slots for each node and reduce energy consumption as all nodes are in sleep condition except the transmitting nodes.	There may be fewer nodes in a cluster which have no data to transmit to the CH in their allocated time slots. CH has to keep its radio on all the time.
LEACH [7]	Distributed cluster formation enables randomized, adaptive, self configuring features.	Overall throughput of the network increases as latency is reduced and system life increases. Collision and interference are overcome by using TDMA and CDMA protocol respectively.	Due to its distributed cluster formation algorithm, it cannot ensure the coverage of entire network. TDMA schedule introduces time delay.
BMA [8]	An intra-cluster communication protocol reduces energy wastes due to idle listening and collisions.	BMA has low complexity, reduces energy wastes due to idle listening and low packet latency. BMA outperforms TDMA and E-TDMA in low and medium traffic loads.	BMA is suitable only for low traffic, i.e., relatively few sensor nodes per cluster. Data may arrive in empty node at any time during node to CH data transmission.

Bit-map assisted (BMA) [8-9] is a schedule-based MAC protocol that reduces energy wastage from idle listening and collisions. The cluster setup phase is identical to LEACH [16] protocol. In BMA sensor nodes forward data to the CH only if a significant event has been observed. BMA protocol reduces energy consumption occurring in conventional TDMA systems due to idle listening in the absence of data in any node in their allocated scheduled time slots. All nodes in the cluster keep their radios on in the contention period and transmit a 1-bit control message during its allocated slot if it has data to transmit, otherwise the slot remains empty. During data transmission period, each source node turns on its radio and sends its data to the CH over its allocated slot and turns off its radio all other times. Non-source nodes keep their radios off during the data transmission period. BMA has low complexity, reduces energy wastes due to idle listening and low packet latency. BMA outperforms TDMA and E-TDMA in low and medium traffic loads. It is an energy-efficient intra-cluster low-latency protocol with low complexity and reduced energy wastes in idle listening. BMA is suitable only for low traffic, i.e., relatively few sensor nodes per cluster [8-9]. Fig. 1 represents a single round for BMA protocol.

### III. ENERGY-EFFICIENT ADAPTIVE TDMA (EA-TDMA) PROTOCOL

Conventional TDMA-based MAC protocols are used to prevent collisions by fixing individual time slots for each node. This scheme also reduces energy consumption as all nodes are sleeping except the transmitting node. Nodes in the cluster send their sensed data to cluster head (CH) in their respective time slots. Nodes with empty buffers still turn on their radio during its scheduled time and the CH also keeps its radio on all the time to listen to the nodes in its cluster, this wastes energy. TDMA-performs better under high-traffic load conditions. A high traffic load means all nodes always have data to transmit. Conventional TDMA is the most suitable for an application that comprises with heavy traffic load and BMA is suitable for an application that comprises with low traffic load.

We have investigated train wagon body acceleration signals using sensor networking techniques to monitor vertical acceleration behaviour of railway wagons. In this application, accelerometer data was collected continuously from sensor nodes placed inside the wagons to investigate the train track irregularities and lateral instability. It has medium to high traffic loads. Therefore considering the application requirements, we have concentrated on developing a protocol suitable for medium to high data traffic and proposed energy-efficient EA-TDMA protocol. In the EA-TDMA protocol every node wakes up its allocated schedule but turns off its radio immediately if there are no data to transmit, otherwise it transmits its data to the CH. This protocol reduces energy consumption during data transmission by reducing idle listening period.

Fig. 2 Operation diagram of EA-TDMA protocol

We assume that the time slot duration in a TDMA schedule is  $T_d$ . The assigned node turns on its radio and transmits data to the CH during this period. If any node has no data to transmit it turns off its radio immediately. Therefore, we assume that the radio is turned off after time  $T_e$ , instead of remaining on for the entire time period of duration  $T_d$ , as illustrated in Fig 2.

To meet the requirements of WSNs, some assumptions of this approach are: nodes are static throughout the network; energy levels of the normal nodes are almost identical but die at almost the same time; CH has higher energy level than normal nodes; and all data slots in a TDMA schedule are the same size. We have divided the operation of the proposed protocol into rounds. Each round comprises of a set-up and a data transmission phase. Both cluster formation and CH selection occur in the setup phase, while data transmission from node to the CH and on to the BS occurs during data transmission phase, as described in the following details.

**Setup Phase:** Considering application area and simplicity in this study we assume the network consists of a multiple fixed cluster in which there is one CH is located in the centre of the cluster. Based on application and cluster size we have considered direct transmission for data communication between source nodes to CH instead of multihop data transmission. In setup phase, the CH builds a TDMA schedule and broadcasts the schedule to all nodes within the cluster. CH also informs all nodes about the start of current round, frame start/stop time, number of frame in a round.

**Data Transmission Phase:** The data transmission phase contains  $l$  frames. The size and duration of each of the frames are fixed. Nodes send their data to the CH once per frame during their allocated time slots. We assume that there is one CH node and  $N$  non-CH nodes in a cluster. During the data transmission period each node turns on its radio in its assigned time-slots and transmits data to the CH. If any node, after turning on its radio finds an empty buffer, i.e., there is no data to transmit, then the node turns off its radio immediately to save energy. The nodes turn into sleep mode instead of idle mode in the absence of data. Non-CH nodes transmit sensed data to the CH's buffer. After receiving all data from the nodes, the CH aggregates the data.

After a predefined time, the system begins the next round and the whole process is repeated. A timing diagram of the proposed EA-TDMA protocol is illustrated in Fig. 3.

Fig. 3: Timing diagram of EA-TDMA protocol

#### IV. ANALYTICAL MODEL OF EA-TDMA PROTOCOL

We analyse our proposed protocol in a cluster-based network in which there are one CH and  $N$  non-CH nodes. Assuming that there are  $l$  frames in a round and  $n_k$  source nodes in the  $k_{th}$  frame. The nodes which have data to transmit are called source nodes. Bernoulli Trail, as used in BMA [9] protocol has been used to calculate the probability that a node has data to transmit. Hence,  $n_k$  is a Binomial random variable and source node in a frame would be  $E[n_k] = Np = n$ ,  $k = 1, 2, \dots, l$  where  $p$  = probability. The number of source nodes has varied from frame to frame. The power consumption in the transmit mode and the receive mode are respectively  $P_t$  and  $P_r$ . The typical power consumption in the proposed protocol occurred during turn on and empty checking period of the idle nodes:  $P_e$ . For simplicity, as stated in [4, 7], the energy required to turn on the radio by the source nodes for transmission or reception is negligible, hence ignored in the analysis here.  $T_d$  is the time required to transmit or receive a data packet, and  $T_c$  is the time required to transmit/receive a control packet. The time required for a node to switch on, check its buffer and turn off its radio is  $T_e$ . Power consumption and energy dissipation of an idle node is  $P_i$  and  $E_{in}$  respectively. The time required for the cluster-head to transmit a control packet for BMA is  $T_{ch}$ .

Initially, an analytical model was developed based on the energy model [9] for the EA-TDMA and then compared with the conventional TDMA and BMA protocol.

**A. EA-TDMA Protocol:** During setup phase, CH and all nodes keep their radios on and communication takes place between the CH and other nodes. In this period, the CH selects time slots for individual nodes for data communication and informs all nodes in the cluster. Therefore, energy consumption by CH to send a control packet is  $E_{ch} = P_t T_c$  and energy consumption by each node to receive control packet is  $E_n = P_r T_c$ . Total energy consumption during setup phase for all nodes is:  $E_C = P_t T_c + N P_r T_c$

Each node transmits a maximum of one packet per frame interval. During a frame, transmission energy dissipated in a data node is  $E_{dn} = P_t T_d$ . Energy dissipated in a node that has

no data to transmit to the CH is  $E_e = P_e T_e$ . The energy  $E_e$  is used to switch on, check transmit buffers and then turn off the radio module. The energy consumed by the CH is  $E_{ch-e} = n P_r T_d + (N - n) P_i T_d$ . Therefore, the system energy dissipation in the  $k_{th}$  frame is:

$$E_{Se} = n P_i T_d + (N - n) P_e T_e + (N - n) P_i T_d + n P_r T_d \quad (1)$$

Assume, there are  $l$  frames in a round. Therefore energy consumption of the system in a round, of the proposed protocol is:

$$E_{EA-TDMA} = P_t T_c + N P_r T_c + l[n P_i T_d + (N - n) P_e T_e + (N - n) P_i T_d + n P_r T_d] \quad (2)$$

**B. TDMA Protocol:** During the  $k_{th}$  frame, the energy dissipation in a source node is  $E_{dn} = P_i T_d$ . A non-source node, i.e., the empty-buffer node turns on its radio and keeps idle during its scheduled time slots consuming energy  $E_{in} = P_i T_d$ . Energy consumption in the CH is  $E_{ch} = n P_r T_d + (N - n) P_i T_d$

Energy consumption during setup phase of TDMA is the same as EA-TDMA. Therefore, the average energy dissipation in a round is

$$E_{TDMA} = P_t T_c + N P_r T_c + l[n P_i T_d + 2(N - n) P_i T_d + n P_r T_d] \quad (3)$$

**C. BMA Protocol:** In BMA there is a contention period in each session when all nodes keep their radios on. Each source node transmits a control packet during its scheduled slot and remains idle  $(N-1)$  slots. Total energy consumption by each source node during a single session is  $E_{dn} = P_t T_c + (N-1) P_i T_c + P_r T_{ch} + P_i T_d$ . Each non source node stays idle during the contention period and keeps its radio off during the data transmission periods and hence energy consumption is  $E_{in} = N P_i T_c + P_r T_{ch}$ . During the contention period the CH node receives  $n$  control packets and stays idle for  $(N-n)$  slots. Energy dissipation by the CH is  $E_{ch} = n (P_r T_c + P_i T_d) + (N-n) P_i T_c + P_t T_{ch}$

The average system energy dissipation in each round in BMA protocol is:

$$E_{BMA} = l[n(P_t T_c + (N-1) P_i T_c + P_r T_{ch} + P_i T_d) + (N-n)(N P_i T_c + P_r T_{ch}) + n(P_r T_c + P_i T_d) + (N-n) P_i T_c + P_t T_{ch}] \quad (4)$$

## V. RESULTS AND ANALYSIS

We compare EA-TDMA protocol with the BMA and conventional TDMA protocol in terms of energy dissipation. For analytical analyses we have used Rockwell's [10] WINS model as used in the BMA protocol. In this model the radio transceiver uses 462 mW for transmitting, 346 mW for receiving and 330 mW for idle listening. The data rate is 24 kbps. Assume a data packet size of 250 bytes and a control packet size of 18 bytes. In this experiment we assume  $P_i = P_e$ . We compare the above three protocol in terms of energy dissipation.

Fig. 4 is drawn by noting the above conditions that provide comparison of the EA-TDMA, TDMA and BMA protocols as a function of probability  $p$ . In this case  $N = 10$  and there are  $l$

$= 2$  frames in a round. It is observed that for very low traffic when  $p = 0.1$  to  $0.2$  the BMA protocol is superior to that of the EA-TDMA and TDMA protocols. However, energy consumption of BMA increases linearly when  $p \geq 0.3$  and EA-TDMA protocol outperforms both BMA and TDMA protocols. EA-TDMA protocol outperforms TDMA protocol except for heavy traffic. For heavy traffic energy dissipation of EA-TDMA and TDMA are same which is much less than the BMA protocol. Therefore, we may conclude that the EA-TDMA protocol is most suitable for medium traffic load.

Fig. 5 compares MAC schemes in terms of energy, where nodes  $N$  are variables and frame  $l = 10$  and probability  $p = 0.6$ . EA-TDMA protocol outperforms both BMA and TDMA protocols in terms of energy consumption. EA-TDMA protocol saves more energy if the number of nodes increases in the network. Hence, EA-TDMA is suitable for large networks.

Fig. 4: Comparing the energy dissipation of EA-TDMA protocol with BMA and conventional TDMA protocol as a function of probability  $p$ .

Fig. 5: Energy dissipation of EA-TDMA, BMA and TDMA protocols as a function of number of nodes in a cluster,  $N$ .

Fig. 6: Comparing the energy dissipation of EA-TDMA with BMA and TDMA protocol as a function of number of frame,  $l$

From Fig. 6, it is observed that EA-TDMA protocol saves more energy if the number of frames per round increases and outperforms BMA and TDMA protocol in terms of energy dissipation.

From the above analytical results we may conclude that EA-TDMA protocol is more energy-efficient than BMA and TDMA protocols in case of medium traffic applications. However, BMA protocol performs better than EA-TDMA and TDMA protocols in case of low traffic applications especially event driven applications. For high traffic load energy consumption of EA-TDMA and TDMA are the same and perform better than the BMA protocol. We have investigated a cluster-based TDMA protocol to develop a monitoring system for railway. This problem demanded medium to high traffic conditions, therefore EA-TDMA protocol is the most suitable for this application.

## VI. CONCLUSION

In this study, considering traffic load of the application, a cluster-based energy-efficient adaptive TDMA-based MAC protocol has been investigated for railway to monitor typical dynamic behaviour of railway wagons. A mathematical model has developed for the proposed EA-TDMA protocol and compares its performance with conventional TDMA and BMA protocols.

Analytical results prove that EA-TDMA protocol outperforms both TDMA and BMA protocols for medium to high traffic. From experimental results it has observed that BMA protocol is superior to EA-TDMA especially for low traffic or event driven applications. However, if the probability  $p \geq 0.3$ , EA-TDMA performs better than BMA protocol which is natural scenario for our railway applications.

This study is still on introductory stage and needs to be developed in different areas. Therefore, it deserves further investigation that focuses on some specific areas such as:

- investigate energy-efficient routing protocols and their integration with the proposed EA-TDMA algorithm.
- validate the analytical results stated in this paper using simulation software.
- reduce power consumption of the protocol by introducing duty cycle in CH.
- increase CHs lifetime by introducing rotational CH in the cluster.
- integrate the protocol with machine learning algorithm to develop monitoring signal.

### Abstract

*With the advent of new upcoming online video services such as IPTV, Video on Demand (VoD) and Peer-to-Peer (P2P) video streaming, content providers are gaining more and more interest in measuring and monitoring video quality as perceived by end-users; also known as Quality of Experience (QoE). Objective video quality metrics provide a means of measuring visual quality degradations but in order to be able to measure QoE, these objective metrics should incorporate all quality affecting parameters such as encoding bitrate, network impairments and error concealment techniques. As a consequence, in order to construct or validate a proper objective video quality metric, extensive video evaluation tests must be performed. In this paper we present a scalable video testing platform that simplifies the management and execution of such video quality evaluation tests. Results indicate that the use of our testing platform drastically reduces overall experiment duration.*

### 1. Introduction

With the advent of new upcoming online video services such as IPTV, Video on Demand (VoD) and Peer-to-Peer (P2P) video streaming, content providers are gaining more and more interest in measuring and monitoring video quality as perceived by end-users; also known as Quality of Experience (QoE). According to the definition in [2], QoE includes all end-to-end system effects which means that in the case of video streaming the influence of both encoding, streaming, decoding and viewing must be taken into account. During the encoding process, encoding artefacts such as blockiness and blurring can be introduced. While streaming the video, packet loss can occur which result in the loss of information. Finally, during decoding and viewing, different error concealment techniques can be used to mask the visual impairments. These are only a few

of the possible system effects that influence the way human observers perceive visual quality. Objective video quality metrics, such as Structural Similarity (SSIM) [7] and Video Quality Metric (VQM) [1], provide a means of measuring visual quality degradation based on a comparison between the original and the received video sequence. Results indicate that these metrics correlate well with scores of subjective quality assessment but they were developed mainly to evaluate video codec quality. As already stated, an end-to-end objective video quality metric should incorporate all possible system effects. As a consequence, in order to construct or validate a proper objective video quality metric extensive video evaluation tests must be performed using different values for each of the quality affecting parameters such as encoding bitrate, packet loss rate and error concealment technique.

In this paper we present a scalable video testing platform that simplifies the management and execution of such video quality evaluation tests. Our proposed platform enables the parallel execution of different test cases at the same time and thus reducing the overall time needed to perform all quality evaluation tests.

The remainder of this paper is structured as follows. In section 2, the individual building blocks of a general video quality experiment are described which, in turn, are used to derive the requirements for a video testing platform. Section 3 provides an overview of the physical testbed and the management software which enable scalable video quality experiments. The performance of our scalable platform is evaluated in section 4 and finally, conclusions and future work are described in section 5.

### 2. Video Quality Evaluation

When a video is streamed across a network, quality can degrade due to packet loss, jitter and delay. The influence

of these network impairments on the video quality can be researched in different ways: through theoretical models, by simulating the network impairments or by emulating them in a real network environment. The last approach is the most realistic one since it enables us to stream video using real-life network conditions and hardware. This is the way we perform our video quality research. In this section, we first analyse a general video quality experiment and break it up into different building blocks.

## 2.1. Video quality experiment: building blocks

A basic video quality experiment, as described in [6], consists of several different test cases which in turn consists of different test steps: *encoding* a reference sequence, *impairing* the encoded sequence and *analysing* the video quality of the impaired sequence.

In the encoding step a raw video sequence is compressed by means of an encoder. An encoder is an implementation of a specific codec like MPEG-2 or H.264. There exist a variety of different encoding standards and encoding tools, each with their own performance and characteristics. Because the quality of a video sequence as experienced by the end user for the same artifacts depends strongly on the type of content used [4, 5], a test should be performed across a number of sequences, all different in terms of spatial and temporal complexity.

Network impairments can be generated through simulation as is done in [6] or by emulating the real network with real streamers. Within our research group we put a strong emphasis on emulation, because we want to test the behaviour and influence of different hardware, real network setups and real streaming servers and packetisation.

**Figure 1. Basic streaming setup: streamer streams video to the client over a network emulated by the impairment node**

A basic video streaming setup for generating network impairments is shown in Figure 1. This basic setup consists of three machines: a streaming server, an impairment node and a client. The streamer streams the video to the client. Different streaming protocols (e.g. UDP, RTP and MPEG-TS) can be used to deliver the video to the client. The behaviour of the network under test is emulated by an impairment node. Input for the impairment node can be: packet

loss rate, types of packets to impair, variable packet delay and so on. The client receives the video stream and captures it. Each client has its own error concealment techniques, so it is important to test with different client software or to control the error concealment technique by means of a custom developed receiver.

In the last step, the actual video quality evaluation is performed. By using one or more quality metrics like Peak Signal-to-Noise Ratio (PSNR), SSIM [7] and VQM [1] the quality degradation of the video can be determined. This test step is the most time consuming step in the experiment due to the complex algorithms and byte by byte comparisons that are used.

Video quality evaluation usually involves extensive testing using different encoding techniques, different amounts of network impairments and different error concealment techniques. As a simple example, the basic video test experiment from [6] involves 4 different video sequences, encoded with 9 different quantization parameters. Each of these encoded sequences was then impaired with 7 different packet loss rates. This resulted in a total number of 252 different test cases. As can be seen, the input parameter space for video quality testing can be extensive and therefore calls for parallel execution of test cases. This parallel execution should be managed by a flexible and scalable video testing management platform.

## 2.2. Video test platform requirements

Based on the description of the general test experiment in the previous section, we can extract the basic requirements for the management software of the video test platform:

- **Distributed application management:** A variety of applications on distributed machines have to be configured, started and stopped. It should not matter to the platform which operating system is running on the machines (e.g. videoclient on Linux or Windows).
- **Distributed file handling:** Video data files and application configuration files have to be distributed to the different servers or other devices (e.g. set-top boxes, traffic generators) before the start of each test. After a test case execution the resulting data files need to be collected to a central repository. The platform should be able to handle this reliably and efficient.
- **Repeatable testing:** We want to be able to repeat a test with slightly different input parameters. For example after doing a test with a set of files with resolution X, the test should be easily repeatable with files with resolution Y. So it should be easy to recall an already executed experiment and tweak some parameters in it.

- **Scalable:** The experiment duration will further increase when we increase the duration of our input sequences or if we want to do more advanced quality analysis (see Section 4.1). As a typical experiment consists of several hundreds of tests, and we still want to perform this in a reasonable amount of time, we will have to come up with a scalable solution that will parallelize some processes and eliminate dead time.
- **Flexible:** A basic setup can be as simple as depicted in Figure 1, but it can be more complex with more devices. The platform should be flexible in terms of the number and types of hardware devices that can be managed. It should be possible to easily create different network situations.

### 3. Video testing management platform

In this section we first describe the architectural solutions that were developed to execute video experiments. Then, we elaborate further on the design of the test management software.

#### 3.1. Video testbed

To execute video experiments we have created a general video testbed as shown in Figure 2. Extra machines can be easily plugged in.

Figure 2. The video test bed

This testbed consists of a number of fixed machines which can be classified based on their specific function.

**streamers** The streamer streams the video across the network. Our testbed supports open source streamers (Darwin Streaming Server and VLC), commercial streamers (Windows Media Server) and our in-house developed streamer (xstreamer which will be described in future papers).

**clients** The client receives a video stream and possibly displays it on screen and/or captures it to disk. We can receive the video with different players: Windows Media Player, Quicktime, VLC, in-house developed receiver, ... Next to streaming the video to regular desktop computers, the testbed also supports streaming video to set-top boxes which in turn are connected to TV sets.

**Click Modular Routers** The Click Modular routers in the testbed are servers which emulate the network. Each of them runs the Click Modular Router software package [3]. Through this software (enhanced with our own models) we can drop packets, introduce jitter and packet delay. Packets can be dropped according to specific models (random, burst, Gilbert, ...). The router near the streamers can act as a traffic shaper, the one near the clients emulates the home gateway and the middle router emulates the core network. We can also choose to stream over a real-life network of an ISP or over a real wireless network.

**sniffers** At specific demarcation points in our testbed we have placed network sniffers. These capture the video streamed over the network. After testing, sniffer files can be used to extract network and failure statistics.

**traffic generator** Additional network traffic can be generated by a dedicated traffic generator like the Spirent SmartBits <sup>1</sup>.

**video quality analyser** One high performant machine will do all the encoding, decoding and quality analysis.

**controller** All the machines in the network are controlled by one machine running the testbed management software. This machine controls the other machines through a separate control network.

This testbed is used for general video quality experiments or for evaluating third party hardware/software. It is clear that this testbed lacks scalability due to its single instantiation, flexibility and complexity. Therefore an adapted solution will be explained in the next section.

#### 3.2. Large scale video testing using the iLab.t Virtual Wall

To perform realistic scalability tests of networks, servers and networked applications the iLab.t Virtual Wall testbed<sup>2</sup> (see Figure 3) was built.

In a first phase we have built a testbed with 100 server machines (see Table 1), with 4 or 6 gigabit Ethernet ports

<sup>1</sup><http://www.spirent.com/>

<sup>2</sup><http://ilabt.ibbt.be/>

**Figure 3. The iLab.t Virtual Wall consists of 100 identical server machines, 20 of them are connected to a monitor**

each connected to a huge nonblocking switch (Force 10 networks E1200) which can be configured to make the interconnections between the servers dynamically and point to point. Twenty of our server machines are also connected to a display, so we can visualize the results of video streaming tests.

CPU	2 x dual core 2.0Ghz
Memory	4GB RAM
Storage	4 SATA disks in RAID 0 configuration

**Table 1. Virtual Wall node: hardware specifications**

By using the Emulab software [8] of the University of Utah<sup>3</sup> it is possible to configure specific network setups and dynamically load operating system images on the allocated servers through a web interface.

With this testbed we can organize our scalable video quality experiments. With the 100 machines we have available, we can create 33 basic streaming setups (see Figure 1) controlled by 1 machine. This way 33 streaming steps can run concurrently. The encoding, decoding and analysing processes can be distributed amongst the 99 machines. And with the 4 cores per machine, even 396 of these processes can run in parallel.

To achieve this we first created a video node disk image. This disk image contains an operating system, all the necessary software tools like streamers, clients, encoders, decoders and quality analysers for performing each individ-

<sup>3</sup><http://www.emulab.net>

ual step in the video quality test process. Within the emulab software we then created an experiment setup with a parameter containing the number of basic streaming setups we want to allocate. When we want to execute a series of video quality tests we just call this setup script with the number of desired setups and allocate them through the emulab software. The emulab software then allocates the server machines, loads the disk image on it and creates the necessary network connections between them. The next step is then the configuration and execution of the different tests. This is the task of our management software and will be discussed in the next section.

### 3.3. Management software

**Figure 4. Management software**

To configure, manage and execute video experiments we have developed a management application in Java (see Figure 4). The central application runs on the control machine and is in charge of the test configuration, control of the distributed processes, distributing and collecting the data files and scheduling the different test steps. On each machine in the test setup a Java service is running and the central application communicates with them through Java Remote Method Invocation (RMI).

Java was chosen for its platform independency, this way we can easily plug in additional devices like set-top boxes or even mobile phones. In the following paragraphs the functionality of the management software will be described.

#### 3.3.1 Configuration

Since repeatability was one of the requirements for our testing platform (Section 2.2), we should be able to reload an executed experiment or reconstruct it. To achieve this, we store our experiment configuration data into xml files. Actually, this is a serialization of our data model into xml. There are two ways to create an experiment configuration: through

a graphical user interface or through the scripting engine. With the interface as shown in Figure 4, one can create a configuration and start up the experiment. During execution the user receives visual feedback about the actions the software takes and the possible errors that occur.

One can imagine that creating several 100 different test cases in this interface is quite a hassle. To facilitate this we have created a script toolbox in JRuby<sup>4</sup>. Within the script we can build up our experiment data model over the ranges of a set of input parameters. We can then serialize the data model to xml, load it in the management software and run the experiment. We can also directly start the experiment from within the script.

### 3.3.2 Application Management

Configuring, starting and stopping the applications on the different devices in the test setup is controlled by the central management application. Configuration of an application is usually done by uploading a configuration file, that is stored locally on the control pc and possibly generated through scripting, to the device. Some applications need to be started in a predefined order, because for example a client cannot request a video stream from a server that is not running, this order is stored in the configuration. The Java service will start the application when it receives an execute request with a process object as argument. This process object contains the command to execute and the arguments to that command. The call to the service is made by means of RMI. The service keeps track of every process that is started. Some applications will terminate automatically, e.g. encoding or decoding, whereas others will run until they are stopped after a predefined time, e.g. servers. This is done by calling the stop method on the service, again with the process object as parameter.

The following code listings present the service and the process objects interface.

```
public interface RemoteRuntime extends Remote {

 Object execute(VTProcess process);
 void stopProcess(VTProcess process);
 Object registerLogServer(InetAddress ip, int port);
 Object unregisterLogServer(InetAddress ip, int port);
}

public interface VTProcess
 extends Serializable, Comparable<VTProcess> {

 public void run();
 public void stop();
 public String getName();
 public void setName(String name);
 public void setWaitFor(boolean b);
 public boolean isWaitFor();
 public String getDescription();
 public void setDescription(String description);
 public List<CopyFileInfo> getFilesToUploadInfo();
}
```

<sup>4</sup><http://jruby.codehaus.org/>

```
public Set<String> getFilesToDownload();
public boolean endsAutomatic();
public VTProcess copy();
public String getCommandToExecute();
}
```

### 3.3.3 File Distribution

The central management software distributes and collects files to and from the devices in the testbed. By default this is done through FTP, because this is the fastest transfer solution. For this, each device will need a ftp server. If it is not possible to install one on a device, we can choose to use sftp (secure ftp), which is a lot slower than ftp, or we can setup sockets in the central application and the services and transfer the files through them.

### 3.3.4 Test Scheduling

The central management application is responsible for scheduling the different test steps in an experiment: encoding, streaming and quality analysis. Steps belonging to the same category can be executed concurrently. But streaming will only start when all encoding processes are finished and quality analysis cannot start before all streaming processes are finished.

This scheduling is defined at configuration time. When configuring an experiment, each step is assigned to a machine or in case of the streaming step assigned to a specific setup. Steps that can run concurrently are then put into batches, these batches will be executed sequentially. We illustrate this with an example. Suppose we have one basic streaming setup (Figure 1) allocated, so we have three testbed servers available and one control machine. We need to encode 1 video sequence 2 times and stream the resulting files each 2 times. The streamed files will each be analysed. So we will have 2 encoding steps that can run in parallel, 4 streaming steps that will run sequentially and 4 analysis steps that will be divided into a batch of 3 and a batch of 1 (we only have three servers in use). Figure 5 shows this test configuration as it appears in the interface.

When a test step is scheduled and executed, the application performs 4 consecutive tasks:

1. Upload input files and configuration files to the devices
2. Start up the processes
3. Stop the processes
4. Download all captured and resulting files

**Figure 5. Experiment configuration: batches are executed sequentially, elements in batches are run in parallel**

## 4. Performance evaluation

### 4.1. Theoretical approach

The processing time of a single test case, that consists of one video sequence that must only be encoded and streamed once, can be calculated using equation (1), where  $t_{enc}$  represents the time needed to encode the video sequence,  $t_{str}$  represents the time needed to stream the encoded sequence and  $t_{an}$  represents the time needed for analysing the received video stream.

$$t_{single} = t_{enc} + t_{str} + t_{an} \quad (1)$$

In case the video sequence in a single test case must be encoded  $n$  different times and streamed using  $m$  different network settings, the total processing time can be calculated using equation (2).

$$t_{multicase} = n \times t_{enc} + n \times m \times t_{str} + n \times m \times t_{an} \quad (2)$$

Furthermore, if the test case can be run in parallel on  $x$  different testbed setups, each consisting of  $\alpha$  machines, the total processing time becomes:

$$t_{process} = \frac{n \times t_{enc}}{\alpha \times x} + \frac{n \times m \times t_{str}}{x} + \frac{n \times m \times t_{an}}{\alpha \times x} \quad (3)$$

Besides processing there is also some time spent in downloading and uploading files:

$$t_{ftp} = t_{upload} + t_{download} \quad (4)$$

Where  $t_{upload}$  is the time to distribute files like raw video files, encoded video files and application configuration files to the servers. The  $t_{download}$  is the time to collect result files like encoded video files and streamed video files to the control machine. The  $t_{ftp}$  is fixed and depends on the number and size of the files to be distributed and collected. Increasing the number of setups will not diminish the time spent downloading and uploading files.

The total execution time for an experiment can thus be computed by combining equations (3) and (4):

$$t_{exp} = t_{ftp} + t_{process} \quad (5)$$

**Figure 6. Experiment execution time in function of the number of setups**

Figure 6 shows the experiment execution time in function of the number of setups used. The dashed line represents the real execution times (See 4.2). The full line represents the theoretically determined values by using equation (5) for the same experiment.

The graph shows that there is a diminishing performance gain with increasing number of setups. When starting from one setup, the performance can be doubled by doubling the number of setups. To have the same relative performance gain the number of setups need to be increased by 4,8,16 and so on. The difference between the theoretical and real durations will be explained in Section 4.2.

The optimal time  $t_{opt}$  is achieved when  $x = \frac{m \times n}{\alpha}$ . At this point the maximum parallelisation of individual test steps is achieved: all encoding steps are run concurrently, then all streaming steps and finally every quality evaluation step is parallelized. The time  $t_{opt}$  is then the total ftp time ( $t_{ftp}$ ) and the sum of the maximum durations of the individual test steps: encoding, streaming and quality evaluation. Increasing the number of setups any further beyond this point would not result in further time gains.

# setups	encoding	streaming	analysing	ftp	total	experiment time	overhead
1	1.21	40.47	318.90	12.58	373.15	376.08	2.93
2	0.61	20.27	174.76	8.39	204.02	206.49	2.47
4	0.33	10.43	105.28	7.75	123.78	126.53	2.75
8	0.33	5.45	72.48	7.90	86.17	89.28	3.11
16	0.33	2.79	45.26	7.66	56.05	59.37	3.33

**Table 2. Profiling data: durations (in minutes) of individual steps in an experiment**

## 4.2. Experiment monitoring

To back up our theoretical model with some real data a video quality evaluation experiment was executed on a different number of setups and the duration of each single test step was measured. One video sequence, with a duration of 20 seconds, was used in the experiment. The sequence had a resolution of 672x384 and its filesize was 184MB. This sequence was encoded using ffmpeg<sup>5</sup> with following parameters: `-vcodec libx264 -b #value`. With `#value` having following bitrate values : [100k, 300k, 500k, 700k, 900k, 1100k, 1300k, 1500k, 1700k, 1900k]. The resulting files were streamed over a network containing random packet loss in % [0, 0.01, 0.02, 0.05, 0.1, 0.2, 0.5, 1, 2, 5]. This way, the experiment consisted of 100 different test cases. The experiment was executed on one, two, four, eight and 16 setups. Each setup is configured as a basic streaming setup as shown in Figure 1.

The measurements are shown in Table 2, each duration is presented in minutes. The execution of the test steps was profiled within the management application to determine the duration of each step. The "total" column is the sum of encoding, streaming, analysing and ftp durations. The "experiment time" is the duration of the execution of the experiment within our application. The difference between these two is the overhead that is created by our management software to schedule the different steps and to perform its management job. We notice that this overhead only slightly increases with the number of setups used.

When the number of setups reaches four (12 machines), all ten encoding steps are run concurrently. At this point we reach the lowest achievable encoding time, increasing the number of setups will not result in a lower encoding time as is shown in the table. Notice that the encoding and the streaming time basically halves when doubling the number of setups, but the analysis duration doesn't. This is because the duration of an analysis step strongly depends on the artefacts in the video sequence and when a batch of concurrent processes is started we have to wait until all processes are finished before a new batch can be started. So the execution time of a batch will be the duration of the longest analysis step within that batch. It could be that within a batch of 10

<sup>5</sup><http://ffmpeg.mplayerhq.hu/>

analysis steps, nine have finished and still need to wait for a few minutes for the last one to finish. It is clear that there is a need for a more dynamic scheduling to more optimally use the available machines in the experiment.

On the contrary to what we expected the ftp time is not constant. It is the highest for one setup, then drops to about 8 minutes for two setups and remains roughly the same when further increasing the number of setups. Transferring files across a network should take up the same amount of time whether they are sent sequential or concurrent. One of the possible causes is that the ftp connection setup consumes some time and when it is run in parallel this time is averaged out. We will need some deeper monitoring to really determine the cause of this.

In this experiment only one video sequence was used as input, if we would use more than one video sequence this will have a few consequences. First of all the number of test cases will lineary increase with the number of input sequences, as a consequence the total experiment duration will also increase lineary. Secondly the durations  $t_{enc}$ ,  $t_{str}$  and  $t_{an}$  will be different for each sequence. So the optimal time we can achieve with our current scheduling will be strongly dependent on the maximum values of these durations.

## 5. Conclusion and future work

Performing video quality evaluation experiments provides challenges to an automated testing platform like an extensive input parameter space and long processing times. We described the solutions we've developed to provide a flexible and scalable platform that allows us to easily repeat different video quality evaluation experiments. Management software was developed to automate test execution. This software handles configuration, distributed application management and file management in a generic and platform independent way. The iLab.t Virtual Wall allows us to drastically reduce the experiment execution time by creating a number of similar network setups and running the different steps in the quality evaluation process concurrently. This performance improvement was proven both theoretically and practically by means of experiment monitoring.

Until now, the Virtual Wall was used to create basic

streaming setups, like the one in Figure 1. In future we want to create and test more complex setups. We could for example create a network with several servers connected through one router to several clients. Some of these servers will act as streaming servers, others as file servers or web servers. Some of the clients can be configured to display the video, others will download files or send requests to the web servers. This way we will be able to monitor the behaviour of a video stream in a more realistic network environment.

With the static scheduling mechanism currently implemented, we do not reach an optimal usage of the resources within the testbed. This is shown by the experiment monitoring, e.g. the quality evaluation duration does not halve when doubling the number of setups in the testbed. In future we will look at implementing a more dynamic scheduling mechanism. This scheduling should happen at run time and keep track of test step dependencies and resource (setup or machine) usage. This way further performance gains can be made.

As the analysis step is the most time consuming, we could look at breaking this process down into different sub-processes so that we can parallelize them.

By now, we reach an acceleration factor of 6 (376 vs 59 minutes) by using 48 servers instead of 3.

## Abstract

*Association rule mining is to extract the interesting correlation and relation between the large volumes of transactions. This process is divided into two sub problem: first problem is to find the frequent itemsets from the transaction and second problem is to construct the rule from the mined frequent itemset. Frequent itemsets generation is the requirement and most time vast process for association rule mining. Nowadays, most efficient Apriori-like algorithms rely heavily on the minimum support constraints to prune the vast amount of non-candidate itemsets. These algorithms store many unwanted itemsets and transactions. In this paper propose a novel frequency itemsets generation algorithm called MTR-FMA (Modified Transaction Reduction based Frequent Itemset Mining algorithm) that maintains its performance even at relative low supports. The experimental reports also show that proposed MTR-FMA algorithm on an outset is faster than High Efficient AprioriTid and other some algorithms.*

## Key words

Association rule mining, Frequent itemsets, Modified Transaction Reduction, MTR-FMA

## 1. Introduction

Data Mining refers to extracting or mining knowledge from large amounts of data. In 1993, Agarwal, Imielinski, and Swami introduced a class of regularities, association rules and gave an algorithm for finding such rules [3]. The typical example for association rule mining is Market Basket analysis. The Bar code technology has made it possible for retail organizations to collect and store massive amounts of sales data. A record in it typically consists of itemsets bought in each transaction in each row. Finding association rules for such basket data will improve the

sales and cross marketing. Other applications include store layout, add on sales and customer segmentation.

In general, the work of association rule can be decomposed into two phases:

(1) Frequent itemsets generation - find out all itemsets that sufficiently exceed the minsup, and (2) Rules construction - from the frequent itemsets, generate all association rules having confidence higher than the minconf. Since the second phase is straightforward and less expensive, This paper concentrate only on the first phase for finding all frequent itemsets.

This paper has proposed a new algorithm called MTR-FMA (Modified Transaction Reduction based Frequent Itemset Mining algorithm) to efficiently mine frequent itemsets. This paper has also proved that the proposed algorithm MTR-FMA has an edge over existing algorithms like Apriori, AprioriTID, HEA (High Efficient AprioriTid) and FP-Growth in terms of transaction reduction and speed. The rest of the paper is organized as follows. A review of the previous works regarding AprioriTid and HEA are given in the next section. Then this paper will describe the proposed theorem with proof and the proposed algorithm called MTR-FMA for finding frequent item sets. Empirical evaluations and results of the proposed algorithm (MTR-FMA) over other algorithms using FIMI's dataset (retail.dat) and other synthetic data sets are described in the next section. Conclusions are stated in the last section.

## 2. Previous Works

### 2.1. Apriori Algorithm

The *Apriori* [3-6] algorithm is a level wise search algorithm for mining frequent itemsets for boolean association rules. The large itemsets are computed through iterations. In each iteration, the database is scanned once and all large itemsets of same size are computed. The large itemsets are computed in the

ascending order of their sizes. In the first iteration, the size 1- large itemsets are computed by scanning the database once. Subsequently, in the  $k$ th iteration ( $k > 1$ ), a set of candidate sets  $C_k$  is created by applying the candidate set generating function Apriori-gen on  $L_{k-1}$ , where  $L_{k-1}$  is the set of all large  $(k-1)$  - itemsets found in the iteration  $k-1$ . Apriori-gen generates only those  $k$ -itemsets whose every  $(k-1)$ -itemsets subset is in  $L_{k-1}$ . The support counts of the candidate itemsets in  $C_k$  are then computed by scanning the database once and the size- $k$  large itemsets are extracted from the candidates. The drawback of Apriori is that when the cardinality of the longest frequent itemsets is  $k$ , Apriori needs  $k$  passes of database scans. In addition, this algorithm is computation intensive in generating the candidate itemsets and computing the support values, especially for application with very low support threshold and / or vast amount of items. In this algorithm, if the number of first itemsets element is  $k$ , DB will be scanned  $k$  times at least. So it will have low efficiency. It is a base point to reduce the number of itemset for improving the Apriori algorithm.

## 2.2. AprioriTID Algorithm

The *AprioriTID* [2] is another variant of Apriori which reduces the time needed for the frequency counting procedure by replacing every transaction in the database by the set of candidate sets that occurs in that transaction. This is done repeatedly at every iteration  $k$ . The adapted transaction database is denoted by  $\bar{C}_k$ . Although the AprioriTID algorithm is much faster in later iterations, it performs much slower than Apriori in early iterations. This is mainly due to the additional overhead that is created when  $\bar{C}_k$  does not fit into main memory and has to be written to disk [7-10]. If a transaction does not contain any candidate  $k$ -sets, then  $\bar{C}_k$  will not have an entry for this transaction. Hence, the number of entries in  $\bar{C}_k$  may be smaller than the number of transactions in the database, especially at later iterations of the algorithm. The AprioriTid algorithm also uses the Apriori-gen function to determine the candidate itemsets before the pass begins.

The transaction in  $\bar{C}_k$  will be of the form  $\langle TID, \{X_k\} \rangle$ , where each  $X_k$  is a potentially large  $k$ -itemset present in the transaction with identifier TID. The member of  $\bar{C}_k$  corresponding to the transaction  $t$  is defined as

$$\bar{C}_k = \langle t.TID, \{c \in C_k \mid c \text{ contained } t\} \rangle$$

The drawbacks of AprioriTID are that the modified data structure can be much larger than the initial database and only faster in the later stage of the passes.

## 2.3. High Efficient AprioriTid Algorithm

*HEA* [1] is the improved algorithm of AprioriTID.

Here, the member of  $\bar{C}_k$  corresponding to the transaction  $t$  is defined as

$$\bar{C}_k = \langle t.TID, \{c \in C_k \mid c \text{ contained } t, c.support \geq minsup\} \rangle$$

This considerably decreases the size of stored data in  $\bar{C}_k$  [1]. Moreover, searching data scale is reduced when computing support of itemsets in  $C_k$ . At the same time, it reduces much time of I/O and running. The process is described as follows: (a). Confirming itemset  $c$  in  $C_k$ , then the transaction set  $T_c$  presented with TID including the item of  $c$ , is computed. (b). The number of entries computed in  $T_c$ , defined as the  $|T_c|$ , which is support of itemset  $c$ . (c). If  $|T_c| \geq minsup$ ,  $c$  is included into  $L_k$  and  $\bar{C}_k$ , otherwise deleting  $c$ . Through the above process, with the computed support in  $C_k$ , void itemset can be directly deleted from  $\bar{C}_k$  or added to  $\bar{C}_k$  and  $L_k$ . After analyzing this algorithm, this paper found that HEA can be further improved by reducing unwanted transactions and itemsets which is explained in next section through the proposed new algorithm MTR-FMA.

## 3. Proposed MTR-FMA Algorithm

MTR-FMA-Modified Transaction Reduction based Frequent Itemset Mining algorithm in Figure 1 is an improvement algorithm of AprioriTid and HEA whose idea is based on the theorem described in next sub section. Here relationship of transaction  $t$  with the entry in  $\bar{C}_k$  is defined as

$$\bar{C}_k = \langle t.TID, \{c \in C_k \mid c \text{ contained } t, c.support \geq minsup, T_{items} > k, t.no-of \text{ combinations} > 1\} \rangle$$

Each member of the set  $\bar{C}_k$  will be of the form  $\langle TID, \{X_k\} \rangle$  where each  $X_k$  is a potentially large  $k$ -itemset present in the transaction with identifier TID.

### 3.1. Theorem and Proof

**Theorem:** If  $c \in C_{k-1}$  and  $c.support < minsup, T_{items} \leq k, m = 1$ , then  $c$  is useless in  $\bar{C}_{k-1}$  where  $T_{items}$  is total itemcount in each transaction and  $m$  is the no. of combinations.

**Proof: 1. [For  $T_{\text{items}} \leq k$ ]**

From the Apriori-gen algorithm, it is known that  $C_k$  is formed from  $L_{k-1}$ . Consider a transaction  $T_i = \{I_1, I_2, I_3, \dots, I_m\}$ . The candidate generation would lineup from  $C_1 = \langle \{I_1\}, \{I_2\}, \{I_3\}, \dots, \{I_m\} \rangle$ ;  $C_2 = \langle \{I_1, I_2\}, \{I_1, I_3\}, \dots, \{I_1, I_m\}, \{I_2, I_3\}, \dots, \{I_{m-1}, I_m\} \rangle$ ;

$C_3 = \langle \{I_1, I_2, I_3\}, \{I_1, I_2, I_4\}, \dots, \{I_2, I_3, I_4\}, \dots, \{I_{m-2}, I_{m-1}, I_m\} \rangle$ ;

and it will go up to  $C_m = \langle \{I_1, I_2, I_3, \dots, I_m\} \rangle$ . So  $\{I_1, I_2, I_3, \dots, I_m\}$  will not appear in  $C_{m+1}$ . That is to say that this algorithm need not compute the  $C_{m+1}$  in  $T_i$ .

Hence,  $\forall T_i \in \bar{C}_{m+1}$ ,  $T_i$  need not be taken into account. So,  $T_i$  can be rejected in  $\bar{C}_{m+1}$ . Hence the proof.

**2. [For  $m = 1$ , where  $m$  is no. of combinations]**

Now consider the same transaction  $T_i = \{I_1, I_2, I_3, \dots, I_m\}$ . In general the candidate generation would have  $\langle \{I_1\}, \{I_2\}, \dots, \{I_1, I_2\}, \dots, \{I_1, I_m\}, \dots, \{I_2, I_m\}, \dots, \{I_1, I_2, \dots, I_m\} \rangle$

If all the itemsets in  $C_k$  except one is rejected during  $L_{m-1}$  due to above hypothesis (say  $A_b$  remains) then  $\bar{C}_{k+1}$  will contain only  $\langle \{A_b\} \rangle$ . So  $\langle \{A_b\} \rangle$  alone will not able to form a candidate in  $C_{k+1}$ . Hence in Such  $\forall T_i \in \bar{C}_{k+1}$ ,  $T_i$  can be rejected in  $\bar{C}_{k+1}$ . Hence the proof.

**Figure 1. MTR-FMA Algorithm**

- 18) end
- 19) end
- 20) end
- 21) end
- 22)  $\text{Ans} = \bigcup_k L_k$ ;

**3.2. MTR-FMA Algorithm Details**

Let consider the following example in Table 1 to show how MTR-FMA works. The algorithm starts by scanning the database to generate 1- frequent itemset  $L_1$ .  $\bar{C}_1$  is generated with itemsets that are present in  $L_1$ . For  $k = 1$ ,  $\bar{C}_1$  corresponds to the database  $D$  although conceptually each item  $I$  is replaced by the itemset  $\{i\}$ . For  $k > 1$ ,  $C_k$  is generated by the apriori-gen algorithm. Confirming itemset  $c$  in  $C_k$ , then the transaction set  $T_c$  presented with TID, including itemset  $c$  is computed. The number of entries is computed in  $T_c$  defined as  $|T_c|$  which is support of itemset  $c$ . If  $|T_c| \geq \text{minsup}$ ,  $c$  is included into  $L_k$  and  $\bar{C}_k$ , otherwise deleting  $c$ .

If the total itemcount of a transaction  $T_{\text{items}} \leq k$ , then that transaction  $t$  is deleted from  $\bar{C}_{k-1}$ . Also, if  $|\bar{C}_k| = 1$ , then it is also not included in  $\bar{C}_k$  and that transaction is deleted from  $\bar{C}_{k-1}$ . Thus the entries in  $\bar{C}_k$  may be smaller than the transaction in database especially for large values of  $k$ . The corresponding  $L_k$  and  $\bar{C}_k$  are shown in Tables 2, 3, 4, 5, 6 and 7.

#### 4. Result and Discussion

The proposed algorithm have tested various datasets like FIMI data set [16] and synthetic dataset and compared them with Apriori, and FP growth whose implementations were used from [17] and [18]. Since no public implementation of AprioriTID and HEA is available this paper used the own implementations to compare with MTR-FMA algorithm. Using a sample Database of 1020 transactions with 9 items this paper tested MTR-FMA with AprioriTID and HEA. With the minimum support as 20%, the results are as shown in the Table 8 [11 – 15] and figure 2.

**Table 8. Contrast of Record numbers**

Records	AprioriTID	HEA	MTR-FMA
$\bar{C}_1$	2720	2720	2584
$\bar{C}_2$	2584	1524	1088
$\bar{C}_3$	340	204	0
$\bar{C}_4$	0	0	0

**Figure 2. Comparison of Apriori , HEA and MTR-FMA**

From the Table 8 it is observed that number of records is averagely reduced to 35 % when compared to AprioriTID and 18 % when compared to HEA. Hence the execution will also be considerably reduced. The graph in the Figure 2 is plotted with the help of the Table 8.

**Figure 3.Execution times of Apriori and MTR-FMA**

This paper also compared proposed MTR-FMA algorithm with Apriori using the synthetic dataset whose transaction varies from 1000 to 500000 and with a constant minimum support of 3% in Figure 3.

This paper used the dataset retail.dat from FIMI site [16] with 17822 transactions and 9999 items. The experiment is performed on HP dx 2280 with processor clock cycle 2.0 GHz, 512 MB of main memory. The Figure 4 shows the result up to the minimum support of 8%.

**Figure 4.Execution Times of FP- Growth and MTR-FMA on retail.dat**

## 5. Conclusion

This paper proposed a novel data structure, an MTR-FMA algorithm to mine frequent itemsets. The advantages of MTR-FMA over existing algorithms include (1) Interactive mining with different supports (2) Faster execution time (3) Infrequently used item are not stored and hence improves the size of the query data. This paper has implemented MTR-FMA algorithm and compared proposed approach with other known algorithms. From the experimental results, MTR-FMA is shown to be more efficient and scalable to large amount of transactions and out perform other algorithms.

### Abstract

*The aim of this study is to investigate the effects of white matter (WM) and skull inhomogeneous anisotropic tissue conductivities on human head modeling. The inhomogeneity of WM and skull is included using fractional anisotropy (FA) method and the anisotropy is included according to Volume constraint in the head model construction. A five-layered spherical head model implemented using finite element method (FEM) is used as a volume conductor with a known current source to measure the electroencephalogram (EEG) on the head surface. Statistical measurement techniques are applied to analyze the EEGs obtained from inhomogeneous anisotropic head models and a homogeneous isotropic model. This study finds that the effects of WM and skull inhomogeneous anisotropy on EEG are significant.*

**Keywords:** Fractional anisotropy, finite element method, inhomogeneous anisotropic conductivity, EEG, and forward problem

### 1. Introduction

The electroencephalogram (EEG) is the measurement of the electric potential differences on scalp caused by neural activity inside the brain. The estimation of these electrical potential differences is known as forward problem [1]. The neural activity is modeled by a distribution of current sources and its implementation technique is known as inverse problem or source localization [1][2][3]. The inverse problem, solved by iterative solving forward problem, is a

valuable tool in pre-surgical evaluation of patients suffering from epilepsy and other neurological disorders [3]. Therefore, the importance of the solution of forward problem is significant. The accuracy of this solution depends on assigning the appropriate conductivity to each tissue which is still a challenging research because of its complicated inhomogeneous and anisotropic properties [1]. However, many head model implementations neglect the inhomogeneous anisotropic conductivities inherent to brain tissues, such as the white matter (WM) and skull. WM has the mean resistivity (reciprocal of conductivity) of 700  $\Omega\text{cm}$ , with 350  $\Omega\text{cm}$  and 1050  $\Omega\text{cm}$  values for lower and upper bounds, respectively, and having the variation of  $\pm 50\%$  [4]. Skull resistivity varies between 1360  $\Omega\text{cm}$  and 21400  $\Omega\text{cm}$ , with a mean of 7560  $\Omega\text{cm}$  and a standard deviation of 4230  $\Omega\text{cm}$  [1]. In WM, the conductivity ratio between longitudinal and transversal directions is 10:1 while it is 1:10 between radial and tangential directions for the skull layer. However, there are no reliable algorithms to measure this ratio non-invasively. Baser *et al* [5] proposed the relation between the electrical conductivity tensors and effective water diffusion tensors measured by diffusion tensor magnetic resonance imaging (DT-MRI). The authors proposed that the tissue conductivity tensors share the same eigen vectors with the effective diffusion tensor. In DT-MRI, the conductivity tensors are not derived directly but inferred from diffusion tensors which describe the movement of water molecules and electrically charged particles (ions) [6]. Later on, Tuch *et al* [7] applied a differential effective medium approach and derived a linear relationship among the eigen values of DT-MRI and the conductivity tensors. However, the eigen values are not equal in the same tissue layer and vary according to

direction. These make the tissue layer as inhomogeneous and anisotropy. The anisotropy depends on the volume of tissues and directions of tissue fibers, which are affected by some conductivity tensor reconstruction obstacles. To overcome these obstacles, C. H. Wolters [2] proposed Volume constraint which restricts the geometric mean with the conductivity tensor.

C. H. Wolters [2] investigated the effects of anisotropic conductivities on EEG for WM and skull tissue layers. The author applied transversal: longitudinal conductivity ratio with the values of 1:1 (isotropic), 1:2, 1:5, and 1:10 for WM tissues. He also applied the same values for radial: tangential conductivity ratio for skull tissues. By applying these conductivity ratios, he found some effects of anisotropy on EEG for Volume constrained WM and skull tissues. Gullmar *et al* [6] also used the same anisotropy ratios for Volume constrained WM on a rabbit head model and found the same results like Wolters. However, they neglected the inhomogeneity of WM anisotropic properties. Li *et al* [8] proposed inhomogeneous anisotropy properties using fractional anisotropy (FA) by step and linear functions for Volume constrained WM. Hallez *et al* [3] implemented five-layered spherical head model to investigate the Volume constrained WM and skull anisotropic tissue conductivities for source localization. They found that neglecting the skull anisotropy resulted on an average of 13.73 mm with a maximum of 24.51 mm dipole localization errors. Most recently, Hallez *et al* [9] implemented a realistic head model incorporating Volume constrained anisotropic WM conductivity and found that WM anisotropy plays a vital role in EEG source localization. Anwender *et al* [10] investigated the influence of WM and skull anisotropic conductivities and found some significant effects on source localization. In our previous paper [11], we investigated the influence of WM inhomogeneous anisotropic conductivity on EEG using conductivity ratio approximation (CRA) and statistical conductivity approximation (SCA) techniques. We found that there are strong effects of WM inhomogeneous anisotropic conductivity on the scalp EEG. In the paper, we didn't consider skull tissue inhomogeneity and anisotropy. From an extensive literature review, we realize, most of the researchers investigate effects of tissue anisotropy on EEG, however, they didn't mention about the effects of tissue inhomogeneity.

The goal of this study is to evaluate the effects of WM and skull inhomogeneous anisotropic tissue conductivities on the scalp EEG by means of finite element method (FEM). We classify the inhomogeneity

by the discrepancy of the ratio longitudinal over transverse eigen values ( $R_{lt}$ ). We construct a spherical head model by means of varying FA and Volume constraint to simulate the head volume conductor with inhomogeneous anisotropic conductivity settings. We model a current dipole inside gray matter (GM) to simulate brain electrical activity. And we assess the effects of WM and skull inhomogeneous anisotropic tissue conductivities on the scalp EEG by comparing the potential differences generated by the inhomogeneous anisotropic and homogeneous isotropic head models.

The organization of this paper is as follows. Introduction section describes background and the importance of this study with literature review in Section I. Section II illustrates the methods of fractional anisotropy, head model construction, homogeneous and inhomogeneous anisotropic conductivity allocation, forward solution using FEM and similarity measurement techniques. Simulation setup is described in Section III. Experimental results are presented in Section IV. Finally, Section V concludes our research findings.

## 2. Methods

### 2.1 Fractional anisotropy (FA)

FA is a technique to measure the extent of the anisotropy property for each voxel (element). Let us suppose that  $\lambda_1, \lambda_2$ , and  $\lambda_3$  ( $\lambda_1 \geq \lambda_2 \geq \lambda_3$ ) are the three eigen values of a diffusion tensor matrix and  $\lambda$  is the average eigen value. Then FA is defined as [12]:

$$FA = \frac{\sqrt{3}}{\sqrt{2}} \frac{\sqrt{(\lambda_1 - \lambda)^2 + (\lambda_2 - \lambda)^2 + (\lambda_3 - \lambda)^2}}{\sqrt{\lambda_1^2 + \lambda_2^2 + \lambda_3^2}} \quad \dots \quad (1)$$

The FA is in the range of 0 to 1 [12]. A fully anisotropic tissue has a factor FA=1, and an isotropic tissue has a factor FA=0.

### 2.2 Head model

Anatomically, human head consists scalp, skull, cerebrospinal fluid (CSF), gray matter (GM) and WM. Based on this anatomical concept and different literature [2][3], we consider a five-layered spherical head model. We segment the five-layered sphere and perform mesh generation to produce tetrahedral elements for FEM model. The conductivity tensor in WM or skull of a multi-sphered head model is a diagonal matrix [3]. We assume that the conductivity

tensors share the same eigen vectors with the effective diffusion tensors measured by (DT-MRI) [2][5][6][8]. Then, we consider the conductivity tensor for a WM finite element as [2] [6]:

$$\sigma_{WM} = S \begin{pmatrix} \sigma_{long} & 0 & 0 \\ 0 & \sigma_{trans} & 0 \\ 0 & 0 & \sigma_{trans} \end{pmatrix} S^{-1} \quad \dots\dots\dots(2)$$

where  $S$  is orthogonal matrix of unit length eigenvectors of the measured diffusion tensor at the barycentre of the WM finite element,  $\sigma_{long}$  is the parallel (longitudinal) eigen value and  $\sigma_{trans}$  is the perpendicular (transverse) eigen value where  $\sigma_{long} \geq \sigma_{trans}$ . We also consider the conductivity tensor for a skull finite element as [2] [13]:

$$\sigma_{Skull} = S \begin{pmatrix} \sigma_{tan} & 0 & 0 \\ 0 & \sigma_{tan} & 0 \\ 0 & 0 & \sigma_{rad} \end{pmatrix} S^{-1} \quad \dots\dots\dots(3)$$

where  $\sigma_{tan}$  is the tangential (parallel) eigen value and  $\sigma_{rad}$  is the radial (perpendicular) eigen value where  $\sigma_{rad} \geq \sigma_{tan}$ . Assigning the conductivity, we apply FEM for a known current source to solve forward problem.

### 2.3 Homogeneous anisotropic conductivity allocation

Modeling of the conductivity tensor eigen values is a difficult task involving layer's boundary segmentation, inhomogeneous resistivity, tissue type, and fibre orientation. Therefore, we use isotropic conductivity to simulate the anisotropic conductivity using  $\sigma_{trans}$ :  $\sigma_{long}$  ratios according to literature [2][13]. Then, we calculate the longitudinal and transversal eigen values based on Volume constraint.

#### 2.3.1 Volume constraint

The Volume constraint remains constant of the geometric mean and the volume of the conductivity tensor. The volume constraint is defined as [2][6],

$$\frac{4}{3}\pi\sigma_{long}(\sigma_{trans})^2 = \frac{4}{3}\pi\sigma_{iso}^3 \quad \dots\dots\dots(4)$$

where  $\sigma_{iso}$  is isotropic conductivity.

### 2.4 Inhomogeneous anisotropic conductivity allocation

For the homogeneous anisotropic model, all elements share the same conductivity ratio ( $R_{lt}$ ) between longitudinal and transversal conductivities. However,  $R_{lt}$  varies for inhomogeneous anisotropy.  $R_{lt}$  reflects the extent of anisotropy property as FA does, so we set  $R_{lt}$  as a variable of FA. We establish the relation between FA and  $R_{lt}$  by implementing eq(1). The results are shown in Figure 1. Though the values of FA lie between 0 and 1 [12], we found the values of FA ranging from 0 to 0.9. Considering Figure 1, we define  $R_{lt}$  using multi-steps FA function as presented in eq(5).

**Figure 1:** Conductivity ratio Vs fractional anisotropy (FA).

$$R_{lt} = \begin{cases} 10, & FA > 0.8 \\ 6, & FA > 0.7 \\ 4, & FA > 0.4 \\ 2, & otherwise \end{cases} \quad \dots\dots\dots(5)$$

Using  $R_{lt}$ , we generate longitudinal and transversal inhomogeneous conductivities for Volume constrained WM and skull tissue layers.

### 2.5 Forward solutions using finite element method

The electric potential field generated by a current source in a head is described by the Poission's equation as [2][14]:

$$\nabla \cdot \sigma (\nabla \phi) = -I_{sv} \text{ in } \Omega \quad \dots\dots\dots(6)$$

where  $\sigma$  is conductivity tensor,  $\phi$  is electric potential field, and  $I_{sv}$  is internal current source per unit volume due to current dipoles placed within the brain.

The FEM provides a convenient way to assign the conductivity tensor for a small region. Using Galerkin approximation [15] in the framework of FEM and boundary conditions, the solution of eq(6) can be written in a matrix form as [14]:

$$[K]\{\phi\} = \{F\} \quad \dots\dots\dots(7)$$

where K is the stiffness matrix [15],  $\phi$  is the vector of nodal electric potentials, and F is the force vector including the boundary conditions and the current sources. The matrix K contains the head geometry and conductivity information for the forward problem and has the properties being sparse, symmetric, and positive definite. As K is symmetric and positive definite, we use Choleski preconditioner [16] to accelerate the rate of convergence of iterative solvers. We apply the preconditioned conjugate method (pcg) to iteratively solve the linear equation stated in eq(7).

## 2.6 Similarity measurements

We calculate the electric potential differences produced by a single dipole measured using 64 electrodes positioned at different places on a head surface. The forward computed data obtained from the homogeneous isotropic and inhomogeneous anisotropic model are analyzed by calculating relative difference measure (RDM) for the topology error (minimum error: RDM=0) and magnitude difference (MAG) values (minimum error: MAG=1) of the scalp electric potentials. The RDM and MAG values are calculated as follows [2][6][11][13]

$$RDM = \sqrt{\sum_{i=1}^n \left( \frac{ref_i}{\sqrt{\sum_{i=1}^n ref_i}} - \frac{meas_i}{\sqrt{\sum_{i=1}^n meas_i}} \right)^2} \quad \dots\dots\dots (8)$$

$$MAG = \sqrt{\frac{\sum_{i=1}^n meas_i^2}{\sum_{i=1}^n ref_i^2}} \quad \dots\dots\dots (9)$$

where the values obtained from the homogeneous isotropic model are interpreted as reference (ref) and the values obtained from the inhomogeneous anisotropic model are defined as measurement (meas) [11]. The index i represents the number of electrodes.

## 3. Simulation setup

First, we implement a five-layered spherical head model according to the radii of Table 1 (row 2) using Matlab [16]. We segment the head model into surfaces,

perform tessellation for mesh generation and then, apply a constrained Delaunay tessellation [16] using Tetgen® package provided by BrainStorm [17]. The details of head model construction are described in our previous paper [11]. The mesh generation produces 112 K tetrahedral elements from 19 K nodes as shown in Table 1 (last row). We use these tetrahedral elements for FEM modeling. For homogeneous isotropic model, we assign the mean conductivity to each tissue layer (row 3 in Table 1). However, we assign the conductivities produced by implementing multi-steps FA function (described in eq(5)) to individual elements of WM and skull having other tissue layers isotropic for the inhomogeneous anisotropic head model. We also implement multi-steps FA technique stated in eq(5) using Matlab coded software. After assigning conductivities, we perform EEG forward computation using the adopted FEM tool provided by BrainStorm [17] for a fixed current dipole inside the GM. We assume that the dipole is located in axial, coronal and sagittal planes with the azimuth angle of  $\pi/4$  and elevation angle of  $\pi/5$ , and having the unit magnitude. A dipole can be decomposed into three orthogonal dipoles along the main axes [9]. For each dipole location, we consider three orthogonal orientations: along left-right (X orientation), along back-front (Y orientation) and along bottom-top (Z orientation). Figure 2 shows the logical head model with different tissue compartments and dipole orientations. We measure the EEGs by putting 64 electrodes on head surface. Finally, we apply RDM and MAG techniques to analyze the results. We perform this computation using an Intel® dual core 2.0 Ghz processor with 2GB RAM. It takes approximately an hour to execute each computation.

**Table1:** Head model parameters

	Scalp	Skull	CSF	GM	WM
Radii (cm)	9.2	8.4	8.0	7.6	5.0
Means (S/m)	0.33	0.0042	1.0	0.14	0.33
Elements	19397	24563	21379	20674	26841

**Figure 2:** Head model construction showing different head compartments and dipole (source) location.

#### 4. Experimental results

To study the influences of inhomogeneous anisotropic WM and skull tissue conductivities, we carry out four independent experiments.

1. We measure EEG from the reference model.
2. We measure EEG from the measurement model where inhomogeneous anisotropic conductivity is assigned to WM while other tissue layers are homogeneous and isotropic.
3. We measure EEG by assigning inhomogeneous anisotropic conductivity to skull while other layers are homogeneous and isotropic.
4. We measure EEG by assigning the WM and skull inhomogeneous anisotropic conductivities considering other layers homogeneous and isotropic.

Table 2 shows the RDM and MAG errors caused by the inhomogeneous anisotropic WM conductivity generated using the Volume constraint. We found that the RDM (1.59% ~ 18.87%) and MAG (0.95 ~ 1.12) values are far from their ideal values, 0 and 1, respectively. These results indicate that WM inhomogeneous anisotropy affects the scalp EEG strongly. The longitudinal inhomogeneous conductivity produces fewer errors than those of transversal conductivity. We found that the obtained results for WM inhomogeneous anisotropic models are consistent with those published from different literature for WM anisotropic model neglecting inhomogeneity [2][10][13]. We conclude that WM inhomogeneous anisotropic conductivity has significant effects on EEG and WM transversal inhomogeneous conductivity has

more effects on EEG than longitudinal inhomogeneous conductivity.

**Table 2:** RDM and MAG values generated by inhomogeneous anisotropic WM conductivity

Conductivity	Dipole orientation	RDM	MAG
Longitudinal	X	4.04%	1.02
	Y	5.91%	1.12
	Z	4.21%	1.03
Transversal	X	18.87%	1.07
	Y	1.59%	0.97
	Z	7.3%	0.95

Table 3 shows the topological and magnitude difference errors due to anisotropic inhomogeneous skull conductivity. Note that the RDM values range from 4.37% to 17.19% and MAG values are between 0.84 and 1.11. It demonstrates that the effects of inhomogeneous anisotropic skull tissue conductivity on EEG are significant. Radial inhomogeneous conductivity results more errors than tangential inhomogeneous conductivity. These results are also consistent with different literature where inhomogeneity was absent [2] [13].

**Table 3:** RDM and MAG values generated by inhomogeneous anisotropic skull conductivity

Conductivity	Dipole orientation	RDM	MAG
Radial	X	17.19%	0.89
	Y	7.93%	0.84
	Z	7.17%	0.96
Tangential	X	8.18%	1.09
	Y	4.37%	1.11
	Z	4.64%	1.03

Table 4 shows the RDM and MAG errors generated by combining the inhomogeneous anisotropic WM and skull tissue conductivities. The longitudinal conductivity produces 1.23% to 5.9% RDM and 0.95 to 1.01 MAG errors while the transverse conductivity produces 7.03% to 20.39% RDM and 1.04 to 1.09 MAG errors. It clearly demonstrates that the combination of inhomogeneous anisotropic WM and skull conductivities have significant effects on EEG. By contrasting Table 2 and Table 4, we found the similar results, namely, EEGs are more affected by transversal conductivity than longitudinal conductivity.

**Table 4:** RDM and MAG values generated by inhomogeneous anisotropic WM and skull conductivities.

Conductivity	Dipole orientation	RDM	MAG
Longitudinal	X	5.9%	0.95
	Y	1.23%	1.01
	Z	4.48%	0.99
Transversal	X	20.39%	1.09
	Y	8.96%	1.08
	Z	7.03%	1.04

## 5. Conclusion

In the present study, we have investigated the influences of WM and skull inhomogeneous anisotropic tissue conductivities on EEG forward computing using a spherical head model by means of Volume constraint. We have implemented the multi-steps FA to generate Volume constrained anisotropic conductivity and various anisotropy ratios to generate inhomogeneity. From our experiment results, we find that WM inhomogeneous anisotropic tissue conductivity results maximum 18.87% RDM and 1.12 MAG errors and skull inhomogeneous anisotropic tissue conductivity results maximum 17.17% RDM and 1.11 MAG errors. Combining WM and skull inhomogeneous anisotropic conductivities result maximum 20.39% RDM and 1.09 MAG errors. This study also finds that the WM inhomogeneous transversal and skull inhomogeneous radial conductivities have more effect on EEG.

## Abstract

*Principal component analysis (PCA) is a widely used technique in optical emission spectroscopy (OES) sensor data analysis for the low dimension representation of high dimensional datasets. While PCA produces a linear combination of all the variables in each loading, sparse principal component analysis (SPCA) focuses on using a subset of variables in each loading. Therefore, SPCA can be used as a key variable selection technique. This paper shows that, using SPCA to analyze 2046 variable OES data sets, the number of selected variables can be traded off against variance explained to identifying a subset of key wavelengths, with an acceptable level of variance explained. SPCA-related issues such as selection of the tuning parameter and the grouping effect are discussed.*

## 1. Introduction

Principal component analysis (PCA) is widely known as a dimension reduction technique. Using PCA, a high dimensional data set can be decomposed into the sum of a small number of principal components (PCs). Given an  $n \times m$  data matrix  $\mathbf{X}$ ,  $n$  being the number of observations and  $m$  being the number of variables, there is [3]

$$\mathbf{X} = \mathbf{TP}^T \quad (\mathbf{T} \in \mathbb{R}^{n \times p}, \mathbf{P} \in \mathbb{R}^{m \times p}), \quad (1)$$

where  $\mathbf{P}^T \mathbf{P} = \mathbf{I}_p$ .  $\mathbf{T}$  and  $\mathbf{P}$  are referred to as score and loading matrices, respectively. Since the loading of each PC is generally a linear combination of *all* the original variables, PCA cannot be used directly for variable selection.

Research on obtaining sparse components has been conducted for over two decades. The earliest method, proposed in 1958, is referred to as varimax [7]. Using varimax rotation, a number of the coefficients of the loading vectors can be adjusted to have greater values than the remaining coefficients. Such adjustment can help in the selection of key

variables, but it is hard to quantify the distinction between small and large coefficients.

Jeffers [5] proposed a straight-forward method for achieving PCA sparsity. For each loading, any coefficients that are less than 70% of the greatest one are set to zero, regardless of their sign. This method can lead to a selection deficiency in two cases, one where the variables have small coefficients and the other where the variables have high mutual correlations [1].

In [10], the 'simple principal components' is proposed. This focuses on restricting the coefficients of the loadings to have integer values, such as -1, 0 and 1, to help simplify variable selection.

The first true algorithmic method for achieving sparse loadings was proposed in 2003 by Jolliffe *et al.* [6] and is known as SCoTLASS (Simplified Component Technique for Least Absolute Shrinkage and Selection). This employs a penalty term referred to as the Least Absolute Shrinkage and Selection Operator (LASSO) [9] to force loadings to be sparse. Nevertheless, it is not practical due to the relatively high computational cost [12].

A recently proposed algorithm, known as semidefinite programming, is described in [2]. Using this method, the normal loadings are constrained by a cardinality condition, that is, a limit on the number of the nonzero elements in each loading. By relaxing this constraint, the problem is converted into a convex optimization problem and hence, can use semidefinite programming as a solution. The generated PCs are shown to be able to explain larger variance than competing algorithms, but the computational cost is high.

In 2004 Zou *et al.* [12] proposed an alternative approach to solving the SPCA problem, which they referred to as elastic net for SPCA (EN-SPCA). EN-SPCA can be implemented in two forms. One is similar to an approach used to solving the LASSO problem, details of which will be provided in the next section, and the other is the so called soft thresholding algorithm, designed for handling large data sets (thousands of variables). Both EN-SPCA

implementations are computational alternatives to semidefinite programming, but the later implementation has the key advantage that it can scale to much larger problems than the semidefinite programming algorithm.

This paper explores the application of SPCA to key variable selection in optical emission spectroscopy (OES). OES is an optical emission detection technique, used for detecting the optical intensity of the chemicals in a plasma as a function of wavelength and time. Because the wavelengths are the ‘fingerprints’ of the corresponding chemical species, OES data can be used to trace the chemical reactions in a plasma chamber. Consequently, OES is increasingly being used by semiconductor manufacturing to assist with the monitoring and control of plasma etch processes. However, in practice direct use of OES spectra is limited due to the difficulties with handling and interpreting the large number of variables that are associated with such spectra.

The remainder of the paper is organized as follows. Section 2 gives a theoretical description of SPCA. Section 3 describes the methods used to estimate SPCA model accuracy. Section 4 shows experimental results on the application of SPCA to Optical Emission Spectroscopy (OES) data from a semiconductor manufacturing plasma etch process. Finally, the conclusions are presented in Section 5.

## 2 Theoretical Framework and Numerical Solution

EN-SPCA employs a penalised regression estimator to solve the SPCA problem. This exploits the fact that PCA can be formulated as a least squares regression problem, thereby facilitating the inclusion of the LASSO penalty, which is known from regression theory to yield sparse solutions. The theory of LASSO and EN-SPCA are quite involved, hence only a brief overview will be provided here. For a more complete development of the algorithms see [9],[12] and [11].

### 2.1 PCA as a LS problem

Given a data matrix  $\mathbf{X}$  (as defined in Eq. (1)) and defining its transpose as the matrix  $\mathbf{Z} = \mathbf{X}^T$ , the LS estimation of the PCA loading matrix  $\mathbf{P} \in \mathbb{R}^{m \times p}$  can be expressed as

$$(\hat{\mathbf{A}}, \hat{\mathbf{P}}) = \arg \min_{\mathbf{A}, \mathbf{P}} \left\{ \sum_{i=1}^n \|\mathbf{z}_i - \mathbf{A}\mathbf{P}^T \mathbf{z}_i\|_2^2 \right\}, \quad (2)$$

$$\text{s.t. } \mathbf{A}^T \mathbf{A} = \mathbf{I},$$

Where  $\mathbf{z}_i$  are the columns of  $\mathbf{Z}$ . The constraint on matrix  $\mathbf{A}$  ensures that the orthogonality of  $\mathbf{P}$  is guaranteed. While theoretically the LS estimate is the best unbiased estimate of  $\mathbf{P}$  [9], in practice better mean square error performance can

be obtained by biasing the regression coefficients towards zero. This is typically achieved by adding either an  $L_1$  or an  $L_2$  norm penalty to the LS cost function. The  $L_2$  implementation, referred to as Ridge regression or regularisation, is frequently employed to address data ill-conditioning and singularity issues and benefits from a straightforward algebraic solution. In contrast, the  $L_1$  implementation has traditionally been avoided due to the associated computational issues, but in recent years it has been receiving increasing attention as a variable selection method, due to its tendency to yield sparse solutions. In this context it is referred to as LASSO [9].

### 2.2 Ridge Estimation

The Ridge estimate of  $\mathbf{A}$  and  $\mathbf{P}$  (denoted by  $\hat{\mathbf{A}}^R$  and  $\hat{\mathbf{P}}^R$ ) is expressed as

$$(\hat{\mathbf{A}}^R, \hat{\mathbf{P}}^R) = \arg \min_{\mathbf{A}, \mathbf{P}} \left\{ \sum_{i=1}^n \|\mathbf{z}_i - \mathbf{A}\mathbf{P}^T \mathbf{z}_i\|_2^2 + \gamma_2 \sum_{j=1}^p \|\mathbf{p}_j\|_2^2 \right\}, \quad \text{s.t. } \mathbf{A}^T \mathbf{A} = \mathbf{I}, \quad (3)$$

where  $\|\cdot\|_2$  represents the  $L_2$  norm,  $\gamma_2$  is the Ridge tuning parameter ( $\gamma_2 \geq 0$ ) and  $\mathbf{p}_j$  is the  $j$ th column vector of  $\mathbf{P}^R$ . The main benefit of employing the Ridge estimator is that it can handle data matrices in which the number of observations is less than the number of variables. Unlike regression this comes at no cost since the Ridge estimate of  $\mathbf{P}$  is simply a scaled version of the LS estimate and scaling does not affect the PCA decomposition.

### 2.3 LASSO Estimation

Mathematically, the LASSO estimate of  $\mathbf{A}$  and  $\mathbf{P}$ , denoted by  $\hat{\mathbf{A}}^L$  and  $\hat{\mathbf{P}}^L$  can be expressed as

$$(\hat{\mathbf{A}}^L, \hat{\mathbf{P}}^L) = \arg \min_{\mathbf{A}, \mathbf{P}} \left\{ \sum_{i=1}^n \|\mathbf{z}_i - \mathbf{A}\mathbf{P}^T \mathbf{z}_i\|_2^2 + \gamma_1 \sum_{j=1}^p \|\mathbf{p}_j\|_1 \right\}, \quad \text{s.t. } \mathbf{A}^T \mathbf{A} = \mathbf{I}, \quad (4)$$

or equivalently as

$$(\hat{\mathbf{A}}^L, \hat{\mathbf{P}}^L) = \arg \min_{\mathbf{A}, \mathbf{P}} \left\{ \sum_{i=1}^n \|\mathbf{z}_i - \mathbf{A}\mathbf{P}^T \mathbf{z}_i\|_2^2 \right\}, \quad (5)$$

$$\text{s.t. } \sum_{j=1}^p \|\mathbf{p}_j\|_1 \leq c_1 \text{ and } \mathbf{A}^T \mathbf{A} = \mathbf{I},$$

where  $\|\mathbf{p}_j\|_1 = \sum_{i=1}^m |b_{ij}|$ ,  $\gamma_1$  is the LASSO tuning parameter and  $c_1$  is a corresponding upper bound. For each  $\gamma_1$ ,

there exists a  $c_1$  that gives an equivalent constraint on the regression coefficients. The second formulation (Eq. (5)) has the attraction that it is in the form of a quadratic programming problem with linear inequality constraints making its solution mathematically tractable.

Although the Ridge and LASSO penalty both cause the regression coefficients to shrink towards zero a powerful feature of the LASSO is that it is more likely to drive coefficients to exactly zero, hence generating sparse solutions. This arises because of the distinctive shape of the LASSO penalty as illustrated in Fig.1 for the 2-D case. This shows the elliptical contours of a LS quadratic cost function with the feasible region corresponding to the  $L_1$  (LASSO) constraint indicated in grey. The  $L_1$  norm produces a diamond shaped region with corners aligned with the axes. In contrast, as illustrated in Fig.1(b), the  $L_2$  norm generates a circular boundary. Increasing the constraint penalty causes the feasible regions to shrink towards the origin. As this happens there is a tendency for the optimum elliptical contour to intersect the diamond region at the corners and since these are aligned with the axes this leads to sparse solutions. This is not the case with the circular boundary of the Ridge penalty.

## 2.4 Naive Elastic Net and Elastic Net

The drawback of LASSO is that if the number of observations ( $n$ ) is less than the number of the variables ( $m$ ), LASSO will at most choose  $n$  variables. In contrast, Ridge can extend the selection to  $m$  variables. However, Ridge cannot provide sparse solutions. The naive elastic net method was developed to address these problems. Mathematically, the naive elastic net estimate is defined as:

$$(\hat{\mathbf{A}}^N, \hat{\mathbf{P}}^N) = \arg \min_{\mathbf{A}, \mathbf{P}} \left\{ \sum_{i=1}^n |\mathbf{z}_i - \mathbf{A} \mathbf{P}^T \mathbf{z}_i|^2 + \gamma_2 \sum_{j=1}^k \|\mathbf{p}_j\|_2^2 + \sum_{j=1}^k \gamma_{1j} \|\mathbf{p}_j\|_1 \right\}, \text{ s.t. } \mathbf{A}^T \mathbf{A} = \mathbf{I}, \quad (6)$$

where  $\gamma_{1j}, j=1 \dots k$  are scalars used to individually penalize the loadings.

In [11], Zou and Hastie argue that naive elastic net estimation introduces a double bias, but that the reduction in estimation variance is no greater than with LASSO or Ridge estimation alone. To correct for this double shrinkage, the authors propose re-scaling the naive elastic net estimate by a factor  $(1 + \gamma_2)$ , giving the final elastic net SPCA estimate as:

$$(\hat{\mathbf{A}}^{\text{EN}}, \hat{\mathbf{P}}^{\text{EN}}) = (1 + \gamma_2)(\hat{\mathbf{A}}^N, \hat{\mathbf{P}}^N). \quad (7)$$

Because the constraint function  $\gamma_2 \|\mathbf{p}_j\|_2^2 + \gamma_{1j} \|\mathbf{p}_j\|_1$  is strictly convex, elastic net estimation retains a special property of least squares regression known as the grouping effect

[12]. This means that highly correlated variables will be assigned similar regression coefficients. While this property can be beneficial in many applications, as will be demonstrated later, it is not ideal for variable selection.

Figure 1. Solution for different estimators

## 2.5 Numerical Solution

Simple matrix transformations can be used to estimate the least squares or Ridge regression estimates of  $\mathbf{P}$ , but efficient computation of the LASSO estimate is much more challenging, and was only effectively addressed with the development of the least angle regression (LARS) algorithm in 2002 [8] (S refers to its close relation to LASSO and stagewise regression).

In LARS, all the coefficients are first set to zero and then revised successively until the least squares solution is reached. LARS-EN is a modified implementation of LARS designed to fit the elastic net framework [8]. In particular, it includes a special algorithm, called soft-thresholding, that is scalable to high dimensional data sets [12].

## 3 Estimating Model Accuracy

### 3.1 Variance Explained

SPCA employs a similar approach to PCA, known as adjusted variance [12], to measure the estimation accuracy. Like PCA, the sparse scores ( $\hat{\mathbf{T}}^S$ ) are used to calculate the variance as:

$$\hat{\mathbf{T}}^S = \mathbf{X} \hat{\mathbf{P}}^{\text{EN}}, \quad (8)$$

where  $\hat{\mathbf{P}}^{\text{EN}}$  denotes  $\hat{\mathbf{P}}^{\text{EN}}$  normalized to have unit length columns. However, unlike PCA,  $\hat{\mathbf{P}}^{\text{EN}}$  is not orthogonal, hence the variances explained by individual PCs are not independent of each other and hence not additive. To correct for this the sparse scores matrix must first be orthogonalised leading to the following variance estimation algorithm [4, 8].

- Orthogonalize  $\hat{\mathbf{t}}_j^S$  (the  $j$ th column vector of  $\hat{\mathbf{T}}^S$ ) by applying the recursion

$$\hat{\mathbf{t}}_j^{S*} = \hat{\mathbf{t}}_j^S - \hat{\mathbf{T}}_{(j-1)}^S [(\hat{\mathbf{T}}_{(j-1)}^S)^T (\hat{\mathbf{T}}_{(j-1)}^S)]^{-1} (\hat{\mathbf{T}}_{(j-1)}^S)^T \hat{\mathbf{t}}_j^S,$$

for  $j = 1, \dots, p$  ( $p$  is the number of sparse principal components), where  $\hat{\mathbf{T}}_{(j)}^S = [\hat{\mathbf{t}}_{(1)}^S, \dots, \hat{\mathbf{t}}_{(j)}^S]$ .

- Collect the orthogonalized vectors into a matrix  $\hat{\mathbf{T}}^{S*}$ , *i.e.*

$$\hat{\mathbf{T}}^{S*} = [\hat{\mathbf{t}}_1^{S*}, \dots, \hat{\mathbf{t}}_j^{S*}, \dots, \hat{\mathbf{t}}_p^{S*}]. \quad (9)$$

- Compute the variance explained ( $V_e$ ) by the  $p$  sparse components as

$$V_e = \text{trace}\{(\hat{\mathbf{T}}^{S*})^T \hat{\mathbf{T}}^{S*}\}. \quad (10)$$

The  $j$ th diagonal entry of  $(\hat{\mathbf{T}}^{S*})^T \hat{\mathbf{T}}^{S*}$  corresponds to the variance explained by the  $j$ th sparse PC.

### 3.2 SPMSE

When using sparse PCs to reconstruct a data set, many columns of the reconstructed data are in fact zero, because of the zero elements in the sparse loadings. Therefore, a fairer assessment of the accuracy of reconstruction is to only compare the reconstruction against the original data over the regions where the reconstruction exists. Here, a sparse mean square error measure is proposed, denoted SPMSE, where S stands for the sparse, P for percentage and MSE for mean square error. This is given by

$$SPMSE = \frac{\|\hat{\mathbf{X}}_s - \mathbf{X}_s\|_f^2}{\|\mathbf{X}_s\|_f^2} \times 100\%, \quad (11)$$

where  $\|\cdot\|_f$  is the Frobenius norm,  $\hat{\mathbf{X}}_s$  consists of the nonzero columns of the reconstructed data matrix  $\hat{\mathbf{X}}$  and  $\mathbf{X}_s$  is the corresponding subset of the original data matrix  $\mathbf{X}$ . Based on SPMSE,  $SV_e$ , variance explained by the sparse components, is proposed as

$$SV_e = 100\% - SPMSE. \quad (12)$$

In contrast to  $V_e$  (Eq. 10),  $SV_e$  only calculates the variance for the non-zero reconstructed-channels, so  $SV_e$  can more effectively reflect the reconstruction accuracy. Note, that since the sparse components are not orthogonal, the reconstruction of  $\mathbf{X}$  is defined as

$$\hat{\mathbf{X}} = \hat{\mathbf{T}}^S (\hat{\mathbf{P}}^{\text{EN}})^T [\hat{\mathbf{P}}^{\text{EN}} (\hat{\mathbf{P}}^{\text{EN}})^T]^{-1}. \quad (13)$$

Figure 2. Diagram of OES data collection

Figure 3. Sample OES data set

## 4 Results

### 4.1 Data Description

The OES data under consideration is from a plasma etch chamber used in the manufacture of semiconductor chips (Fig. 2). It is collected for the exhaust plasma leaving the chamber and consists of 2046 channels (each channel corresponds to one wavelength) recorded at a sampling interval of 0.76s. Fig. 3 shows a typical data set collected for a 77s etch step on a single wafer. The data, which has been mean-centred, is clearly highly redundant. A PCA analysis reveals that a single PC can capture 95.8% of the variance in the data.

### 4.2 Selecting the EN-SPCA Tuning Parameters

As noted previously when the number of variables is large (in this case 2046) the soft-thresholding EN-SPCA algorithm developed in [12] can be used to efficiently compute components. In this formulation the  $L_2$  penalty tuning

**Figure 4.** The relationship between  $N_{NE}$  and  $V_e$

parameter ( $\gamma_2$ ) is set to infinity leaving only the  $L_1$  penalty parameters ( $\gamma_{1j}$  - one for each computed PC,  $j=1 \dots p$ ) to be determined experimentally. These parameters essentially determine the sparseness of the corresponding PCs.

For example, Table 4.2, shows how the number of nonzero elements ( $N_{NE}$ ) varies as a function of  $\gamma_{11}$ , for the first sparse component of the OES data. The table also shows how the variance explained by the component (expressed as a percentage of the total data variance). As might be expected  $V_e$  decreases as more and more components are forced to zero. In contrast, the  $SV_e$  value remains large for all values of  $\gamma_{11}$  demonstrating that the sparse PC achieves good accuracy for those channels where a reconstruction exists.

Fig. 4 demonstrates the corresponding relationship between  $N_{NE}$  and  $V_e$  and provides a useful guide for making a judgment call on the trade-off between sparsity and variance explained. As can be seen, in this instance there is a 'knee' in the graph at  $N_{NE} = 25$ , beyond which there is a marked decrease in the rate of variance increase with included variables. This corresponds to choosing  $\gamma_{11}$  as 29000.

The variance explained by the sparse PC for  $\gamma_{11} = 29000$  is 47% which compares to 95.8% for the unrestricted principal component. The corresponding  $SV_e$  value, which measures the reconstruction accuracy on the non-zero reconstructed-channels only, is more than 91%, by the 25 channels used in its computation.

### 4.3 The Grouping Effect

Figure 5 shows the distribution of the first sparse loading computed with  $\gamma_{11} = 290000$ . For comparison purposes the distribution of the first PCA component loading is included in Figure 6. The PCA loading elements are all

$\gamma_{11}$	$N_{NE}$	$V_e$ (%)	$SV_e$ (%)
0	2046	95.8057	95.8057
5000	1564	95.6068	96.129
10000	1373	95.0602	95.9379
50000	611	84.1086	89.6853
100000	189	65.0638	85.9841
150000	68	58.2831	90.3285
170000	54	56.3396	90.88
190000	48	54.5187	89.956
210000	43	52.7259	89.0393
230000	38	50.9482	88.6207
250000	30	49.4871	91.1976
270000	28	48.2702	90.5483
<b>290000</b>	<b>25</b>	<b>47.0887</b>	<b>91.127</b>
310000	25	45.8107	88.6538
330000	24	44.3460	86.9806
350000	24	42.5365	83.4315
370000	21	40.7546	84.3206
390000	19	38.9135	84.0687
410000	17	37.2303	84.522
430000	17	35.4131	80.3966
450000	14	33.3417	83.5658
470000	13	31.9432	83.0192
490000	11	30.4860	86.5150

**Table 1.**  $N_{NE}$ ,  $V_e$  and  $SV_e$ , corresponding to different  $\gamma_{11}$  values for the first sparse PC

**Figure 5.** The loading of the first sparse principal component obtained for the sample OES spectra in Fig. 3 using SPCA with  $\gamma_{11} = 29000$

non-zero with several clusters of large values centered on the active OES channels. These clusters arise because of the spectral bleed between adjacent channels. In contrast, the SPCA loading has only 25 non-zero entries and these are in four distinct clusters of points. Analysis of these four sets of points show that they are all highly correlated as can be seen in Fig. 7 (correlation coefficient  $> 0.99$ ). This is a direct consequence of the grouping effect that is a feature of EN-SPCA, that is, EN-SPCA has a tendency to give equal weighting to strongly correlated variables and, as such, selects all the correlated variables as a group, rather than selecting a single representative example. This is useful when trying to identify groups of related variables, but is not ideal for a variable selection algorithm.

**Figure 6. The loading of the first principal component obtained for the sample OES data in Fig. 3 using PCA**

**Figure 7. Intensity changes of the nonzero loadings (over time) for the first sparse PC of the OES data**

## 5 Conclusions

This paper introduces SPCA as a variable selection tool for the identification of key variables in large data sets. SPMSE has been proposed as a measure that better reflects the estimation accuracy of SPCA, given the sparse structure of the model. Using analysis of OES data from a plasma etch chamber the main features of SPCA have been illustrated, particularly in relation to how it provides a trade-off between variance explained and a sparse representation. The existence of a grouping effect in the selection of variables has also been highlighted as a weakness of the method.

### Abstract

*Due to the recent competition in the retailing industry, retailers are striving to improve their operations in order to run their stores more efficiently. One of the most important factors that encourages customers to buy products is discount. The effects of discount on sales have rarely been dealt with academically. Moreover, in few previous researches in this case, the temporal characteristics of product discount have not been noticed. The problem addressed in this paper is the consideration of products' discounts in discovering association rules in different time intervals that a specific discount appears on a specific product and finding optimal discount for each product with the aim of maximizing total profits. Additionally, experiments on real world data demonstrate the effectiveness of the proposed approach.*

### 1. Introduction

Recently, the capabilities of generating and collecting data have been increasing rapidly. Widespread use of bar codes for most commercial products, the computerization of many business, and the advance in data collection tools have provided us with huge amount of retail data. This explosive growth in data and databases has generated an urgent need for data mining techniques and tools [7, 11] that can extract implicit, previously unknown and potentially useful information from data in data storages. One of the most popular data mining approaches is "association rules", which is commonly applied to analyze market baskets to help managers to determine which items are frequently purchased together by customers [5, 15]. It is, originally, presented by Agrawal et al. [1]. It studies the frequency of items occurring together in transactional database. Generally,

there are two phases for mining association rules. In the first phase, we find large itemsets, whose supports are larger than or equal to the user-defined minimum support. In the second phase, we use large itemsets generated in the first phase to generate effective association rules. An association rule is effective, if its confidence is larger than or equal to the user-defined minimum confidence. The problem of discovering association rules progressively followed by refinements, generalizations, improvements and extensions, including generalized association rules and multi-level patterns [10, 14, 19, 24]; finding association rules with categorical and numeric attributes [4, 12, 13, 21, 22, 23]; qualified association rules [16]; temporal association rules [3, 9, 20]; spatial association rules [18, 25].

Standard association rules algorithms [2, 17] applied in market basket analysis mainly determines what products customers purchase together in a static fashion. In fact, dynamic changes in discounts rates on products and its effect on sales have been disregarded. In previous work [8], patterns with discount information are discovered. They, however, assume that each product may have different discounts over different time periods, but the periods are fixed for all products. That is, if our pre-specified period is 2 weeks, the discount rate on items A and B will not be changed in corresponding period. But, in practical situations, the period in which item A has a fixed discount rate could differ from item B. For example, in first week, item A could be sold with 10% discount and in the next week, with 20% discount. On the other hand, item B could be sold with 30% discount in the entire 2 weeks. Moreover, in previous studies [6, 8], optimal discount for assorted products has not been extracted.

In this paper, the best discount for each product is selected based on the total profitability that it generates, including profits from cross-selling.

To deal with this problem a more sophisticated algorithm is developed. Thus, our approach needs a differently formatted data warehouse that must have discount information and temporal content. Such information is available, since transactions not only record purchased items, but also their discounts and the time of purchase. This approach could help reveal reasons behind purchasing certain items together frequently. It may be due to the discount rate on each item or other customer behavior.

The proposed procedure of finding optimal discount for each product begins with an algorithm that discovers temporal association rules with discount information. Next, the procedure proceeds to product discount selection in which the profits of frequent itemsets are considered.

The rest of the paper is organized as follows. In section 2, we define the problem. In section 3, a new algorithm for mining association rules with consideration of product discount is proposed. In section 4, the product discounts selection optimization model is developed. In section 5, the results of the empirical study are presented. Finally, in section 6 we draw conclusions.

## 2. The problem and definitions

Let  $I = \{i_1, i_2, \dots, i_n\}$  denote the set of items. Consider a transaction database  $D$ , which consists of a set of transactions  $\langle Tid_i, s_i, t_{Tid_i} \rangle$ , where  $Tid_i$  is a transaction identifier associated with each transaction,  $s_i$  is a set of items appearing in a transaction ( $s_i \in I$ ), and  $t_{Tid_i}$  is a time epoch expressing the time that  $Tid_i$  occurs (see Table 1).

In our approach, we partition the discounts rates into intervals and denote each discount rate included in  $i$ th interval by  $dr_i$ . For example, assume that we have five discount intervals as follows: [0%, 10%], (10%, 20%], (20%, 30%], (30%, 40%], (40%, 50%] and (50%, 100%]. Therefore, we have a set of discounts rates denoted by  $Dr = \{dr_1, dr_2, \dots, dr_n\}$ . Also, if  $i < j$  then  $dr_i < dr_j$ .

**Table 1: Transaction table D**

Tid	Item	Time
1	ABCD	2
2	ABE	7
3	AC	15
4	BED	20
5	ABCD	21
6	C	23
7	AC	26

The discount list of products is recorded in table  $P$ , which consists of  $\langle i_i, dr_p, T_{i,dr_p} \rangle$ , and expresses the period  $T_i$  in which item  $i_i$  has  $dr_p$  discount (see Table 2).

**Definition2.1:** Let  $X$  be an itemset which is a subset of  $I$ . A set of transactions in  $D$  containing  $X$  indicated by  $V(X, D) = \{s | s \in D \wedge X \subseteq s\}$ . If  $|X| = k$ , we call it  $k$ -itemset.

**Definition2.2:** Let  $PD = \{ps_1, ps_2, \dots, ps_d\}$  be transaction database  $D$  incorporated with discount information of discount table  $P$ . In fact, each  $ps_i$  indicates that each item in  $s_i$  has appeared with how much discount when it was purchased.

Let  $d$ -itemset  $X_d$  be an itemset carrying discount information and denoted by a set of pairs  $(i_x, dr_p)$ ; we can define two separate sets:  $X_d^1 = \{i_i | (i_x, dr_p) \in X_d\}$  and  $X_d^2 = \{dr_p | (i_x, dr_p) \in X_d\}$ . If  $|X_d| = k$ , we call it  $k$ - $d$ -itemset. The set of transactions in  $PD$  containing  $d$ -itemset  $X_d$  indicated by  $(X_d, PD) = \{ps | ps \in PD \wedge X_d \subseteq ps\}$ .

**Table 2: Discount list P**

Item	Discount rate	Time
A	$dr_2$	[0,8]
A	$dr_1$	[9,20]
A	$dr_2$	[21,30]
B	$dr_3$	[0,10]
B	$dr_1$	[11,30]
C	$dr_2$	[0,15]
C	$dr_4$	[16,22]
C	$dr_5$	[23,30]
D	$dr_4$	[0,8]
D	$dr_2$	[9,22]
D	$dr_1$	[23,30]
E	$dr_1$	[0,9]
E	$dr_3$	[10,20]
E	$dr_2$	[21,30]

**Definition2.3:** As we mentioned in definition 2.1, the time interval in which item  $i_i$  has  $dr_p$  discount, denoted by  $T_{i,dr_p}$ . It is simply an interval  $[t_i, t_j]$ , where  $t_i < t_j$ . Therefore, we can express the lifespan of  $k$ - $d$ -itemset  $X_d$ , with  $k > 1$ , by  $T_{X_d}$  and define it as follows; suppose  $T_{X_d}$  is an interval indicated by  $[t_{x_{d_i}}, t_{x_{d_j}}]$ , where  $t_{x_{d_i}} = \max\{t_i | [t_i, t_j] \text{ is the time period of an item } i_i \text{ in } X_d\}$  and  $t_{x_{d_j}} = \min\{t_j | [t_i, t_j] \text{ is the time period of an item } i_i \text{ in } X_d\}$ . It shows the period that  $X_d$  may occur. If  $t_{x_{d_j}} < t_{x_{d_i}}$ , means items in  $X_d$  do not have time intersection and this itemset is not

feasible. We also should define  $PD_{X_d} = \{ps | ps \in PD \wedge \text{the time of } ps \text{ is in time interval } T_{X_d}\}$  as a set of transaction in  $PD$  where  $X_d$  may occur.

For example, by considering Table 2, we have  $T_{A,dr_2} = [0,8] \cup [21,30]$ ,  $T_{B,dr_3} = [0,10]$ , and  $T_{C,dr_2} = [0,15]$ . Suppose  $X_d = \{(A, dr_2)(B, dr_3)(C, dr_2)\}$ , so we have  $T_{X_d} = [0,8]$  and  $Tid_{X_d} = \{1, 2\}$ .

**Definition2.4:** The global support of itemset  $X$  in database  $D$ , denoted by  $s(X, D)$ , is the fraction of transactions in  $D$  that contains  $X$ . Hence, we have  $s(X, D) = |V(X, D)| / |D|$ . Given a global support threshold  $\sigma_g \in [0, 1]$ ,  $X$  is a frequent itemset if  $s(X, D) \geq \sigma_g$ .

**Definition2.5:** The local support of extended itemset  $X_d$  in database  $D$ , denoted by  $ls(X_d, PD)$ , is the fraction of extended transactions in  $PD$  that contains  $X_d$ . Thus, we have  $ls(X_d, PD) = |V(X_d, PD)| / |PD|$ . Given a local support threshold  $\sigma_l \in [0, 1]$ ,  $X_d$  is frequent d-itemset if  $ls(X_d, PD) \geq \sigma_l$ .

**Definition2.6:** The real support of extended itemset  $X_d$ , denoted by  $rs(X_d, PD)$ , is the fraction of extended transactions in  $PD_{X_d}$  that contains  $X_d$ . Hence, we have  $rs(X_d, PD) = |V(X_d, PD_{X_d})| / |PD_{X_d}|$ . In order to determine the effect of discounts on sales we use  $EF = rs(X_d, PD) / s(X, D)$ . If this fraction results in a value which is greater than the threshold  $gf$ , it means this discount combination encourages sales. On the other hand, if  $EF$  is smaller than the threshold  $sf$ , it implies that this discount combination decrease sales. Note that  $sf$  and  $gf$  specified by users or experts.

**Definition2.7:** In this paper we need to remove  $d$ -itemsets  $X_d$  with very short  $T_{X_d}$ . Since a set of items may appear with a specific discount combination in a very short period of time, it is not reasonable to consider such itemset. For instance, assume that  $X_d = \{(A, dr_2)(C, dr_4)\}$ , so we have  $T_{X_d} = [21, 22]$ . Therefore with the help of definition 2.6, its real support is 100%. Without consideration of very short period that items A and C appeared with discounts rates  $dr_2$  and  $dr_4$ , respectively, we may mislead about its positive effect on sales. Therefore, we need a temporal support, denoted by  $ts(X_d)$ , and represented by  $ts(X_d) = |T_{X_d}|$ . Given a temporal support threshold  $\sigma_t$ ,  $T_{X_d}$  is big enough to judge about the real support of  $X_d$  if  $ts(X_d) \geq \sigma_t$ .

**Definition2.8:** If  $X_d$  is a large- $d$ -itemset and  $X'_d \subset X_d$ ,  $X'_d \neq \emptyset$ , The confidence of a rule  $X'_d \Rightarrow X_d - X'_d$ , where  $X_d$  and  $X'_d$  are set of pairs  $(i_x, dr_p)$ , is computed as follows:

$$C(X'_d \rightarrow X_d - X'_d) = \frac{ls(X_d - X'_d, T_{X_d}, PD)}{ls(X'_d, T_{X_d}, PD)},$$

Where  $ls(X_d - X'_d, T_{X_d}, PD)$  and  $ls(X'_d, T_{X_d}, PD)$  computed in time intervals  $T_{X_d}$  which is an intersection of periods of every pairs in  $X_d$  that they could possibly occur. We call a rule an interesting one, if  $C(X_d \rightarrow X'_d) \geq \sigma_c$ .

### 3. The Apriori-Td algorithm

The algorithm proposed in this paper differs from Apriori [2] and Apriori-like [8] algorithms for mining frequent itemsets. However, It takes advantage of approach represented in Chen et al.[8] and makes changes in algorithm in such a way that temporal concept is taken into account. We introduce two filtering operators,  $ts$  and  $ls$ . The former filters d-itemsets occurred in a very short period of time, since there is no sufficient data to judge on its support and consequently its effects. The later removes d-itemsets which is not frequent enough. Otherwise, we will face problem that a mining process produces a very large number of rules, thus proving to be of little value to the user.

Function Apriori-Td

- 1)  $GL_1 = \text{get-global-large-1-itemsets}(D);$
- 2) For( $k=1$ ;  $LL_{k-1} \neq \text{null}; k++$ ) {
- 3)   If ( $k==1$ ) {
- 4)      $LC_1 = \text{get-local-candidate-1-d-itemset}(GL_1, P);$
- 5)      $LL_1 = \text{get-large-local-k-d-itemset}(LC_1);$  }
- 6)   Else {
- 7)      $LC_k = \text{get-local-candidate-k-d-itemset}(LL_{k-1});$
- 8)      $LL_k = \text{get-large-local-k-d-itemset}(LC_k);$  }
- 9) }  $\cup LL_k;$

**Figure 1: Apriori-Td algorithm**

This approach needs more input data than Apriori-like algorithm. They would be discount list  $P$  and thresholds  $\sigma_l$  and  $\sigma_t$ .

We present the framework of the algorithm in Figure1. In the first step, we find large 1-itemsets, that exceed the global support threshold  $\sigma_g$ , labeled  $GL_1$ . In contrast with Apriori-like algorithm, we only find large 1-itemset in very first step and there is no need to extract  $k$ -itemsets,  $GL_k$ , in future phases. Since the main reason for extracting  $k$ -itemsets in Apriori-like algorithm is finding frequent  $k$ -d-itemsets, using Apriori-Td algorithm proposed in this paper we can acquire frequent  $k$ -d-itemsets directly from  $(k-1)$ -d-itemsets and we do not have to scan database once again.

Then in line 4 we join discount information to frequent items by the use of discount list  $P$ . The

description of the function illustrated in Figure 2. The function of making local candidate 1-itemsets,  $LC_1$ , differs from achieving  $LC_k$ , which is described later. In contrary, finding  $LL_1$  and  $LL_k$  are done by the same function. Hence, interesting discount patterns,  $LL_k$ , are discovered by applying *Function get-large-local-k-d-itemset*. As illustrated in Figure 3, in order to find a period in which k-d-itemset could possibly occur, we compute  $T_{x_d}$  (see definition 2.3). All itemsets which do not satisfy temporal condition  $|T_{x_d}| \geq \sigma_t$  and local threshold  $ls(X_d, PD) \geq \sigma_l$  are eliminated. Then, the number of transactions in corresponding period is determined and the computation of real support  $X_d$  and  $EF$  is done to find out the effect of such pattern on sales (see Figure 3).

Function	get-local-candidate-set-1-d-itemset( $GL_1, P$ )
1)	For each item $i_i$ in $X \in GL_1$
2)	From table $P$ Determine every different discount levels for $i_i$ ;
3)	Determine the time interval in which item $i_i$ appears with each discount level;

**Figure 2: Function of get local 1-d-itemsets candidates**

In line 7, we generate candidate of k-d-itemset from large  $(k-1)$ -d-itemset. The method is similar to Apriori algorithm, but it has some extra conditions. Inasmuch as our itemsets carrying extra information about their discount combination, when two  $(k-1)$ -d-itemset is joined, we have to consider whether this combination has actually happened. If  $T_{x_d''} \cap T_{x_d'} = \emptyset$ , it means  $x_d''$  and  $x_d'$  cannot occur simultaneously. This condition automatically satisfies the fact that one item could not occur with different discounts rates in a specific period. Moreover, the set of first components of pairs  $(i_x, dr_p)$  in  $x_d''$  and  $x_d'$  should not be equal (see Figure 4).

Function	get-large-local-k-d-itemset( $LC_k$ )
1)	For each pairs in $LC_k$ Find $T_{x_d}$
2)	If $ T_{x_d}  \geq \sigma_t$
3)	If $(ls(X_d, PD) \geq \sigma_l)$
4)	Insert $X_d$ to $LL_k$ ;
5)	Compute the number of transaction in $T_{x_d}$ ;
5)	Compute the real support $T_{x_d}, rs$ ;
6)	Compute $s(X_d^1, D)$ ;
7)	Compute the $EF = rs(X_d, PD) / s(X_d^1, D)$ ;
8)	If $(EF \geq gf)$ this discount combination increases sales;
9)	If $(EF \leq sf)$ this discount combination decreases sales;

**Figure 3: Function of get large k-d-itemset**

After finding large k-d-itemsets, the set of association rules can be derived from  $\cup LL_k$ . Results obtained from this approach are more complete than previous work because time information has been included. In this algorithm, generating association rules has a kind of time constrain and the rules is derived by the use of definition 2.8.

Function	get-local-candidate-set-k-d-itemset( $LL_{k-1}$ )
Each two $(k-1)$ -d-itemset $x_d', x_d'' \in LL_{k-1}$ join to construct a k-d-itemset $x_d$ , providing that (1) $x_d'^1 \neq x_d''^1$ , (2) $x_d''$ and $x_d'$ share $(k-2)$ pairs items $(i_x, dr_p)$ , (3) $T_{x_d''} \cap T_{x_d'} \neq \emptyset$ , (4) all $(k-1)$ -d-subsets of $x_d$ should be in $LL_{k-1}$ .	

**Figure 4: Function of get local k-d-itemsets candidates**

Example 3.1: In order to demonstrate the proposed Apriori-Td algorithm, a simple example is presented. Assume the transaction database  $D$  and discount list  $P$  are as shown in Tables 1 and 2, respectively. Also suppose that the predefined parameters are as follows:  $\sigma_g=0.4$ ,  $\sigma_l=0.2$ ,  $\sigma_t=3$ ,  $\sigma_c=0.5$ ,  $sf=1.3$ , and  $gf=0.7$ .

The large 1-itemsets satisfying  $\sigma_g=0.4$  is derived in the first step. As a result, we have  $A, B, C$ , and  $D$  as frequent global items with global supports 0.71, 0.57, 0.71, and 0.42, respectively. After each frequent item incorporated to their discount level, the computation of  $T_{x_d}$  and  $ls$  are done to find large 1-d-itemsets for the next step (see Table 3).

**Table 3: Generate  $LC_1$  from  $GL_1$**

$LC_1$	Time	$ T_{x_d} $	$ls$
$(A, dr_2)$	$[0,8] \cup [21,30]$	19	0.57
$(A, dr_1)$	$[9,20]$	12	0.14
$(B, dr_3)$	$[0,10]$	11	0.28
$(B, dr_1)$	$[11,30]$	20	0.28
$(C, dr_2)$	$[0,15]$	16	0.28
$(C, dr_4)$	$[16,22]$	7	0.14
$(C, dr_5)$	$[23,30]$	8	0.28
$(D, dr_4)$	$[0,8]$	9	0.14
$(D, dr_2)$	$[9,22]$	14	0.28
$(D, dr_1)$	$[23,30]$	8	0.0

We must calculate the real support of items with that specific discount level in the corresponding time interval so that we are able to determine their effects. As shown in Table 4, when item  $B$  appears with  $dr_3$  discount may further encourage customers to purchase it rather than other discount levels. On the other hand,

its  $dr_1$  discount may lead to the sales reduction. Item  $A$  with  $dr_2$  discount does not have significant influence on sales and this combination is neutral.

**Table 4: generate  $LL_1$  from  $LC_1$**

$LL_1$	Time	$rs$	$s$	$EF$	Effect
$(A, dr_2)$	$[0,8] \cup [21,30]$	0.8	0.71	1.13	
$(B, dr_3)$	$[0,10]$	1	0.57	1.75	+
$(B, dr_1)$	$[11,30]$	0.4	0.57	0.7	-
$(C, dr_2)$	$[0,15]$	0.67	0.71	0.94	
$(C, dr_5)$	$[23,30]$	1	0.71	1.4	+
$(D, dr_2)$	$[9,22]$	0.67	0.42	1.59	+

**Table 5: Generation of large 2-d-itemsets**

$LC_2$	Time	$ T_{x_d} $	$ls$	$s$
$(A, dr_2; B, dr_3)$	$[0,8]$	9	0.28	0.42
$(A, dr_2; B, dr_1)$	$[21,30]$	10	0.14	0.42
$(A, dr_2; C, dr_2)$	$[0,8]$	9	0.14	0.57
$(A, dr_2; C, dr_5)$	$[23,30]$	8	0.14	0.57
$(A, dr_2; D, dr_2)$	$[21,22]$	2		
$(B, dr_3; C, dr_2)$	$[0,10]$	11	0.14	0.28
$(B, dr_3; D, dr_2)$	$[9,10]$	2		
$(B, dr_1; C, dr_2)$	$[11,15]$	5	0.0	0.28
$(B, dr_1; C, dr_5)$	$[23,30]$	8	0.0	0.28
$(B, dr_1; D, dr_2)$	$[11,22]$	12	0.28	0.42
$(C, dr_2; D, dr_2)$	$[9,15]$	7	0.0	0.28

$LL_2$	Time	$rs$	$s$	$EF$	Effect
$(A, dr_2; B, dr_3)$	$[0,8]$	1	0.42	2.38	+
$(B, dr_1; D, dr_2)$	$[11,22]$	0.67	0.42	1.59	+

From  $LL_1$ , we get 2-d-itemsets candidates. As earlier mentioned, owing to the fact that there exist situations where specific discount combinations of itemsets do not simultaneously fall within the same database time interval (lack of intersection), hence, they do not satisfy the temporal conditions to join together. For example, there might not be a situation where  $B$  is sold with discount level  $dr_3$  and  $C$  with

$dr_5$ . So  $(B, dr_3; C, dr_5)$  is considered obsolete. It is illustrated in Table 5,  $(A, dr_2; D, dr_2)$  and  $(B, dr_3; D, dr_2)$  may occur in very short period of time, so for these two 2-d-itemsets, the program does not continue computing their local support.

Finally, large 2-d-itemsets, which their local supports exceed local threshold, are extracted from  $LC_2$  and the result reveals that when item  $A$  is sold with  $dr_2$  discount and item  $B$  with  $dr_3$ , customers purchase these two more frequently. Also,  $(B, dr_1; D, dr_2)$  has a positive influence on sales.

It is the time for finding interesting rules, which their confidence is greater than  $\sigma_c$ . For example, consider the case when  $(A, dr_2) \Rightarrow (B, dr_3)$ , the confidence is  $\left(\frac{2}{2}\right) / \left(\frac{2}{2}\right) = 1$ . Note that local support for  $(A, dr_2; B, dr_3)$  and  $(A, dr_2)$  are computed in time intervals  $[0, 8]$ , which this combination could possibly occur.

After the execution of this algorithm, we have frequent  $d$ -itemsets and also their effects on sales. In the next step, the zero-one programming is presented to find the optimal product discount with the aim of maximizing the profits of frequent  $d$ -itemsets.

#### 4. The product discount selection procedure

In this study, by the use of Apriori-Td algorithm, we can specify which products with how much discount are frequently bought by customers at the same market baskets. In this section, a microeconomic zero-one integer programming model is introduced for product discount selection. That is, the proposed model provides us the products that should be on sale and of course, the discount rates of these selected products. The results of the optimization problem may express that some products should not be sold with discount.

In the first step of the procedure, the gross margins of frequent itemsets with consideration of the product discount are estimated. The profit estimation follows the idea of Brijs et al.[6]. In their approach, besides considering individual profit generated by a specific product, the cross-selling effects with other products in the assortment are taken into account. In fact, Brijs et al. addressed the product assortment problem. However, in this paper, we assume that the products are assorted. So, we deal with the problem of finding best combination of discounts for assorted products. The constructed model is able to select an optimal discount for each product which yields the maximum overall profit. By using frequent  $d$ -itemsets, the model takes into account cross-selling effects.

Before specifying the microeconomic optimization model, we describe the method of estimating profit of frequent itemsets [6].

#### 4.1. Estimating the gross margin

The parameters of the method are as follows:

$T_j$	Items and their discount level included in the $j$ th transaction
$F_l$	The collection of all frequent $d$ -itemsets of $T_j$
$SP_i$	The selling price of product $i$
$PP_i$	The purchase price of product $i$
$D_i$	The discount rate of product $i$
$q_i$	Quantity of product $i$ that was purchased in $T_j$
$X_{dmax}$	The maximal frequent $d$ -itemset in the $j$ th transaction
$Y_{dmax}$	The second maximal frequent $d$ -itemset in the $j$ th transaction
$\theta_{T_j}(X_d)$	The probability of selecting $X_d$ in $T_j$ to allocate gross margin, $\theta_{T_j}(X_d) = \frac{localSupport(X_{dmax})}{\sum_{Y_{dmax} \in T_j} localSupport(Y_{dmax})}$
$T_j/X_d$	Items and their discount level included in $j$ th transaction after eliminating frequent itemset $X_d$
$m(X_d)$	The profit of products in frequent $d$ -itemsets $X_d$ , $m(X_d) = \sum_{i \in X_d} [(D_i \times SP_i) - PP_i] \times q_i$
$M(X_d)$	The summation of $m(X_d)$

The method of estimating the profit of frequent itemset is illustrated in Figure 5.

**Figure 5: Function of estimation of gross margin**

#### 4.2. The discount selection model

In this section, we propose an optimization problem for discovering the best discount combination for products.

The goal of the optimization problem maximizes the overall profitability of the frequent  $d$ -itemsets. The key point in this paper is that not only are the frequency and quantity of a purchased product with a specific discount level taken into account, but also the effect of such a discount level on selling other products is considered.

The parameters of the model are given in below:

$M_i(X_d)$	The estimated gross margin of $i$ th frequent $d$ -itemsets
$LL_i$	The set of items incorporated with their discount level in the $i$ th frequent $d$ -itemset

Decision variables:

$$p_i = \begin{cases} 1, & \text{if any item in frequent d-itemset } LL_i \text{ is selected;} \\ 0, & \text{otherwise.} \end{cases}$$

$$dis_{jl} = \begin{cases} 1, & \text{if item } j \text{ with discount level } l \text{ is selected;} \\ 0, & \text{otherwise.} \end{cases}$$

The mathematical model of product discount selection is as follows:

Maximize  $\sum_i M_i(X_d) p_i$

Subject to:

- (1)  $dis_{jl} \geq p_i \quad \forall i, \forall j_l \in LL_i$
- (2)  $\sum_i dis_{jl} \leq 1 \quad \forall j$
- (3)  $p_i \in \{0,1\}, dis_{jl} \in \{0,1\}$

Constraint (1) ensures that once a frequent  $d$ -itemset is selected, the product with their discount level in this frequent itemset have to be selected. Constraint (2) forces the model to select just one discount level for each assorted product. Constraint (3) limits the decision variables to be binary.

If no specific discount is selected for an item, it means that it does not exist in any frequent itemsets. One probable reason for this fact is that it is sold rarely with any discount rate. So, it does not appear in frequent itemsets. The second likely reason is that its sell is not low in whole, but it is not sensitive about its discount and it is sold uniformly in almost low rate. So, any discount rate could not have great influence on its

sale. So, it would be better not to put this item on sale and sell it with its original price.

## 5. The experiment

In this section, we use a real dataset to assess the performance of proposed model for finding optimal product discount. The Apriori-Td algorithm was implemented in VB 2000. The real data set is derived from the retail data of chain supermarket in Iran over a period of 4 months in Microsoft SQL Server 2000. Each transaction records purchase data, purchase time, purchased items, prices, discounts, and quantities. These transactions consist of 1241 different products and totally there are 7305 sales transactions.

In the first phase of the procedure, in order to discover frequent  $d$ -itemsets, we partition the discounts rates into 6 intervals, as shown in Table 6. These frequent itemsets work as input for optimization model for finding best product discount in the second phase. The minimum global support, local support, and confidence are set to 0.3, 0.2, 0.1. The minimum temporal support is set to 3 days. These thresholds are set very low in order to discover enough association rules for further analysis. By the use of Apriori-Td algorithm, 1871  $d$ -frequent itemsets were obtained.

This approach uses only  $d$ -frequent itemsets. The discovery of association rules, however, will be helpful for interpreting the output of the optimization model.

**Table 6: Discount level**

Level	dr <sub>1</sub>	dr <sub>2</sub>	dr <sub>3</sub>	dr <sub>4</sub>	dr <sub>5</sub>	dr <sub>6</sub>
Dis. rate(%)	0	1-19	20-39	40-59	60-79	>80

The optimization model can exploit cross-sales potential between items with different discount rates. The effect of a product with a selected discount rate on total profitability can be assessed by means of sensitivity analysis. That is, a specific discount rate, which is assigned to a product by the use of proposed optimization model, is replaced by the best discount rate outside the result of the optimization model and its impact on profitability can be observed through its contribution to increasing the objective function. The best discount rate for a product outside the optimization model is the discount rate that has the greatest impact on cross-selling.

Figure 6 illustrates the profit impact of the replacement of each selected discount rate. It indicates that the discount rates for some of the products such as  $i_2$ ,  $i_4$ ,  $i_{10}$ ,  $i_{13}$ ,  $i_{25}$ , and  $i_{31}$  have great influence on profitability and should not be replaced by other discount rates.

**Figure 6: Impact of replacement on profitability**

In this approach, although some of the selected discount rates have low total profit margin individually, they have considerable cross-selling opportunities with some of the other selected discount combinations. For instance, the empirical results indicate that 30% discount rate on *chips* does not provide high profit with regard to the total margin and its  $EF = 1.53$  (if  $fg = 1.4$ , its  $EF$  does not show strong positive effect on its sale). It is, however, selected as the optimal discount combination for *chips*. The reason is that 30% discount for *chips* encourages costumers to purchase other items (*yogurt*, 10%; *ketchup*, 0%) with lower discounts rates more frequently and in high quantity. So, it makes the total profit increase significantly. It, also, can easily be obtained from evaluation of the association rules.

$(Chips, 30\%) \Rightarrow (Yogurt, 10\%; ketchup, 0\%)$

Minimum local support=0.39

Minimum confidence=0.95

$(Yogurt, 10\%; ketchup, 0\%) \Rightarrow (Chips, 30\%)$

Minimum local support=0.39

Minimum confidence=0.83

The rules illustrate that when a customer buys *chips* with 30% discount he will often also buy *Yogurt* with 10% discount and *ketchup* with no discount. Other direction of the rule demonstrate that when a customer purchases *Yogurt* with 10% discount and *ketchup* with no discount in most of the time (0.85) he also purchases *chips* with 30%.

## 6. Conclusions and future work

In the first phase of this paper, we presented an algorithm for discovery association rules in market baskets with consideration of discount information and their temporal characteristics. In previous studies, this problem is not viewed as a temporal association rules mining. In real world, the discount rates on a product

could, however, change with different periods and these periods differ from product to product. In the second phase of the paper, we integrated the notion of frequent itemsets with some important microeconomic parameters and the best discount rate selected by means of zero-one integer programming. Finally, we used a real dataset from a retail data of chain supermarket to empirically validate our approach. The results indicate the effectiveness and usefulness of the approach.

In the future, we plan to improve the pruning conditions of the Apriori-Td algorithm. Also, we are going to extend our approach to shelf allocation problem.

### Abstract

*Predicting stock market movements is always difficult. Investors try to guess a stock's behavior, but it often backfires. Thumb rules and intuition seems to be the major tools. One approach suggested that instead of trying to predict one particular stock's movement with respect to the whole market, it may be easier to predict a stock  $A$ 's movement based on another stock  $B$ 's movement, because  $A$  may get affected by  $B$  after  $B$ 's movement. This may provide the investor invaluable time advantage. It would be very useful if a general framework can be introduced that can predict such dependence between stocks based on any user defined criterion. This article attempts to lay down one such framework, where the stock time series is encoded as a binary string. This binary representation depends on the user defined criterion. The string distances between two such encoded time series has been used as a measure of dependence. Further, this technique has been used in the 'Pairs Trading strategy'; in fact, it is more powerful as varied user defined criterion can be handled while detecting similarity. The presented technique has been demonstrated with one typical user defined criterion.*

### 1. Introduction

Algorithmic trading [1] tries to identify possible "windows of opportunities" automatically, using algorithms, for performing stock trading, from the historical data. Stock data is a time series data [7], describes how the stock values behave over time. The most frequently used values for visu-

alizing and predicting stock movement over a time window (Week/Day/Time) are, price at trading opening time, maximum value on that window, lowest value on that window, price at closing time and total volume of transaction within that window.

One interesting related problem is to find out how one stock affects another. It is quite important from the viewpoint of investors; as it gives the investor an idea about how the markets are moving and also provides some unforeseen insights. As a simple example, if stock  $B$  has been found to closely follow stock  $A$  within three days period, steady increase in  $A$ , may provide the investor some idea about  $B$ 's growth. This  $A - B$  relation might provide some useful information along with  $B$ 's individual pattern.

In the well known *Pairs Trading strategy* [4], [21], two similar stocks are chosen so that, if the behavior of one stock outperforms the average performance it is sold short, whereas, if the behavior of one stock falls below average, it is bought in the hope that it will reach average behavior sometime. The key concept behind pairs trading strategy is that a well chosen pair tend to cancel each other's deviations and thus, a loss in one will be gained in the other. Evidently, it would be very useful if a general framework can be introduced that can predict such dependence between stocks, that could be used for pairs trading strategy. For pairs trading, the most commonly used index is a correlation coefficient [19], and investors often also check other metrics like relative strength index [22, 3] and Bollinger band [5, 3].

There have been some attempts to evaluate the stocks' similarity *e.g.*, indicators, price ratio and price comparison [3]. However, these have been largely for the purpose of finding strong stocks rather than dependences between

them. Researchers have used clustering techniques [12], association rule mining [20, 18, 16], and geometric properties [9, 6] to find stock similarity. The metric distances and methods based on topological properties and random matrix theory [8, 13] have also been used for the purpose. However, these methods are complicated and could not provide simple yet practical indicators useful for investors which are applicable both for short term and long term dependencies. Also, all these metrics invariably try to find similarity between stocks in terms on one fixed distance measure. In [10], this problem has been addressed and three simple metrics are introduced which effectively predicts two stocks' dependence on each other. However, those metrics were applicable only for a certain class of dependence (for example, if the opening price pattern of one stock follows the opening price pattern of another). In practice, an investor may need completely different criteria for measuring distances between two stocks depending on the requirement, time and market conditions. Naturally, it would be more useful if some generic framework could be devised that would enable an investor check for dependence between stocks with respect to a criterion defined by the investor.

In this article, a simple framework based on the concepts of events and episodes, first introduced in [17] is developed. It is shown that, given a user defined criterion, it is possible to encode any stock's time series data using a finite alphabet, and then the distance between these two encoded series efficiently measures dependence. Some practical results for one particular user defined criterion is also provided. It has been shown that the proposed technique can be used effectively for pairs trading; in fact, this technique is more powerful as it can model different user requirements while finding similarity. The data set has been taken from Standard and Poor 500 [2]. This data shows daily price and volume fluctuations (opening price, closing price, maximum price, minimum price and volume) over an year for some well-known stocks. Most of the stocks have a series of 252 numbers; thus we have a time series of length 252. This paper is organized as follows. In Section 2, we define events and episodes. Section 3 describes the framework. Section 4 gives results, and Section 5 concludes the paper.

## 2 Events and Episodes

As defined in [17], an event is an occurrence of a particular type which has a time stamp attached to it. Given a set  $\bar{E}$  of event types, an event  $\alpha$  is a pair  $(A, t) \in \bar{E} \times \mathcal{N}$ ,  $\mathcal{N}$  set of natural numbers, where  $A \in \bar{E}$  is an event type and  $t$  is an integer, the occurrence time of the event. Mathematically, a time series can be seen as an ordered sequence of events  $\{\alpha_i\} = \{(e_i, t_i)\}$  where  $e_i$  is an occurrence of a particular type and  $t_i$  is the time stamp. For example, for a stock time

series, the set of event types can be (daily opening price, daily closing price, daily trading volume, daily maximum price and daily minimum price) and the time series can be described by any of these four event types by giving the value associated with the day. An episode is a sequence of events. An episode is a triple  $(V, <, g)$  where  $V$  is a set of nodes,  $<$  is a partial order on  $V$ , and  $g : V \rightarrow \bar{E}$  is a mapping associating each node with an event type. In the above article, authors gave algorithms for identifying frequently occurring episodes in a sequence of events.

Therefore, each stock data time series can be viewed as a series of events, where each event is a value (the opening price, or closing price, or volume traded and so on) associated with a time. Now, a user can define an episode as a predefined sequence of events. For example, the user can define "three successive days of trading volume increase" as an episode  $(T_i < T_{i+1} < T_{i+2}, T_i = \text{Trading Volume value on } i^{\text{th}} \text{ day})$ .

Note that the definition implicitly assumes that an episode is defined completely only by the event type and their partial ordering. However, it may not be enough for defining somewhat complicated episodes where conditionals or temporal behavior comes into play, *e.g.*, the episode "closing price lower than opening price, occurring at least twice a week". The problem here lies in the fact that the episode does not only need a sequence of events, but also a quantifier on the time.

To evaluate the similarities between stock prices based on their time series data, the episodes in that data should be found in a time sequential order. In this article an episode is defined as a sequence of events together with a restriction on the values as well as the time stamps of the events. Thus, an episode is

$$E = \{(e_i, t_i) \in \bar{E} \times \mathcal{N} : f(e_i), g(t_i)\},$$

where  $f(e_i)$  and  $g(t_i)$  are functions of  $e_i$  and  $t_i$  respectively, and events are always found from left to right. Suppose  $O_i$  is the opening price on  $i^{\text{th}}$  day for the stock data. An example of  $f$  and  $g$  can be seen from the episode "Opening price of stock is more than 10 USD for two days in succession", which is equivalent to  $O_i > 10, O_j > 10, j = i + 1$ . Here the event type is opening price,  $f$  defines the relationship between opening price and the value 10, and  $g$  defines the relationship between  $i$  and  $j$ . Note that, as we are defining an episode in terms of a set of events detected from left to right, each event's position in time gets fixed and the ordering is automatic. We will call a sequence of events which satisfy the complementary conditions as a complementary episode.

It is possible that a wrong choice of  $f()$  and  $g()$  may generate very poor results. However, as we are relying on

experienced investor inputs, we expect  $f()$  and  $g()$  to be good. In fact, generating well behaved  $f()$  and  $g()$  may be a good future research direction.

Given a definition of an episode, we can find all occurrences of the episode from a time series. Below, we give an outline of the algorithm that finds all episodes, and its complements from a time series.

```

ALGORITHM FIND_EPISODES_FROM_STOCK_TIME_SERIES
Read time series $S(t)$, $t = 1, \dots, N$
Read episode def. $E = \{(e_i, t_i) : f(e_i), g(t_i)\}$
episode_index = 1
complementary_episode_index = 1
for $i = 1, \dots, N$ do
 Check if $(S(t_i), t_i)$ satisfies the conditions
 or complementary conditions
 If neither, push $(S(t_i), t_i)$ to candidate_list
 If satisfies conditions
 push candidate_list and $(S(t_i), t_i)$ to
 episode[episode_index]
 set episode_index += 1
 endif
 If satisfies complementary conditions
 push candidate_list and $(S(t_i), t_i)$ to
 complementary_episode_index[episode_index]
 set complementary_episode_index += 1
 endif
enddo

```

With this definition, the episode “closing price is lower than opening price, occurring at least twice in the same week” will be:

$$\{(C_i, t_i), (O_i, t_i), (C_j, t_j), (O_j, t_j) \text{ such that ,} \\ C_i < O_i, C_j < O_j, \\ |i - j| \leq 7, i, j \text{ not part of a member already}\}. \quad (1)$$

Where  $C_i$  and  $O_i$  are the closing and opening prices, respectively on  $i^{th}$  day. Similarly, an episode “the stock opening price increases by  $X$  and does not decrease by  $Y$  or more anywhere in the same period” will be described as

$$\{(O_k, t_k), \quad k = i, i + 1, \dots, j \text{ such that ,} \\ O_j - O_i \geq X, O_m - O_l < X, \forall m \neq j, \forall l \neq i, m > l \\ O_m - O_l < Y, \forall \{m, l\} \in (i, i + 1, \dots, j), m < l, \\ \text{no } k \in \{i, i + 1, \dots, j - 1\} \\ \text{a part of a member already}\}. \quad (2)$$

Note the definition of  $k$ ;  $j$  can be a part of two members and exactly two members which share the boundary.

### 3 Framework

Given such an episode definition  $E$ , it is possible to encode a stock time series  $S(t)$ ,  $t = 1, \dots, N$  as a binary

string. Suppose the user defined episode is  $E$ , viz., the set of events and their time stamps, subject to  $f(.)$  and  $g(.)$  as defined by the user. Now, consider every episode  $E$  present in the time series, which is a set  $\{(e_i, t_i)\}$ . To encode the stock time series in binary, for every event member of an episode, the corresponding value of the time series gets encoded to ‘1’, where as complementary event member gets ‘0’. Mathematically, suppose  $S(t)$ ,  $t = 1, \dots, N$  is the stock time series, and  $E'$  is the set of all episodes in  $S(t)$ , each episode  $E$  defined as  $\{(e_i, t_i) : f(e_i), g(t_i)\}$  found from  $S(t)$ .

$$\begin{aligned} &\text{Define } h : \{1, \dots, N\} \rightarrow \{0, 1\} \text{ such that,} \\ &\forall \text{ event } e = (e_i, t_i) \in E, \forall E \in E' \\ &h(t_i) = 1, h(t) = 0 \text{ otherwise.} \end{aligned} \quad (3)$$

Note that this encoding removes all dependence on amplitude and therefore, no normalization is needed.

Further after binary encoding, string size is shortened by replacing any contiguous block of 1s in a single episode with a single 1, and any contiguous block of 0 in a single complementary episode with a single 0. This is meaningful in the following way. Consider the episode “the stock opening price increases by  $X$  and does not decrease by  $Y$  or more anywhere in the same period”. Thus, intuitively, the entire period of movement over which the price increased is one single episode instance, and the whole set should be seen as ‘1’. The function  $h$  as defined above replaces each time stamp of that period by a 1, and so replacing the entire block by a single 1 gives us the intuitive picture. Also note that, in case of two successive instances of episodes, we get two successive 1s.

```

ALGORITHM FIND_ENCODING_OF_STOCK_TIME_SERIES
Read episode description
 $E = \{(e_i, t_i) : f(e_i), g(t_i)\}$, $B = \phi$
for each $i = 1, \dots, N$,
($N = \text{length of time series}$)
do
 if t_i belongs to a member of episode
 description
 $B = B. '1'$
 else $B = B. '0'$
 enddo
for each episode do
 replace contiguous block of ‘1’ by a single
 ‘1’
enddo
for each complementary episode do
 replace contiguous block of ‘0’ by a single
 ‘0’
enddo

```

Figure 1 shows a snapshot of Apple’s stock opening value data over 16 days. Let us try to encode this with re-

**Figure 1. Stock time series snapshot for Apple**

spect to the episode “the stock opening price increases by 1 USD and does not decrease by 1 USD or more anywhere in the same period”. Note that the first two points show a significant rise, so  $h$  will return 11. Then, points 2 and 3 show a marked decrease, so it will return 00. Points 3 to 7 show another marked dip, returning 00000. Points 7 to 11 shows yet another large dip, giving 00000. Points 11 to 14 show a rise, giving 1111. Points 14 to 16 show a large rise, giving 111. Overall,  $h$  returns the following binary string: 1100000000000111111. Finally, we collapse each member, which gives 100011. Intuitively, this means that Apple’s stock opening value showed a marked rise, followed by three successive significant drops, followed by two marked rises.

Now, after binary encoding of the stock time series, the similarity between two stocks  $S_1$  and  $S_2$  with respect to the episode definition can simply be seen as  $d(S_1, S_2)$ , where  $d(.,.)$  is a string distance measure, like Hamming distance. We use Levenshtein distance [15] and Jaro string distance [14] metric for measuring the distance between two strings.

## 4 Results

Quite clearly, the results are the most important part for evaluating a framework like the one defined above. We try to do that in this section. We have computed results for all pairs of companies across Standard and Poor 500 data set using the full range of 252 days’ data. However, lack of space prohibits a complete discussion across all pairs, so we give a few typical examples.

We define an episode similar to that used for the above example. We look at the opening prices of each stock, and define an episode as “the stock opening price increases by at least 1 USD and does not decrease by 1 USD or more anywhere in the same period”. This is a typical investor cue: is the stock price increasing, and is it increasing sufficiently? If it is, then it may be a good idea to follow it up and invest.

The process of finding the results is as follows. We took

**Figure 2. Stock time series for 6 stocks**

Standard and Poor 500 data set and selected all the companies which had 252 data points. Then we run our algorithm for every pair of companies with the given episode. The data spans over one year. As not all companies in the original data set had full 252 days’ data, the effective number of companies used in the test is 420. Also, observe that the same technique can be successfully used for finding similarities for a group of companies instead of just a pair.

On the basis of the above episode the stock series are first encoded in binary. The similarity between these encoded series is then estimated using Levenshtein and Jaro distances. In this article the threshold for similarity has been taken as 20 and 0.20 for Levenshtein and Jaro distances, respectively. Since the time series that has been used has 252 values for each stock data, when encoded, a binary string of the length of the same order is expected. Therefore, a distance of 20 or less will imply that the two strings are less than 10% different. Jaro metric is somewhat stronger as it considers transpositions, so the condition has been relaxed and a threshold of 0.2 is taken.

All the experiments have been conducted on Standard and Poor 500 data set. However, because of lack of space, we give only a selected set of results here. First, we take six companies which have the first six ticker symbols in S&P 500 data. Second, we take Starbucks, and show the results for some companies whose stock time series follow Starbucks closely. Third, we take Microsoft, and show the results for a set of companies whose stock time series follow Microsoft closely. The aim in this article is to show that hidden similarities often exist in completely unrelated areas, which an investor may not be aware about. In order to highlight the significance of the concept formulated in this article, the results of the proposed approach together with the correlation coefficients are provided.

Figure 2 shows the stock time series for 6 companies viz., Series 1: Agilent Technologies (IT), Series 2: Alcoa Inc. (Materials), Series 3: Apple (IT), Series 4: AmerisourceBergen Corp (Healthcare), Series 5: Applera Corp-Applied Biosystems Group (Healthcare), and Series 6: Ambac Financial Group (Financial).

**Table 1. Values of Levenshtein, Jaro distance and correlation coefficient in an  $X/Y/Z$  form**

	Agilent	Alcoa	Apple	Amerisource	Applera	Ambac
Agilent	0/0/1	12/0.10/0.67	81/0.28/0.86	18/0.14/0.46	13/0.16/ - 0.15	33/0.25/0.59
Alcoa		0/0/1	78/0.30/0.79	14/0.11/0.63	17/0.18/ - 0.60	32/0.22/0.62
Apple			0/0/1	72/0.27/0.65	90/0.36/ - 0.29	51/0.22/0.65
Amerisource				0/0/1	20/0.22/ - 0.41	26/0.18/0.65
Applera					0/0/1	42/0.29/ - 0.24
Ambac						0/0/1

**Figure 3. Stock time series for Agilent and Apple stocks**

From Figure 2, we see that series 1, 2 and 5 are very close, series 4 is slightly off, and series 3 and 6 are quite far away. Interestingly, Agilent Technologies closely follows Alcoa, which are in completely different areas and therefore an investor might not have any cue of this fact unless specifically pointed out. Similarly, Apple seem to be very far from Agilent even though both are in IT sector. The string distances for these set of series are given in Table 1.

As we can see, the pairs (1, 2), (1, 5), (1, 4), (2, 4), (2, 5) are close. (4, 5) is just slightly off (expected, given that 4 is deviating from 5. This is an exact match with the graphically observed result. Note that there are some significant differences if we consider the correlation coefficient, e.g., according to the proposed method, investor should not look at Agilent-Apple pair, while the correlation coefficient suggests that they are close. From Figure 3 it is evident that Agilent is more or less stable in its movement, i.e., it moves up and down without too much fluctuations, as compared to Apple. Recall that the episode definition says that the stocks should increase by 1 USD *without any substantial fall in the same period*. Thus, the investor is looking for only *stable, not fluctuating* stocks that rise or fall steadily. In that respect, even though Apple and Agilent tends to show a high degree of correlation, they are *not good* candidates for a pair trading, and that is exactly what is reflected in the measure proposed. Thus, the string metric helped a cautious in-

**Figure 4. Stock time series for Starbucks stock vs few others**

vestor to detect candidates for a pairs trading with respected to the investor's requirement and not necessarily by a standard, fixed criterion. The other differences are explained similarly.

Figure 4 shows the time series for Starbucks and some similar companies. As is evident, AMD, Circuit City Group, Washington Mutual and Starbucks are very alike in graphs and so are their values in Table 2. However, the correlation coefficients show some disagreement. Consider the plots of AMD and Starbucks as in Figure 5. Recall that the investor is looking for stable movements without too much fluctuations. Note that in the initial period, the two stocks follow each other closely, and around 80th time step, AMD falls but Starbucks gains, making these a perfect pairs trading candidate. Later, the stocks move steadily without much fluctuations and they follow each other closely. Thus, the investor's criterion is well captured even though the correlation metric is ambivalent.

Figure 6 depicts the closeness of Bank of NY to Century Telephones, and that of Microsoft, Symantec and Time Warner to each other. The computed values also reflect these similarities faithfully in Table 3. Note that Time Warner and Microsoft work in different areas, and thus such a strong similarity, though exists and can be very helpful, is not easy to find for an investor. Interestingly, in this case also, the correlation coefficients differ from the string distance measure at times. Consider Figure 7. Here, for both

**Table 2. Values of Levenshtein, Jaro distance and correlation coefficient in an  $X/Y/Z$  form for Figure 4**

	AMD	Circuit City Group	Starbucks	Washington Mutual
AMD	0/0/1	12/0.098/0.82	10/0.12/0.50	11/0.14/0.31
Circuit City Group		0/0/1	12/0.085/0.59	10/0.11/0.29
Starbucks			0/0/1	14/0.135/0.29
Washington Mutual				0/0/1

	Bank of NY Mellon	Century Telephone	Microsoft	Symantec	Time Warner
Bank of NY Mellon	0/0/1	08/0.16/0.89	07/0.16/0.76	06/0.12/0.04	10/0.21/0.84
Century Telephone		0/0/1	11/0.20/0.79	09/0.20/0.16	14/0.27/0.79
Microsoft			0/0/1	03/0.08/0.51	04/0.12/0.92
Symantec				0/0/1	06/0.15/0.33

**Figure 5. Stock time series for AMD and Starbucks stocks**

**Figure 7. Stock time series for Bank of NY and Symantec**

**Figure 6. Stock time series for Microsoft stock vs few other stocks**

**Figure 8. Stock time series for Microsoft and Time Warner stocks, Distance/Correlation Computed 4/0.12/0.93**

**Figure 9. Stock time series for Nicor Inc. and Pinnacle West Capital stocks, Distance/Correlation Computed 12/0.11/0.729**

**Figure 10. Stock time series for Microsoft and Starbucks stocks, Distance/Correlation Computed 26/0.30/ - 0.075**

**Figure 11. Stock time series for Dominion Resources and Ford Motors stocks, Distance/Correlation Computed 54/0.38/0.18**

the stocks the steady fluctuations parts match; and when they diverge they do so by about the same amount from the average, making them an ideal pair for a pairs trade, which is exactly what the string metric suggested, while the correlation coefficient stayed conservative. For a better visualization, two one-one relationships plots are provided. Microsoft vs Time Warner group's similarity is shown in Figure 8, where as that of Nicor Inc. vs Pinnacle West's stocks in Figure 9. Microsoft vs Time Warner, seems to follow each other's pattern quite faithfully, and with a high correlation coefficient of 0.93 they are strong contenders for a pairs trading unit. Nicor vs Pinnacle West has a correlation coefficient of 0.729, and is therefore a sufficiently good pair for pairs trading. Observe the movement of Nicor and Pinnacle West; as Nicor falls Pinnacle grows and they tend to balance each other, making a pairs trading justified from an investor's perspective. In both these cases the similarities are pronounced even though the companies are from different areas.

To illustrate that the algorithm identifies difference between stocks too, the graphs in Figure 10 and 11 show two pairs of very different time series, namely, for Microsoft vs Starbucks, and Dominion Resources vs Ford Motors, respectively. The calculations also show a large separation. Microsoft vs Starbucks show a negative (though close to zero) correlation coefficient, while Dominion and Ford shows a low correlation, making them unsatisfactory pair for a pairs trading.

Finally, we take one example from an expert opinion [11]. The stocks under consideration are Wells Fargo bank and Washington Mutual. In [11], it was shown that these two were good candidates for a pairs trading though it may not be obvious. Our method gave the distance between these two as 16/0.28, whereas the correlation coefficient is 0.47. Thus, the correlation coefficient is not very positive, whereas in our case the indication given by Levenshtein measure is strong, helping the investor to get a better idea about the possible pair.

## 5 Conclusions

The similarity computation between the stocks could be very useful as the dependence between two stocks can reveal some unforeseen insights. This may be more useful if such similarities are computed on the basis of some user defined criterion. It has been shown in this article that such criterion may be defined mathematically. On the basis of such a definition the stock time series is encoded into binary followed by the binary distance computation between them. This computation gives the measure of similarity between the stocks. One such criterion has been used in this article for the illustration using the Standard and Poor 500 data. The results have been found quite significant. This strategy has been explored for the pair trading with some very significant results. Here, it is to be noted that we find the relationship between two stocks without determining if there is a cause and effect relationship. We plan to look at that in future. It is possible to include some other events not dependent on stock time series explicitly, but have significant impact on its growth, e.g., company policy. Such a case is under consideration.

### Abstract

*Behavior-based robots have come under the spotlight in recent years by making their presence known in diverse fields of human interest. Applications in behavior-based robotics have continued to grow in areas such as demining, search and rescue, office automation, health care, etc and continue to replace human beings in risky and menial tasks. With this inspiration, this paper investigates a variety of aspects in behavior-based robotics and the reactive paradigm in the context of their origins, concepts, applications and current research and is intended to provide a comprehensive overview about this area in robotics. The paper will review several central issues including a brief history of robotics, transition of robotic systems from hierarchical paradigm to reactive paradigm, biological/ethological inspiration for behavior-based robots, fundamentals of the reactive paradigm, architectures for controlling robotic behavior and the hybrid deliberative/reactive paradigm.*

### 1. Introduction

The human desire to mechanically model living creatures dates back to pre-Aristotle era (before 350BC), as far as the times where a Greek mathematician, Archytas, is thought to have built a mechanical bird, the first mechanical artifact of the sort [1]. History reveals a large number of examples where humans have attempted to build animal-like artifacts and instances like Leonardo's robot (a knight-like mechanical artifact designed by Leonardo Da Vinci around 1495AD) are mere examples of a larger lot [1]. Thousands of years of such experiments have led us to the present era in which we deal with cognitively advanced robots.

The field of behavior inspired robotics began shaping in the 1950s with the inspiring work done by Grey Walter with

his invention of the electronic tortoise, the first robot to display reactive behavior [7]. Even without any knowledge of its environment or any representation of its world state, the electronic tortoise was able to produce reactive behavior by responding to various forms (the intensity) of light in different ways. Such inventions gave way to a more structured approach to design and implement robots, namely, the hierarchical paradigm. Section 2 covers in detail the characteristics of the hierarchical paradigm and why, after few decades of prevalence, it gave way to the reactive paradigm.

The extent of inspiration from ethological studies in shaping the reactive paradigm has been immense. Thus, section 3 delves into identifying the similarities between animal behavior and robots that are built on reactive behavior. Section 3 also considers how animal behavior relates to perception and action, how multiple behaviors are controlled and coordinated in animals and how schema theory can be adopted to represent these behaviors. Section 4 catalogs the reactive paradigm in detail and discusses how it emerged from ethological studies and became the leading underlying architecture for robotic systems for many years ahead. Several other related topics including how this paradigm deviated from the hierarchical paradigm, its prominent methods for controlling behaviors, the mechanisms to integrate competing behaviors and the shortcomings of this paradigm will be discussed in detail.

Section 5 describes the hybrid deliberative/reactive paradigm. This paradigm addressed the shortcomings of the purely reactive systems by incorporating the planning element into the methodology and has been identified currently as the most favorable architecture to design and implement the robotic systems. A large number of control architectures that are built upon the hybrid paradigm have appeared overtime and section 5 will take into account some of these architectures in order to exemplify the use of the hybrid paradigm.

## 2. Hierarchy Matters

### 2.1. The Unseparable Trilogy

In designing the architectures for robotic control, the earliest robotic systems used a high level structured approach known as the hierarchical paradigm. In systems that followed this paradigm, the robots followed a strict sequence of distinct states known as the SENSE, PLAN and ACT cycle [19]. In the SENSE stage, the robot would acquire information about its environment using its sensors and use this information to create a representative data structure, known as the world model. According to Murphy (2000), the typical world model would comprise of priori information of the environment, sensing information from the robot's sensors and any other cognitive knowledge that would assist the robot in carrying out the specified task. The PLAN stage receives this world model and devises an action plan for achieving the task. In cases when the final goal comprised of complex situations and world states, the planner would break the goal into sub goals and account for each in turn to achieve the final goal. The ACT stage represents the execution of actuator commands that are generated according to the directives received from the planning stage. When the robot's actuators have carried out the task specified, the cycle begins again and continues until the goal is reached.

Among the representative architectures and methodologies that were built on the hierarchical paradigm, the strips method was a forerunner and was used in Shakey, a robot by the Stanford Research Institute [5]. Strips method measured the difference between the goal state and the current state and chose the best action that would minimize the difference. Constructing the world model was imperative and the action to be chosen at a certain point was selected from a descriptive table called the difference table in which differing actions corresponding to varying differences were listed beforehand. During the planning stage of each cycle a difference-evaluator would measure the difference between the current state and the goal state, enabling the planner to select the corresponding commands from the difference table and pass them on to the actuators.

### 2.2. Two Challenging Problems

Among the biggest issues that made the hierarchical paradigm less inspiring with time were the close world assumption and the frame problem [19], [9]. The close world assumption assumes that the robot has obtained all the information it needs about the environment within the world model. Such an assumption presents a significant problem when the environment changes with time since the planner cannot keep track of all the changes of the environment in a continuous manner.

Hierarchical paradigm also suffered what is known as the frame problem [6]. Frame problem is the inability to represent all the world information that was needed by the robot in a computationally viable method. The required intricacy and the detail of the information of the robot's environment were considerable even for the robot that was meant to achieve the simplest task. Consequently, addressing uncertainty in the event of a bigger problem was too tedious and was not worth the effort.

### 2.3. Relaxing The Hierarchies

The nested hierarchical controller (NHC) proposed by Meystel (1986) suggested a method to resolve the aforementioned issues by enhancing the planner by decomposing it into three distinct components, namely, the mission planner, navigator and the pilot [18]. NHC's most obvious deviation from a pure hierarchical architecture was that the sensors would continuously update the world model while the actuators were carrying out the commands. This gave a more realistic response in terms of the receptiveness to the changes in the environment.

A similar architecture was proposed by Albus through his real-time control system and was an architecture that was heavily influenced by the NHC architecture [8]. Shananhan presented a logic-based high level robotic control approach which also used a hierarchical approach to control the robot's behavior [20].

Even with these proposed strategies to enhance the hierarchical paradigm, the fact that this paradigm fails to address uncertainty has made people look for different paradigms for robotic control. Thus, with the advances in the field of artificial intelligence, cognitive psychology and ethology, people turned to studying animal behavior and understanding how behavior coordination is handled biologically.

## 3. Animals To The Rescue

In the early days of robotics, the notion of using animal behavior as models in developing robotic systems was treated with much detest due to several reasons. The strongest argument against using animal behaviors was the inadequate knowledge of the intricate biological intelligence that was available at the time. Secondly, the available technology at the time was hardly sufficient to model even the simplest animal behaviors that had been identified.

However, the advances in cognitive psychology and ethology combined with the growing limitations faced in the hierarchical paradigm gave the roboticists an incentive to return to these biological studies and to search for new paradigms for robotic control. Still, the findings in these areas were not comprehensive enough to produce a model

for robotic behavior that would directly map to a biological behavior. As a result, roboticists tried to come around this issue by going in the reverse direction, i.e. to build models for robotic behavior and to find confirmation of those behavioral models in biological and ethological findings. Furthermore, animals interact with a much more relaxed, open environment and thus the study of their behaviors provided a foundation to tackle the close world assumption which proved to be the biggest obstacle in the hierarchical paradigm [19].

### 3.1. The Basic Building Block

The foundation of behavior-based architecture for robotics lies in the definition of a behavior. In its simplest form, a behavior is a mapping of sensory inputs to a pattern of actions that in turn carries out a specific task [19]. Animal behaviors have been studied in three broad categories, namely, reflexive behaviors, reactive behaviors and conscious behaviors [19]. Reflexive behaviors are direct stimulus-response mappings in which the response to a particular sensory input is directly wired with a response and which is carried out without any cognitive involvement of the subject. An example for this type of behavior can be the reaction of a person's knee when it is tapped. The second category concerns with the behaviors that are learned over time and are ultimately embodied in the system such as learning to ride a bicycle or learning to walk in early childhood. Every other behavior that requires conscious thought throughout the time of the action is categorized as conscious behavior.

In behavior-based robotics, reflexive behavior prevails over any other behavior type. Therefore, this paper will confine only to the reactive systems and will describe in detail how reactive behavior is introduced in robotics. However, there is a slight difference in the connotations between robotic literature and ethology. The word 'reactive' actually means reflexive behaviors in robotics while in other disciplines the word 'reactive' refers to the learned behaviors.

### 3.2. Behavior Diversity

In studying the reflexive behavior of animals, ethologists have been able to identify three forms of reflexive behaviors [19]. These forms can be explained as follows.

**Reflexes:** Where the magnitude of response is directly proportional to the intensity of the stimulus and lasts as long as the stimulus lasts. This form of behavior is visible in domestic millipedes and certain snails where they would contract their muscles in response to a disturbance [9].

**Taxes:** Where the response is an orientation towards or away from the stimulus. The best examples for this kind of

behavior is the Chemotaxis [2] behavior of trail following ants and the behavior of sea turtles who would head directly to the sea once they are born. It has also been discovered that certain animals react to the magnetic field of the earth and display behavior accordingly [4].

**Fixed Action Patterns:** Where the response lasts for a longer time than the stimulus and where the behavior can be influenced from multiple stimuli rather than from a simple stimulus [3]. Examples are drawn for this sort of behavior in animals fleeing away from predators, the singing of crickets and locust fly patterns [9].

It should not be misunderstood from the above description that a pair of stimulus and response is all that needs in reflexive behavior. A mechanism to release the behavior in the presence of a stimulus should also exist in order to execute the behavior.

Innate Releasing Mechanism (IRM) was a phrase coined by Lorentz and Tinbergen (1973) to denote the mechanism by which a specific behavior is initiated [9]. The underlying explanation is that a behavior will not be initiated even in the presence of sensory inputs unless some mechanism was present to initiate that behavior. One of the simplest examples from the animal world is that most predators would not hunt prey unless they are hungry, even if the prey wanders close by.

A releaser, which can be presumed to be a boolean value, has to be set in order to initiate the behavior. In most occasions, compound releasers, probably both internal and external, have to be present in order to trigger a behavior. This essentially means that IRMs act as control switches for releasing behaviors and provide a low level coordination mechanism for triggering and inhibiting basic behaviors.

### 3.3. Controlling Behaviors

Another advantage of studying animal behavior is the ability to understand how the concurrent, competing behaviors are handled biologically. Ethologists have identified several biological mechanisms that animals portray when they are faced with competing behaviors. These mechanisms that make choices between competing behaviors can assist roboticists in modeling robots with concurrent behaviors and several of such control mechanisms are listed below.

**Equilibrium:** Occurs when a dominant behavior cannot be identified and no behavior takes precedence over the other behaviors. Murphy (2000) illustrates the example of a squirrel on a park bench that sights a bread crumb near a person sitting on the edge of the same bench [19]. Most times it can be seen that the squirrel seems to be lost in a dilemma whether to go for the bread crumb (execute the

feed behavior) or to flee from the situation (execute the flee behavior).

**Dominance:** Occurs when one behavior clearly dominates the others. The obvious example is that animals cannot eat and sleep at the same time.

**Cancellation:** Occurs when the competing behaviors cancel each other out so that a completely new behavior is displayed. Murphy (2000) draws an example from male stickleback fish. Sticklebacks get caught up in between defending their nests and attacking the enemies when their territories are threatened and end up building a new nest altogether in a different place [19].

### 3.4. A Novel Representation

Perception is a crucial factor in animal behavior as it plays a vital role in coordination and selection of different behaviors. Arkin (1998) identifies that perception can be two-fold at the highest level: Proprioception, which refers to perceptions arising from stimuli that are internal to the animal's biological system (For e.g. hunger) and exteroception that relates to perceptions arising from external stimuli such as the cue of a predator nearby [9].

An interesting theory presented by Gibson (1979) that has assisted the way roboticists think in terms of behaviors is the theory of affordances [15]. Affordances differ from stimuli in that affordances take into account the environment in which the stimuli was produced. A better explanation is that an affordance is a potentiality for inherent action [19], [9]. This analysis of perception and affordances leads to the intriguing issue of representing this information in robots. One successful way around this problem was presented by Arbib (1992) through his famous schema theory. Schema theory facilitates the representation of perceptual and motor-action information in a similar way to that of object oriented concepts. A schema is an entity comprising of perceptual data and computational activity that result in motor actions. Accordingly, a behavior is defined as comprising of perceptual schemas and motor schemas, one from each at a bare minimum [21]. Schema theory also backs the concept that complex behaviors can be comprised of much simpler behaviors, thus facilitating the behavior subdivision in robotic systems.

### 3.5. From Animals To Robots

Several concrete implementations stemming from these studies have been surfacing over the years and it appears necessary that a few of those examples be drawn out here. The chemotaxis display of ants has been modeled using robots that can sense a chemical trail left by other robots and these experiments have been a success in the study of multi-robot environments and how behavior coordination is

handled in such environments [9]. The locomotion patterns of the insects such as cockroaches have provided the substance to another research area and this area has concentrated on aspects such as path following in robots and other navigational behaviors. The artificial insect project gives examples for such experiments in great detail [13].

## 4. Planning: To Do Or Not To Do

The highlight of the reactive paradigm was its basic building block - a behavior [9]. As mentioned earlier a behavior is a direct mapping of sensory inputs to the corresponding motor actions. The biggest difference the reactive paradigm had introduced from the earlier hierarchical paradigm is the removal of the planning stage from the Sense-Plan-Act triad. This was due to the popular belief among the roboticists that maintaining world state, history information and planning of actions, no matter how efficiently designed, only adds to the deterioration of the performance of the system. Thus, the reactive paradigm relied on behaviors and the fact that emergent behavior of the system can be produced by different mechanisms that are available to coordinate these behaviors. The concept of a behavior facilitated solid architectures that allowed extension of older behaviors, inhibition of behaviors, parallel execution of behaviors and many other coordination mechanisms that produced the emergent behavior of the complete system [19].

Two other important considerations in behavior-based robotics are the local sensing techniques and the ecological niche. In the case of sensing, reactive paradigm advocates the use of a specific sensor input for each behavior. This effectively means that each behavior takes sensory inputs from a sensor that is local to it and passes this information to the perceptual schema. However, latter systems were built with architectures that can share sensory information where several behaviors would use sensory information from a single sensor.

The other important consideration in reactive robotics is the concept of an ecological niche. An ecological niche, from a purely biological point of view, means the environment in which the animal lives in and relative to which its behavior can be defined. In terms of robotics, this means that the roboticists should design the robot targeting a specific environment since the robot's interaction in a different environment would be meaningless and would not result in the expected outcomes.

### 4.1. Status Representation

In developing reactive architectures, several representational mechanisms have been introduced [19], [9]. Some of these representation mechanisms can be listed as follows.

**Stimulus-Response diagrams:** Presents a very primitive way to represent the collection of behaviors that are coordinated. This mechanism simply portrays each behavior as a mapping of sensory stimuli and the action response.

**Functional Notation:** Presents the behaviors in a procedural manner that is similar to a pseudocode of a general program. Murphy (2000) explains a similar method named scripts that functions as a general script of a play [19].

**Finite State Acceptors:** Presents a general approach that is used in many other areas in computer science that is used to express the situational information of a system. A finite state automata is defined as a tuple  $M = \{Q, \Sigma, \delta, q_0, F\}$  with the symbols representing the set of states, the input alphabet, the transition function, the start state and the set of acceptable final states respectively. This definition is best used in its graphical form and presents a clear method of understanding the interaction of different behaviors.

## 4.2. Building Upon The Reactive Paradigm

Behaviors by themselves are of little importance to a reactive system unless they are coordinated to produce the emergent behavior of the whole system. Several architectures have emerged over the years and have presented varying approaches to coordinate behaviors in robotic systems. This paper focuses on the two most tried architectures of all, namely, subsumption and potential-fields methodology.

In 1986, Brooks presented an inspiring paper titled “Intelligence Without Representation”, in which he questioned the viability of representing the world state and planning the sequence of actions in robotic systems [11]. He vehemently questioned the practicability of using specific data structures and attempting to model the robot’s environment. Instead, he stressed that ‘the world is its own representation’, i.e. that any other representation of the world that was to be used in the robotic systems would be futile since no model can perfectly account for the uncertainties of the real world.

Consequently, Brooks (1987) presented an architecture for controlling and coordinating the robotic behaviors, for which he gave the name, subsumption. Subsumption builds on layers of competencies (or simply, a collection of behaviors that achieved a specific task) that are vertically arranged in the order of their sophistication. Thus, the basic survival behaviors such as collision avoidance are aligned in the lowest layer while more cognitive behaviors such as path mapping are aligned in the higher levels [19]. The higher layers have the ability to inhibit or suppress the behaviors of the lower layers, hence the word, subsumption.

The layers of competences are supposedly executed independently with each behavior having its own sensorial

system and each behavior being unaware of what’s happening in the other layers. Each layer executes a dedicated behavior and this avoids the need for them to know the complete scenario they are trying to solve.

However, this separation of layers calls for a mechanism to control and coordinate the behaviors when several of them are trying to execute simultaneously. Subsumption resolves this issue by always giving the higher layer the ability to take control and override the behaviors of the lower layers. Allowing such superimposing behavior requires that the higher level behaviors embody the competencies of the lower layers.

Subsumption does not come without its shortcomings. First, the inclusion of lower-layer-competencies in higher levels means a waste of resources. Second, there often arises the requirement to pass information between layers and pure subsumption architecture acts in contrast to this by precluding the layers from passing information between themselves [24]. Finally, the subsumption architecture fails to take into account any advantage a planning module can introduce to the system.

Several solutions to address these rigidities of the subsumption architecture were proposed by many and they introduced several alterations to the original architecture. One such proposition (Flanagan et al, 1995) brought in three variations to the original architecture [24]. This method substituted the competences of the subsumption architecture by individual processes with each process carrying out a defined task. The methodology also added a global data structure where each process can post and read interesting data to and from this data structure. Finally, they included a priority scheme that allowed the behaviors to compete for control and made this priority scheme time varying so that no single behavior can hold up the robots control for a long time.

Yongjie, Qidan and Chengtao (2006) presented another modification to the subsumption architecture by assuming a hybrid control approach that was based on subsumption [12] (hybrid control architectures will be discussed in detail in section 5). In addition to the use of processes as in the previous approach, this methodology also introduced a behavior-managing layer. The task of the behavior-managing layer was to adjust the behavior parameters (for e.g. priorities, behavior arithmetic etc) according to a number of factors that effected the robotic system at a certain point in time. Finally, they added a scheduler to the system to select which behavior process will take control of the system and provide the necessary actuator command.

No matter how hard it is tried to reduce the rigidity of the purely reactive subsumption architecture, there always is a tradeoff in performance when planning and its constituent data structures are introduced to the system. However, this tradeoff will be justified in complex systems where purely

reactive systems are insufficient to provide the complete behavior.

Another approach taken by the proponents of the reactive paradigm is a methodology known as the Potential Fields Methodology (PFM). PFMs build on the groundwork that each behavior is represented as a vector and thus the methodology is inherently regarded to be confined to the navigational robots. These behaviors, represented as vectors, are combined in vector summation to produce the emergent behavior.

For presentational purposes, these behaviors are assumed to exert on the robot in the form of force fields by the objects in the environment and are illustrated as magnetic or gravitational fields. For e.g. an obstacle in the environment may be illustrated as emitting a repulsive field from its vicinity as much as a bulb is radiating light whereas a goal in the environment can be illustrated by an attractive field on the surrounding area. In representing these force fields, the general representation of the vectors, where the magnitude of the vector is given by the length of the arrow and the orientation given by the angle, can be used (For e.g. in the case of a navigational robot, the length of the vector represents the velocity and the angle represents the direction of the robot). The robot is assumed to be a particle entered into the force field area and the behavior of the robot is the path the robot takes as a result of the multiple potential fields [19]. Magnitude profiles are used to control the strength of the potential field to avoid the unpleasant outcomes caused by having a constant strength throughout the field (For e.g. to avoid over shooting a goal, the field will be calculated such that the strength of the field is a reducing function of the distance between the robot and the goal. As the robot moves closer to the goal, the magnitude of the force reduces so as to allow collision-free arrival at the goal).

One common misconception is that the PFM requires the calculation of the entire field in one occurrence. However, this is not the case. The robot only needs to calculate the force fields that exert on it in each Sense-Act cycle [19]. Thus the computational load that would appear to exist in designing the complete force field at once is greatly reduced.

The greatest drawback of the PFM is the possibility of local minima existing in the force field environment. A local minimum occurs where the strength and orientation of the vectors cancel each other out so that the robot caught up in such a situation will be stuck there forever. Masoud (1996) proposed a way around this issue by introducing Harmonic Potential Fields [17] while Iianmiao and Bo (1992) introduced time-varying potential fields [9]. Arkin (1987) suggested an approach where random noise can be injected to the fields to shake off the robot out of a local minimum trap [9].

Koren and Borenstein (1991) draw a detailed mathemat-

ical analysis of several other limitations and drawbacks of the PFM and proposed an altogether different methodology for obstacle avoidance in navigational robots in real time environments [10].

Reactive paradigm emerged as the ultimate solution for the rigidities put forth by the hierarchical paradigm. Though this newly found paradigm proved more than satisfactory in robots executing simple tasks, the obvious need for planning in more complex tasks emerged with time. Hence, roboticists looked into new ways of combining the planning process with the reactive behavior of the robots and thus a new breed of architectures under the name Hybrid Deliberative/Reactive paradigm was born.

## **5. One Step Ahead: The Hybrid Deliberative/Reactive Paradigm**

### **5.1. The Need For Planning**

The reactive paradigm started showing its limitations when moving into domains with complex tasks that required cognitive capabilities rather than just reactive behavior. These requirements were presented in the form of efficient path planning, map making and performance evaluation of the robot itself, etc, and the reactive paradigm proved incapable of satisfying these requirements.

The proponents of the hybrid architecture advocate the use of the advantageous aspects of each of the previous two architectures and combining them to produce the desired architecture for the complex scenarios. Effectively, this meant that the planning aspect of the hierarchical paradigm was to be integrated with the rapid execution capabilities of the reactive paradigm. The technological foundations for such an architecture was emerging as well and these technological aspects facilitated such integration in the two paradigms (For e.g. the emergence of multithreaded architecture allowed the planning process to be executed simultaneously with the reactive behaviors but as a separate module from that of the reactive modules).

### **5.2. Integrating Plans**

The hybrid paradigm altered the Sense-Plan-Act trilogy by allowing the Plan stage to be executed separately from the Sense-Act sequence. Arkin (1998) mentions three broad methods for integrating planning with reactive behavior [9]. Hierarchical integration makes the planning layer and the reactive layer to be aligned vertically in which the planning layer provides the information on which the reactive layer acts. Second method involves planning layer working prior to or concurrently with the reactive behaviors, updating the robots behavioral parameters or changing the world state.

Finally, coupled planning-reacting method makes the planning and reactive activities to occur concurrently, allowing each one to interact with the other in real-time.

Another interesting deviation of hybrid architectures from the reactive paradigm is that the sensors that were unique to each behavior in the reactive paradigm are now shared with the planning modules. Planning needs to create world models and to represent the state of the environment and thus the use of sensorial information is imperative.

### 5.3. The Hybrid Features

Though the architectures that fall under the hybrid paradigm vary considerably in their designs, several common features can be identified in most of them [19], [9].

**Sequencer:** The task of the sequencer is to generate the set of behaviors that should be executed and their sequence in order to carry out a specific task. A dependency network or a finite state machine is generally used in coordinating these behaviors.

**Resource Manager:** Introduction of this module was primarily due to the fact that resources such as sensors are now been shared between the planning and reactive modules. Resource manager handles the allocation of sensors and other resources between different modules and selects the best resource that should prove practical for each module.

**Cartographer:** The cartographer module's main application is to create, store and maintain maps of the robotic environment by interacting with the external world. This module facilitates the knowledge representing scheme of the robot by maintaining and updating the data structures pertaining to the world model.

**Mission Planner:** This module's task is two fold. Initially, it presents an interface to the outer world and secondly it transforms the external commands into robotic terms, subdivides the tasks and forwards the subtasks into actuator modules to carryout.

**Performance Monitor:** Robot's performance in executing a given task should be evaluated in order to verify if the robot is carrying out its tasks as it should be. The performance monitor measures the robots performance in comparison to previously set targets by the mission planner and prompts any unfavorable activity.

### 5.4. Hybrid Architectural Styles

Murphy (2000) draws out three architectural styles that are visible in the hybrid paradigm.

Managerial Style architectures pose the general managerial style that is evident in an organizational hierarchy by subdividing the tasks in each module and allowing each

task to be carried out by a subordinate module. Secondly, State Hierarchies style uses the robot's state to determine the appropriate action. The reactive behaviors are thought to maintain no state while the deliberative modules keep track of the world model and the past actions of the robot. Finally, Module-Oriented styles follow architectures that closely resemble the ones in hierarchical paradigm in which most modules have access to the world models individually.

### 5.5. Representative Architectures

In discussing the varied architectures that were based on the hybrid paradigm, Autonomous Robot Architecture (AuRA) proposed by Arkin (1998) draws special interest. In this architecture the previously mentioned five models of a hybrid paradigm were clearly visible and the architecture had clear division between the deliberative and the reactive layers.

Stenzel (2000) presents a utility-based approach to handle the problem of combining commands of different behavior mechanisms [23]. Additionally, his approach uses a priority management system to asses the importance of goals and this system uses subsumption to inhibit the low priority goals giving way to the high priority ones. Egerstedt and others (1999) used hybrid automata to depict each behavior of the robot and allowed the behaviors to fuse rather than to allow one behavior to overpower the other [16]. Li and Feng (1994) proposed a fuzzy logic based approach to coordinate the behaviors of navigational robots. In this approach, they used fuzzy reasoning to weigh the reactive behaviors rather than to inhibit the lower level behaviors as in the subsumption process [14]. A similar behavior-based neuro-fuzzy controller was introduced by Rusu and others (2003) where the coordination system was organized in a top-to-bottom hierarchy and in which command fusion using neuro-fuzzy subsystems were used to handle multiple low level behaviors [25].

A comprehensive study of behavior coordination mechanisms in behavior-based robotics has been presented by Piranian (1999) and this paper covers in detail all the alternative methods in addition to the primary methods discussed above [22].

## 6. Conclusion

The reactive paradigm answered many problems that were persistent in the early robots due to the rigidity that was present in the hierarchical paradigm. Robots that were based on reactive behavior proved much more efficient and showed rapid execution in performing its specified tasks.

However, the inability to cater into much more complex task domains has made the pure reactive behavior-based robots to decline in popularity with the emergence of the

hybrid paradigm. The obvious need for a planning module to provide the necessary information required to handle the complex behaviors and complex environments has made the latter paradigm much popular towards the recent years.

Even the inclusion of the planning element does not make the robots as intelligent as we would expect them to be. It may be true that a robot is able to find the most efficient path to a goal, to measure its performance, to produce efficient representations of the environment, etc but in order to reap the real robotic performance, a learning process has to be integrated to the system. The field of machine learning has been producing a lot of results that cater to this need but the extent to which the robotic world has made use of these mechanisms is still questionable.

Research areas such as cognitive modeling has been devising models to produce intelligent behavior in machines at a conceptual level but the implementation of such models in robots still seems to be at a very rudimentary level. However, it can be expected that with the advancements of such research which try to model human intelligence in machines could take the behavior-based robotics to the next level, a level in which the robots can cope up with the uncertainties of its environment at a highly acceptable level.

Therefore, the future that we are looking at in the context of behavior-based robotics, to a large extent, would focus on hybrid architectures with robotic learning playing an important role. The extent to which robotics can benefit from areas such as machine learning, cognitive modeling, etc leaves us with optimism, where we can hope for the newest robots to be cognitively much more advanced than their precursors.

### Abstract

*In this paper, we present a reversible watermarking algorithm which provides higher embedding capacity and higher PSNR value compared to the existing algorithms. In the proposed algorithm, we utilize a peak point of image histogram and increase the height of the peak by transferring the pixels from the neighbouring gray values to achieve the higher embedding capacity.*

### 1. Introduction

Development of computer technology and widespread use of internet have driven this world into fast-changing digital place. With digitization of multimedia contents, everybody can access multimedia contents more easily than in analog age. Even if digitization of the multimedia contents provides more opportunities to media contents, it also provide easy access paths to copy and distribution of digital contents, because of characteristics of the digital data, represented by 0 and 1. As the copy and distribution of digital contents are widely conducted illegally in internet environment, the copyright holders began to pay attention to copyright protection technologies. Off the technologies that can protect copyright of digital contents, watermarking technology has received keen interests from research communities.

Watermarking technology hides copyright information into original contents to protect copyright, which eventually leads to modification of original contents[1]. However, in order to achieve the goal of imperceptibility, the watermarking technology modifies original contents so that the modification is not perceptible to naked eyes using Human Visual

System (HVS) modelling. As a result, the original image cannot be recovered when the image is watermarked. In the applications where a slight modification can lead to significant difference in final decision making process, such as medical images or military images systems, there has been a requirement of recovery to original contents[2]. For the reason, there have been research efforts of reversible watermark that can recover to original images from watermarked images.

This paper is organised as follows. The overview of the existing scheme and the proposed scheme is presented in section 2. The procedure for the proposed technique is explained in section 3. The section 4 deals with simulation results and analysis with conclusion in section 5.

### 2. Increased Peak Histogram

The Ni et al. [3] utilizes zero or minimum point histogram. If the peak is lower than the zero or minimum point in the histogram, it increases pixel values by one from higher than the peak to lower than the zero or minimum point in the histogram. While embedding, the whole image is scanned. Once a peak-pixel value is encountered, if the bit to be embedded is '1' the pixel is added by '1', else it is kept intact. Alternatively, if the peak is higher than the zero or minimum point in the histogram, the algorithm decreases pixel values by one from lower than the peak to higher than the zero or minimum point in the histogram, and to be embed bit is '1', the encountered peak-pixel value is subtracted by 1. The decoding process is quite simple and opposite of the embedding process.

In this algorithm the maximum amount of data that can be embedded is limited by the peak value of the histogram of the cover image. In the proposed algorithm efforts has been made to increase the peak

to the maximum without changing the perception.

**Figure 1. Host Image (Lena) Histogram.**

**Figure 2. Histogram of Lena (zoomed around peakpoint)**

**Figure 3. Increased Peak Histogram**

The proposed algorithm makes use of the assumption that most of the gray values around the peak has relatively large number of pixels[5][6]. So the embedding capacity is increased by increasing the number of pixels at the peak.

From the histogram of the Lena image of 512 x 512 x 8 size, as shown in the fig 1. it is observed that the maximum peak point or the gray value is at 154( maximum number of pixels) and is represented as 'Peakpoint'. Neighbouring gray values towards the left of Peakpoint such as ...152, 153 and the gray values towards the right of Peakpoint such as 155, 156 ..... are represented as 'Peakpoint-2', 'Peakpoint-1' and 'Peakpoint+1', 'Peakpoint+2' respectively. The number of pixels for various peak points of Lena image is shown in Figure 2.

By transferring the pixels from 'Peakpoint-2', 'Peakpoint-1', 'Peakpoint+1', 'Peakpoint+2' and so on, we could observe the maximum peak point is increased to 22596 bits. This process is continued until there is no perceptual disturbance in the watermarked image. Using this method the number of pixels in the maximum peak can be increased by approximately ten times. The Figure 3. is scaled down, to show the increased peak.

The increase in capacity results in a slight decrease in the PSNR with out changing visual appearance of the image i.e. the image is highly imperceptible.

### 3. Data embedding and extraction

This algorithm makes use of the peak of the histogram of the host image, since the maximum capacity is limited by the peak value of the histogram of the host image, this peak value is modified as discussed in the section 2. to suit for maximum embedding capacity. The proposed algorithm is summarised as follows:

#### 3.1 Data Embedding

**Input:** Host image, Watermark data.

**Output:** Watermarked image.

1. The histogram of the host image is scanned to find the peak point (i.e. the gray level having maximum number of pixels).
2. Then maximum increased peak is achieved as explained in section 2.

3. To embed data the host image is scanned to find 'Peakpoint'. The data to be embedded is then scanned.
  - (i) If a binary value '1' is to be embedded then the pixel gray value is changed from 'peakpoint' to 'peakpoint+1'..
  - (ii) If a binary value '0' is to be embedded then there is no change in the pixel gray value.
4. Step 3 is repeated till the entire data is embedded into the host image to produce the watermarked image.

### 3.2 Extraction

**Input:** Watermarked image

**Output:** Recovered original host image and watermark

1. Watermarked image is scanned to retrieve the information such as size of watermark and the 'Peakpoint'.
2. Once again the watermarked image is scanned pixel by pixel. Each time when we encounter a pixel with gray value 'peakpoint+1' we extract a binary value '1' or when we encounter a pixel with gray value 'peakpoint' we extract binary value '0'. In this way the hidden data is extracted. For example if the watermarked image is Lena, each time when we come across gray level 155 a '1' is extracted and when we come across gray level 154 a '0' is extracted.
3. In order to recover the original host image the reverse of the embedding process is carried out.

The performance of the algorithm is determined by calculating the Peak Signal to Noise Ratio (PSNR)

$$\text{PSNR} = 10 \log_{10}((255 \times 255) / \text{MSE}) \quad (1)$$

Where MSE is the Mean Square Error between the original image and the watermarked image.

### 4. Simulation results

The simulation is carried out using MATLAB. Standard test images of 512 X 512 x 8 grayscale were used in studying the effects of perceptibility and quantity of information hiding or payload, for the reversible data hiding technique.

Watermarked and extracted Lena image is shown in the Figure 4., Figure 5 and 6 show the 193 x 117 size watermark and extracted watermarked image. The above figures show no visual disturbance with this algorithm. The PSNR and payload is calculated for the test images shown in Figure 7.

The comparison between the existing reversible watermarking scheme and proposed scheme in terms of embedding capacity and the PSNR is presented in Table I. The PSNR of minimum 57.13 dB to 61.79 dB is achieved for various test images. There is a 10dB improvement from the existing algorithm.

The embedding capacity for Airplane test image is 58,679 bits using our method, 16,171 bits are embedded using Ni. et al. algorithm whereas 8,155 bits can be embedded without modifying the peak of the original histogram. Data embedding capacity is increased by 3.5 times with Ni.'s algorithm and 7 times with unmodified original histogram.

From the Table I. it is observed that payload for other test images is around 22000 bits with improvement of 300 percent. from the results we can conclude that embedding capacity depends on the nature of the histogram.

Table II shows the variation of PSNR with respect to the brightness of the image. For darker watermark image the PSNR is 64.81 dB and it is decreased to 60.05 dB for brighter image. If the image is a brighter one then PSNR can be improved by negating the watermark before embedding.

**Figure 7. Watermarked Images**

**Table I**  
**Comparison between existing and proposed reversible watermarking method**

Test images	Existing Method		Proposed method		
	PSNR of marked image (dB)	Embedding Capacity (bits)	PSNR of marked image (dB)	Embedding Capacity (bits)	% increase
Airplane	48.3	16,171	57.54	58,679	262
Pepper	48.2	5,449	61.85	22,820	318
Lena	48.2	5,460	61.79	22,596	313
Sailboat	48.2	7,301	60.80	29,382	302
Baboon	48.2	5,421	60.67	27,665	410

**Table II**  
**Brightness of the watermark Vs PSNR**

Number of 1's(%)	Number of 0's(%)	PSNR (dB)
25	75	64.81
40	60	62.78
50	50	61.80
60	40	61.01
75	25	60.05

## 5. Conclusions

Our proposed technique is able to embed about 22kb - 59 kb into a 512 x 512 x 8 gray scale image with the average PSNR of 57 dB. Our algorithm does not depend on the minimum or zero peak point of the histogram and also it is independent of shifting of range cells of the histogram, whereas in the existing algorithm the maximum embedding capacity is limited by the frequency of peak-pixel value in the histogram and also the range of bins towards the minimum peak point gets shifted was contributed for lower PSNR value.

In the existing reversible data embedding methods it has been observed that there is a trade off between higher data embedding capacity and degree of perceptibility. The proposed algorithm achieves both the above mentioned criteria, i.e., high data embedding capacity as well as imperceptibility.

### Abstract

*Web mining is defined as applying data mining techniques to the content, structure, and usage of Web resources. The three areas of Web mining are commonly distinguished: content mining, structure mining, and usage mining. In all these areas, a wide range of general data mining techniques, in particular association rule discovery, clustering, classification, and sequence mining, are employed and developed further to reflect the specific structures of Web resources and the specific questions posed in Web mining. In this paper, we introduced a web document clustering approach that uses WordNet lexical categories and fuzzy c-means algorithm to improve the performance of clustering problem for web document. Experiments show that Fuzzy c-means algorithm achieves great performance optimization with comparison with the recent algorithms for document clustering.*

### 1. Introduction

The Web is a huge collection of documents that comprises some features like (1) semi-structured (HTML, XML) information, (2) hyper-link information, (3) access and usage information and (4) dynamic page generation. The Web has made cheaper the accessibility of a wider audience to various sources of information. The advances in all kinds of digital communication have provided greater access to networks. It has also created free access to a large publishing medium. These factors have allowed people to use the Web and modern digital libraries as a highly interactive medium [3].

Web mining is the application of data mining techniques to the content, structure, and usage of Web resources. It is thus “the nontrivial process of identifying valid, previously unknown, and potentially

useful patterns” [8]. Web mining application works on huge amount of Web data to extract some patterns that can describe this data. Like other data mining applications, Web mining can profit from given structure on data (as in database tables), but it can also be applied to semi-structured or unstructured data like free form text. This means that Web mining is an invaluable help in the transformation from human-understandable content to machine-understandable semantics.

Web content mining can be used to detect co-occurrences of terms in texts. For example, co-occurrences of terms in newswire articles may show that “gold” is frequently mentioned together with “copper” when articles concern Canada, but together with “silver” when articles concern the US. Trends over time may also be discovered, indicating a surge or decline in interest in certain topics such as the programming languages “Java”. Another application area is event detection: the identification of stories in continuous news streams that correspond to new or previously unidentified events [1].

Web content mining analyzes the content of Web resources. Today, it is mostly a form of text mining that can be defined as the process of extracting interesting information and knowledge from unstructured text. Text mining can be also defined as the application of algorithms and methods from the machine learning and statistics fields to texts with the goal of finding useful patterns [4]. In this paper, we deal with web content mining as an application of text mining process for input web documents.

One main reason for applying data mining methods to text document collections is to structure them. A structure can significantly simplify the access to a document collection for a user. Well known access structures are library catalogues or book indexes. However, the problem of manual designed indexes is the time required to maintain them. Therefore, they are

very often not up-to-date and thus not usable for recent publications or frequently changing information sources like the World Wide Web. The existing methods for structuring collections either try to assign keywords to documents based on a given keyword set (classification or categorization methods) or automatically structure document to find groups of similar documents (clustering methods).

Text document clustering can be defined as the process of grouping of text documents into semantically related groups [2]. Clustering methods aims to form the input documents into a set of clusters. Each cluster consists of number of documents that are similar to each other and dissimilar to documents of other clusters.

Many well-known methods of text mining have two problems: first, they don't consider semantically related words/terms (e.g., synonyms or hyper/hyponyms) in the document. For instance, they treat {Vehicle, Car, and Automobile} as different terms even though all these words have very similar meaning. This problem may lead to a very low relevance score for relevant documents because the documents do not always contain the same forms of words/terms.

Second, on vector representations of documents based on the bag-of-words model, text mining methods tend to use all the words/terms in the documents after removing the stop-words. This leads to thousands of dimensions in the vector representation of documents; this is called the "Curse of Dimensionality". However, it is well known that only a very small number of words/terms in documents have distinguishable power on clustering documents [9] and become the key elements of text summaries. Those words/terms are normally the concepts in the domain related to the documents.

Recent studies for fuzzy clustering algorithms [25, 26, 27, 28] have proposed a new approach for using fuzzy clustering algorithms in document clustering process. But these studies neglect the lexical information that can be extracted from text as we used WordNet lexical categories in our proposed approach.

In this paper, we introduced an efficient approach web document clustering approach that uses WordNet lexical categories and fuzzy c-means algorithm to improve the performance of clustering problem for web document. The proposed approach uses WordNet words lexical categories information [12] to reduce the size of vector space and present semantic relationships between words. The generated document vectors will be input for the clustering process. In the clustering process we use fuzzy c-means algorithm to increase the clustering accuracy as shown in the experiments.

The rest of this paper is organized as following; section 2 show the proposed web document clustering approach. In section 3 a set of experiments is presented to compare the performance of the proposed approach with current document clustering algorithms. Related work is discussed and presented in section 4. Finally, conclusion is given in section 5.

## 2. Web Document Clustering Approach

In this section we describe in details the components of the proposed fuzzy web document clustering approach. There are two main processes: first is Feature Extraction that generates output document vectors from input text documents using WordNet lexical information as illustrated in figure 1.

**Figure 1: Fuzzy Web Document Clustering Approach**

The second process is Document Clustering that applies fuzzy c-means algorithm on document vectors to obtain output clusters.

### 2.1. Feature Extraction

The first step in the proposed approach is feature extraction or documents preprocessing which aims to represent the input web documents collection (corpus) into vector space model. In this model a set of words (terms) is extracted from the corpus called "bag-of-words" and represent each document as a vector by the words (terms) it contains and their weights regardless of their order. Documents preprocessing step contains five sub-steps: Text Extraction, PoS Tagging, Stopword Removal, Stemming, and WordNet Lexical Category Mapping.

**2.1.1. Text Extraction.** The first step of the feature extraction process is to extract textual data from the

web pages. Then convert each page into individual text document to apply text preprocessing techniques on it.

This step is applied on input Web documents dataset by scanning the web pages and categorizing the HTML tags in each page. Then exclude the tags that contain no textual information like formatting tags and imaging tags (i.e. <HTML>, <BODY>, <IMG>, etc.). Also exclude all the scripts and codes that are found in the page like JavaScript and VBScript. Then extract the textual data from other tags (like paragraphs, hyperlinks, and metadata tags) and store it into individual text documents as input for next steps.

**2.1.2. PoS Tagging.** The second step is to PoS tag the corpus. The PoS tagger relies on the text structure and morphological differences to determine the appropriate part-of-speech. This requires the words to be in their original order. This process is to be done before any other modifications on the corpora. For this reason, PoS tagging is the first step to be carried out on the text documents as proposed in [2].

**2.1.3. Stopwords Removal.** Stopwords, i.e. words thought not to convey any meaning, are removed from the text. In this work, the proposed approach uses a static list of stopwords with PoS information about all tokens. This process removes all words that are not nouns, verbs or adjectives. For example, stopwords removal process will remove all the words like: he, all, his, from, is, an, of, and so on.

**2.1.4. Stemming.** The stem is the common root-form of the words with the same meaning appear in various morphological forms (e.g. player, played, plays from stem play). In the proposed approach, we use the morphology function provided with WordNet for stemming process. Stemming will find the stems of the output terms to enhance term frequency counting process because terms like “learners” and “learning” come down from the same stem “learn”. This process will output all the stems of extracted terms.

The frequency of each stemmed word across the corpus can be counted and every word occurring less often than the pre-specified threshold (called Minimum Support) is pruned, i.e. removed from the extracted words list, to reduce the document vector dimension. In our implementation we use minimum support value set to 10%, which means that the words found in less than 10% of the input documents is pruned.

**2.1.5. WordNet Lexical Category Mapping.** As proposed in [5], we use WordNet lexical categories to map all the stemmed words in all documents into their lexical categories. We use WordNet 2.1 that has 41

lexical categories for nouns and verbs. For example, the word “dog” and “cat” both belong to the same category “noun.animal”. Some words also has multiple categories like word “Washington” has 3 categories (noun.location, noun.group, noun.person) because it can be the name of the American president, the city place, or a group in the concept of capital.

Some word disambiguation techniques are used to remove the resulting noise added by multiple categories mapping which are concept map and disambiguation by context as discussed with more details in [5].

## 2.2. Document Clustering

After generating the documents' vectors for all the input documents using feature extraction process, the proposed approach continues with the clustering process as shown in figure 1.

The problem of document clustering is defined as follows. Given a set of  $n$  documents called  $DS$ ,  $DS$  is clustered into a user-defined number of  $k$  document clusters  $D_1, D_2, \dots, D_k$ , (i.e.  $\{D_1, D_2, \dots, D_k\} = DS$ ) so that the documents in a document cluster are similar to one another while documents from different clusters are dissimilar.

There are two main approaches to document clustering, hierarchical clustering (agglomerative and divisive) and partitioning clustering algorithms [7]. In this process we apply three different clustering algorithms which are  $k$ -means (partitioning clustering), bisecting  $k$ -means (hierarchical clustering) and fuzzy  $c$ -means (fuzzy clustering).

**2.2.1. K-means and Bisecting k-means.** We have implemented the  $k$ -means and bisecting  $k$ -means algorithms as introduced in [7]. We will state some details on bisecting  $k$ -means algorithm that begins with all data as one cluster then perform the following steps:

1. Choose the largest cluster to split.
2. Use  $k$ -means to split this cluster into two sub-clusters. (Bisecting step)
3. Repeat step 2 for some iterations (in our case 10 times) and choose the split with the highest clustering overall similarity.
4. Go to step 1 again until the desired  $k$  clusters are obtained.

**2.2.2. Fuzzy c-means Algorithm.** Fuzzy  $c$ -means is a data clustering technique wherein each data point belongs to a cluster to some degree that is specified by a membership grade while other classical clustering algorithms assign each data point to exactly one

cluster. This technique was originally introduced by Bezdek [16] as an improvement on earlier clustering methods. It provides a method that shows how to group data points that populate some multidimensional space into a specific number of different clusters. Most fuzzy clustering algorithms are objective function based: they determine an optimal (fuzzy) partition of a given data set  $c$  clusters by minimizing an objective function with some constraints [25].

In the proposed approach, we use the implementation of fuzzy c-means algorithm in MATLAB (fcm function). This function takes the generated document vectors as a matrix and the desired number of clusters then outputs the clusters centers and the optimal objective function values.

### 3. Experimental Results

Some experiments are performed on some real text documents to compare the performance of three text clustering algorithms which are  $k$ -means, bisecting  $k$ -means and fuzzy c-means. There are two main parameters to evaluate the performance of the proposed approach which are clustering quality and running time.

Fuzzy c-means algorithm is implemented in MATLAB and  $k$ -means, bisecting  $k$ -means algorithms are implemented in Java. Feature extraction process is also implemented in Java using Java NetBeans 5.5.1 and Java API for WordNet Searching (JAWS Library) to access WordNet 2.1.

#### 3.1. Silhouette Coefficient (SC) for Clustering Quality Evaluation

For clustering, two measures of cluster "goodness" or quality are used. One type of measure allows us to compare different sets of clusters without reference to external knowledge and is called an internal quality measure. The other type of measures lets us evaluate how well the clustering is working by comparing the groups produced by the clustering techniques to known classes which called an external quality measure [7].

In our application of document clustering, we don't have the knowledge of document classes in order to use external quality measures. We will investigate one of the main internal quality measures which is silhouette coefficient (SC Measure).

To measure the similarity between two documents  $d_1$  and  $d_2$  we use the cosine of the angle between the two document vectors. This measure tries to approach the semantic closeness of documents through the size of the angle between vectors associated to them:

$$\text{dist}(d_1, d_2) = \frac{d_1 \bullet d_2}{|d_1| \cdot |d_2|}$$

Where  $(\bullet)$  denotes vector dot product and  $(| |)$  is the dimension of the vector. A cosine measure of 0 means the two documents are unrelated whereas value closed to 1 means that the documents are closely related [5].

Let  $D_M = \{D_1, \dots, D_k\}$  describe a clustering result, i.e. it is an exhaustive partitioning of the set of documents  $DS$ . The distance of a document  $d \in DS$  to a cluster  $D_i \in D_M$  is given as:

$$\text{dist}(d, D_i) = \frac{\sum_{p \in D_i} \text{dist}(d, p)}{|D_i|}$$

Let further consider  $a(d, D_M) = \text{dist}(d, D_i)$  being the distance of document  $d$  to its cluster  $D_i$  where  $(d \in D_i)$ .  $b(d, D_M) = \min_{d \notin D_i} \text{dist}(d, D_i) \forall D_i \in D_M$  is the distance of document  $d$  to the nearest neighbour cluster. The silhouette  $S(d, D_M)$  of a document  $d$  is then defined as:

$$S(d, D_M) = \frac{b(d, D_M) - a(d, D_M)}{\max(b(d, D_M), a(d, D_M))}$$

The silhouette coefficient as:

$$SC(D_M) = \frac{\sum_{p \in DS} S(p, D_M)}{|DS|}$$

The silhouette coefficient is a measure for the clustering quality that is rather independent from the number of clusters. Experiences, such as documented in [11], show that values between 0.7 and 1.0 indicate clustering results with excellent separation between clusters, viz. data points are very close to the center of their cluster and remote from the next nearest cluster. For the range from 0.5 to 0.7 one finds that data points are clearly assigned to cluster centers. Values from 0.25 to 0.5 indicate that cluster centers can be found, though there is considerable "noise". Below a value of 0.25 it becomes practically impossible to find significant cluster centers and to definitely assign the majority of data points.

#### 3.2. Web Documents Datasets

We evaluate the proposed web document clustering approach on three different web document datasets: SCOTS, EMail1200, and WebKB web documents corpuses. **SCOTS** corpus (Scottish Corpus Of Text and Speech) contains about 1,177 written and spoken texts, with about 4 million words of running text. 80%

of this total is made up of written texts and 20% is made up of spoken texts and can be obtained from [15]. **EEmail1200** corpus contains about 1,245 test email documents for spam email detection and can be downloaded from [14]. **WebKB** dataset contains about 8,282 web pages collected from computer science departments of various universities in January 1997. WebKB dataset is collected by the World Wide Knowledge Base (WebKb) project of the CMU text learning group and can be downloaded from [18].

### 3.3. Results

First, we pass the three document datasets into the feature extraction process to generate the corresponding document vectors. The output vectors are used as an input for each clustering algorithm. We used the following list (2, 5, 10, 20, 50, 70, and 100) as the desired number of clusters for each algorithm. Then output clusters for each dataset are measured using silhouette coefficient (SC Measure) and report the total running time of the whole process.

**3.3.1. Clustering Quality.** Figures 2, 3, and 4 show the silhouette values for the three datasets respectively. In all experiments fuzzy c-means outperforms bisecting *k*-means and *k*-means algorithms in the overall clustering quality using silhouette measure. This shows that the fuzzy clustering is more suitable for the unstructured nature of the text document clustering process itself.

**Figure 2: Silhouette values comparing all clustering algorithms using WebKB dataset**

**Figure 3: Silhouette values comparing all clustering algorithms using EMail1200 dataset**

**Figure 4: Silhouette values comparing all clustering algorithms using SCOTS dataset**

**3.3.2. Running Time.** WebKB dataset, as mentioned in section 3.2, contains about 8,282 web documents. This is considered a real challenge task that faces any clustering approach because of “**Scalability**”. Some clustering techniques that are helpful for small data sets can be overwhelmed by large data sets to the point that they are no longer helpful.

For that reason we test the scalability of our proposed approach with the different algorithms using WebKB dataset. This experiment shows that the fuzzy c-means performs a great running time optimization with comparison to other two clustering algorithms. Also, according to the huge size of WebKB dataset, the proposed approach shows good scalability against document size.

Figure 5 depicts the running time of the different clustering algorithms using WebKB dataset with respect to different values of desired clusters.

**Figure 5: Scalability of all clustering algorithms on WebKB dataset**

## 4. Related Work

In the recent years, text document clustering has been introduced as an efficient method for navigating and browsing large document collections and organizing the results returned by search engines in response to user queries [13]. Many clustering techniques are proposed like k-secting k-means [17] and bisecting k-means [7], FTC and HFTC [19] and many others. From the performed experiments in [7] bisecting k-means overcomes all these algorithms in the performance although FTC and HTFC allows to reduce the dimensionality if the data when working with large datasets.

WordNet is used by Green [20, 21] to construct lexical chains from the occurrences of terms in a document: WordNet senses that are related receive high higher weights than senses that appear in isolation from others in the same document. The senses with the best weights are selected and the corresponding weighted term frequencies constitute a base vector representation of a document.

Other works [22, 23] have explored the possibility to use WordNet for retrieving documents by carefully choosing a search keyword. Dave [24] uses WordNet synsets as features for document representation and subsequent clustering. But the word sense disambiguation has not been performed showing that WordNet synsets decreases clustering performance in all the experiments. Hotho et al. [10] uses WordNet in an unsupervised scenario taking into account the WordNet ontology and lexicon and some strategy for word sense disambiguation achieving improvements of the clustering results.

Another technique for feature selection by using WordNet to discover synonymous terms based on

cross-referencing is introduced in [6]. First, terms with overlapping word senses co-occurring in a category are selected. A signature for a sense is a synset containing synonyms. Then, the list of noun synsets is checked for all senses for signatures similarity. The semantic context of a category is aggregated by overlapping synsets of different terms senses. The original terms from the category that belongs to the similar synsets will be finally added as features for category representation.

In [2] the authors explore the benefits of partial disambiguation of words by their PoS and the inclusion of WordNet concepts. They show how taking into account synonyms and hypernyms, disambiguated only by PoS tags, is not successful in improving clustering effectiveness because the noise produced by all the incorrect senses extracted from WordNet. Adding all synonyms and all hypernyms into the document vectors seems to increase the noise.

Reforgiato [5] presented a new unsupervised method for document clustering by using WordNet lexical and conceptual relations. In this work, Reforgiato uses WordNet lexical categories and WordNet ontology in order to create a well structured document vector space whose low dimensionality allows common clustering algorithms to perform well. For the clustering step he has chosen the bisecting k-means and the Multipole tree algorithms for their accuracy and speed.

Friedman et al. [26] introduced FDCM algorithm for clustering documents that are represented by vectors of variable size. The algorithm utilizes fuzzy logic to construct the cluster center and introduces a fuzzy based similarity measure which provided reasonably good results in the area of web document monitoring.

Rodrigues and Sacks [28] have modified the Fuzzy c-means algorithm for clustering text documents based on the cosine similarity coefficient rather than on the Euclidean distance. The modified algorithm works with normalized  $k$ -dimensional data vectors that lie in hyper-sphere of unit radius and hence has been named Hyper-spherical Fuzzy c-means (H-FCM). Also they proposed a hierarchical fuzzy clustering algorithm ( $H^2$ -FCM) to discover relationships between information resources based on their textual content, as well as to represent knowledge through the association of topics covered by those resources [27].

The main problem about these studies is that they neglect any lexical information about the textual data in the documents. This information helps in improving clustering quality as shown in section 3.3.

## 5. Conclusion

In this paper we proposed a fuzzy web document clustering approach based on the WordNet lexical categories and fuzzy c-means clustering algorithm. The proposed approach generates documents vectors using the lexical category mapping of WordNet after preprocessing the input web documents. We apply three different clustering algorithms, *k*-means, bisecting *k*-means and fuzzy *c*-means, to the generated documents vectors for clustering process. Output clusters of each algorithm are evaluated using silhouette coefficient as an internal cluster quality measure.

We have obtained some points that appeared in this work which are:

- Using WordNet lexical categories in feature extraction process reduces the dimension of the generated documents vectors and achieves higher clustering quality.
- Fuzzy *c*-means clustering algorithm achieves higher clustering quality than classical clustering algorithms like *k*-means (partitioning clustering), and bisecting *k*-means (hierarchical clustering).

From the shown experimental results, we found that the proposed approach shows good scalability against the huge number of documents as in WebKB dataset along with different values of desired clusters.

### Abstract

*We present a general viewpoint using Bregman divergences and exponential family properties that contains as special cases the three following algorithms: 1) exponential family Principal Component Analysis (exponential PCA), 2) Semi-Parametric exponential family Principal Component Analysis (SP-PCA) and 3) Bregman soft clustering. This framework is equivalent to a mixed data-type hierarchical Bayes graphical model assumption with latent variables constrained to a low-dimensional parameter subspace. We show that within this framework exponential PCA and SP-PCA are similar to the Bregman soft clustering technique with the addition of a linear constraint in the parameter space. We implement the resulting modifications to SP-PCA and Bregman soft clustering for mixed (continuous and/or discrete) data sets, and add a nonparametric estimation of the point-mass probabilities to exponential PCA. Finally, we compare the relative performances of the three algorithms in a clustering setting for mixed data sets.*

### 1. Introduction

We present a general point of view that relates the exponential family Principal Component Analysis (exponential PCA) technique of [7] to the Semi-Parametric Principal Component Analysis (SP-PCA) technique of [20] and to the Bregman soft clustering method presented in [4]. The proposed standpoint is then illustrated with a clustering problem in mixed data sets.

The three techniques considered here all utilize Bregman divergences and can all be explained within a single hierarchical Bayes graphical model framework shown in Figure 1. They are not separate unrelated algorithms but different manifestations of parameter choices taken within a common

framework. The proposed model is mathematically equivalent to equation (6) and we will demonstrate that various parametric choices symbolically shown in Figure 2 determine the three algorithms. Because of this insight, we will readily extend the algorithms to deal with the important mixed data type case.

There are two ways in which Bregman divergences are important. First, they generalize the squared Euclidean distance to a class of distances that all share similar properties. Second, there exists a bijection between Bregman divergences and exponential family distributions [3, 4]. Recently, researchers have shown that many important algorithms can be generalized from Euclidean metrics to distances defined by a Bregman divergence [7, 20, 4, 6], i.e., from Gaussian distributed data components to data components distributed according to an exponential family, such as binary- or integer-valued.

Data mining techniques seek potentially useful information contained in complex data sets. Complexity of these data generally comes from a high number of components and also from the fact that the components usually are of mixed data types (categorical, count, continuous, etc.). In order to address the latter, techniques should allow for the components to have different parametric forms by using the large range of exponential family distributions and their associated Bregman divergences. While a modification for mixed data sets was presented in [12] for exponential PCA, we implement here a modification for SP-PCA and Bregman soft clustering. The issue of a high number of components of the original data is addressed by exponential PCA and SP-PCA through dimensionality reduction by projecting the data to a low-dimensional parameter subspace.

Finally, we consider synthetic data examples of mixed types. We demonstrate that exponential PCA, with the addition of a nonparametric estimation tool, rivals SP-PCA and Bregman soft clustering in terms of clustering performance.

## 2. Theoretical background

To motivate theoretical developments, the hierarchical Bayes graphical model for hidden or latent variables shown in Figure 1 is considered.

Figure 1. Graphical model for our framework.

The row vector  $\mathbf{x} = [x_1, \dots, x_d] \in \mathbb{R}^d$  consists of observed features in a  $d$ -dimensional space. It is assumed that training points can be drawn from populations having class-conditional probability density functions

$$p(\mathbf{x}|\boldsymbol{\theta}) = p_1(x_1|\theta_1) \cdot \dots \cdot p_d(x_d|\theta_d), \quad (1)$$

where, when conditioned on the random parameter vector  $\boldsymbol{\theta} = [\theta_1, \dots, \theta_d] \in \mathbb{R}^d$ , the components of  $\mathbf{x}$  are independent. It is further assumed that  $\boldsymbol{\theta}$  can be written as

$$\boldsymbol{\theta} = \mathbf{a}\mathbf{V} + \mathbf{b}$$

with the hidden or latent variable  $\mathbf{a} = [a_1, \dots, a_q] \in \mathbb{R}^q$  random and unknown with  $q < d$  (and ideally  $q \ll d$ ),  $\mathbf{V} \in \mathbb{R}^{q \times d}$  and  $\mathbf{b} \in \mathbb{R}^d$  deterministic and unknown. The latent variable  $\mathbf{a}$  in some way explains part (or all) of the random behavior of the observed variables. The subscript  $i$  on  $p_i(\cdot|\cdot)$  serves to indicate that the marginal densities can all be different, allowing for the possibility of  $\mathbf{x}$  containing categorical, discrete, and continuous valued components. Also, the marginal densities are each assumed to be one-parameter exponential family densities, and  $\theta_i$  is taken to be the natural parameter (or some simple bijective function of it) of the exponential family density  $p_i$ . Hence, each component density  $p_i(x_i|\theta_i)$  in (1) for  $x_i \in \mathcal{X}_i, i = 1, \dots, d$ , is of the form

$$p(x_i|\theta_i) = \exp(\theta_i x_i - G(\theta_i)), \quad (2)$$

where  $G(\cdot)$  is the cumulant generating function defined as

$$G(\theta_i) = \log \int_{\mathcal{X}_i} \exp(\theta_i x_i) \nu(dx_i), \quad (3)$$

with  $\nu(\cdot)$  a  $\sigma$ -finite measure that generates the exponential family. It can be shown, using Fubini's theorem [11], that  $G(\boldsymbol{\theta}) = \sum_{i=1}^d G(\theta_i)$ .

The maximum likelihood identification of the blind random effect model

$$p(\mathbf{x}) = \int p(\mathbf{x}|\boldsymbol{\theta})\pi(\boldsymbol{\theta})d\boldsymbol{\theta} = \int \prod_{i=1}^d p_i(x_i|\theta_i)\pi(\boldsymbol{\theta})d\boldsymbol{\theta}, \quad (4)$$

where  $\pi(\boldsymbol{\theta})$  is the probability density function of  $\boldsymbol{\theta}$ , is quite a difficult problem. It corresponds to identifying  $\pi(\boldsymbol{\theta})$ , which, under the condition  $\boldsymbol{\theta} = \mathbf{a}\mathbf{V} + \mathbf{b}$ , corresponds to identifying the matrix  $\mathbf{V}$ , the vector  $\mathbf{b}$ , and a density function on the random effect  $\mathbf{a}$  via a maximization of the likelihood function  $p(\mathbf{X})$  with respect to  $\mathbf{V}$ ,  $\mathbf{b}$ , and the random effect density function, where

$$\begin{aligned} p(\mathbf{X}) &= \prod_{k=1}^n p(\mathbf{x}[k]) = \prod_{k=1}^n \int p(\mathbf{x}[k]|\boldsymbol{\theta})\pi(\boldsymbol{\theta})d\boldsymbol{\theta} \\ &= \prod_{k=1}^n \int \prod_{i=1}^d p_i(x_i[k]|\theta_i)\pi(\boldsymbol{\theta})d\boldsymbol{\theta}, \end{aligned} \quad (5)$$

and  $\mathbf{X}$  is the  $(n \times d)$  observation matrix

$$\mathbf{X} = \begin{pmatrix} \mathbf{x}[1] \\ \mathbf{x}[2] \\ \vdots \\ \mathbf{x}[n] \end{pmatrix} = \begin{pmatrix} x_1[1] & \dots & x_d[1] \\ x_1[2] & \dots & x_d[2] \\ \vdots & \ddots & \vdots \\ x_1[n] & \dots & x_d[n] \end{pmatrix}.$$

This difficulty can be avoided by NonParametric Maximum Likelihood (NPML) estimation of the random effect distribution, concurrently with the structural model parameters. The NPML estimate is known to be a discrete distribution on a finite number of support points or “atoms” [9, 10, 13]. Finding the NPML estimate is widely regarded as computationally intensive, the particular difficulty being the location of the atoms [1].

As shown in [12], with  $\boldsymbol{\theta} = \mathbf{a}\mathbf{V} + \mathbf{b}$ , with  $\mathbf{V}$ ,  $\mathbf{b}$  fixed and  $\mathbf{a}$  random, the single-sample likelihood (4) is equal to

$$p(\mathbf{x}) = \sum_{l=1}^m p(\mathbf{x}|\boldsymbol{\theta}[l])\pi_l = \sum_{l=1}^m p(\mathbf{x}|\mathbf{a}[l]\mathbf{V} + \mathbf{b})\pi_l$$

and the data likelihood (5) is equal to

$$p(\mathbf{X}) = \prod_{k=1}^n \sum_{l=1}^m p(\mathbf{x}[k]|\boldsymbol{\theta}[l])\pi_l = \prod_{k=1}^n \sum_{l=1}^m p(\mathbf{x}[k]|\mathbf{a}[l]\mathbf{V} + \mathbf{b})\pi_l, \quad (6)$$

with point-mass probability estimates  $\pi_l$ , unknown point-mass support points  $\mathbf{a}[l]$ , and the linear predictor  $\boldsymbol{\theta}[l] = \mathbf{a}[l]\mathbf{V} + \mathbf{b}$  in the  $l$ th mixture component,  $l = 1, \dots, m$ .

The data likelihood is thus approximately the likelihood of a finite mixture of exponential family densities with unknown mixture proportions or point-mass probability estimates  $\pi_l$  and unknown point-mass support points  $\mathbf{a}[l]$ ,

with the linear predictor  $\theta[l] = \mathbf{a}[l]\mathbf{V} + \mathbf{b}$  in the  $l$ th mixture component [2]. The combined problem of Maximum Likelihood Estimation (MLE) of the parameters  $\mathbf{V}$ ,  $\mathbf{b}$ , the point-mass support points (atoms)  $\mathbf{a}[l]$  and the point-mass probability estimates  $\pi_l, l = 1, \dots, m$ , is known as the Semiparametric Maximum Likelihood mixture density Estimation (SMLE) problem [14, 16]. It can be attacked by using the Expectation-Maximization (EM) algorithm [8, 10, 13, 19, 15, 2, 5, 16, 18], as done in particular in the Semi-Parametric Principal Component Analysis (SP-PCA) technique proposed in [20] and discussed below. Note that, historically, [10] appears to be generally acknowledged as the first paper that proposed the EM algorithm for NPML estimation in the mixture density context; then, [13] improved upon the theoretical foundations of the NPML estimation approach and later [15] further explored some of the fundamental issues raised in [13].

However, the SMLE problem can also be attacked by simply considering the special case of uniform point-mass probabilities, i.e.,  $\pi_l = 1/m$  for  $l = 1, \dots, m$ , for which the number of support points equals the number of data samples, i.e.,  $m = n$ . It was demonstrated in [12] that this special uniform case corresponds to exponential PCA.

### 3. A unifying framework

Within the proposed hierarchical Bayes graphical model framework, exponential PCA, SP-PCA and Bregman soft clustering are not separate uncorrelated algorithms but different manifestations of parameter choices.

Figure 2 considers the number of atoms as a common characteristic for comparison purposes. It symbolizes how various parametric choices determine the three algorithms. Whereas the exponential PCA approach requires a number of atoms equal to the number of data points and hence can be seen as an extreme case of the NPML technique, SP-PCA deals with a smaller number of atoms. Finally, the Bregman soft clustering approach considers an even smaller number of atoms, viewed as cluster centers, since its primary goal is clustering. Furthermore, both exponential PCA and SP-PCA impose a low-dimensional (unknown) latent variable subspace in their structure. However, Bregman soft clustering does not impose this lower dimensional constraint and hence can be seen as a degenerate case.

It becomes clear while looking at Table 1, Table 2 and Table 3 shown below that both SP-PCA and Bregman soft clustering utilize the EM algorithm for estimation purposes whereas exponential PCA does not. This is because exponential PCA assumes uniform point-mass probabilities and does not need to estimate them. Both exponential PCA and SP-PCA impose the low-dimensional parameter subspace

constraint, hence the need for the Newton-Raphson iterative algorithm to find it as discussed below.

**Figure 2. General point of view on SP-PCA, exponential PCA and Bregman soft clustering based on the number of NPML atoms.**

## 4. Extensions to mixed data sets

Now that the relationship between exponential PCA, SP-PCA and Bregman soft clustering has been demonstrated within a unifying mixed data type framework, we can extend SP-PCA and Bregman soft clustering to deal with the important mixed data case. Recalling the modifications on exponential PCA presented in [12], we also introduce a penalty function that improves exponential PCA convergence efficiency. Towards these ends, following the notation in [5], we use the *mixing distribution*  $\mathcal{Q} = \{\theta[l], \pi_l\}_{l=1}^m$  which contains the parameters  $\theta[l]$  and their associated point-mass probabilities  $\pi_l$ . The mixing distribution needs to be estimated in all three algorithms.

### 4.1. Semi-parametric exponential PCA

The Semi-Parametric exponential family Principal Component Analysis (SP-PCA) approach presented in [20] attacks the Semiparametric Maximum Likelihood mixture density Estimation (SMLE) problem by using the Expectation-Maximization (EM) algorithm [8]. As done previously in [12] for exponential PCA, we present an SP-PCA modified approach for mixed data types. For simplicity of presentation, we consider that the  $f$  first attributes are distributed according to the exponential family distribution  $p^{(1)}$  and the  $(d - f)$  last attributes are distributed according to the exponential family distribution  $p^{(2)}$ . The following notation is used:

$$\begin{aligned} \mathbf{x}[k] &= [x_1[k], \dots, x_f[k], x_{f+1}[k], \dots, x_d[k]] \\ &= [\mathbf{x}^{(1)}[k] | \mathbf{x}^{(2)}[k]], \end{aligned}$$

for  $k = 1, \dots, n$ , and similarly for the observation matrix,

$$\mathbf{X} = (\mathbf{X}^{(1)} | \mathbf{X}^{(2)}).$$

The EM approach introduces a *missing* (unobserved) variable  $\mathbf{z}_k = [z_{k1}, \dots, z_{km}]$ , for  $k = 1, \dots, n$ . This variable is an  $m$ -dimensional binary vector whose  $l$ th component equals 1 if the observed variable  $\mathbf{x}[k]$  was drawn from the  $l$ th mixture component and 0 otherwise; its value is estimated during the E-step. Using this information, a *complete* log-likelihood function is defined as follows:

$$L^{(c)}(\mathcal{Q}, \{\mathbf{z}_k\}_{k=1}^n) = \log \prod_{k=1}^n \prod_{l=1}^m p(\mathbf{x}[k]|\boldsymbol{\theta}[l])^{z_{kl}} \pi_l^{z_{kl}},$$

with  $\boldsymbol{\theta}[l] = \mathbf{a}[l]\mathbf{V} + \mathbf{b}$ . Its maximization during the M-step yields parameters  $\mathbf{A}$ ,  $\mathbf{V}$  and  $\mathbf{b}$  estimates. Then,

$$p(\mathbf{x}[k]|\boldsymbol{\theta}[l]) = p^{(1)}(\mathbf{x}^{(1)}[k]|\boldsymbol{\theta}^{(1)}[l]) \cdot p^{(2)}(\mathbf{x}^{(2)}[k]|\boldsymbol{\theta}^{(2)}[l]) \quad (7)$$

using the assumption from (1), where, for  $l = 1, \dots, m$ ,

$$\boldsymbol{\theta}[l] = [\theta_1[l], \dots, \theta_f[l], \theta_{f+1}[l], \dots, \theta_d[l]] = [\boldsymbol{\theta}^{(1)}[l] | \boldsymbol{\theta}^{(2)}[l]],$$

$$\boldsymbol{\Theta} = \begin{pmatrix} \boldsymbol{\theta}[1] \\ \boldsymbol{\theta}[2] \\ \vdots \\ \boldsymbol{\theta}[n] \end{pmatrix} = (\boldsymbol{\Theta}^{(1)} | \boldsymbol{\Theta}^{(2)}).$$

The following decompositions arise:

$$\mathbf{V} = (\mathbf{V}^{(1)} | \mathbf{V}^{(2)}),$$

$$\mathbf{B} = (\mathbf{B}^{(1)} | \mathbf{B}^{(2)}),$$

where  $\mathbf{B}^{(1)} = [\mathbf{b}^{(1)}, \dots, \mathbf{b}^{(1)}]^T$  and  $\mathbf{b}^{(1)} = [b_1, \dots, b_f]$ ,  $\mathbf{B}^{(2)} = [\mathbf{b}^{(2)}, \dots, \mathbf{b}^{(2)}]^T$  and  $\mathbf{b}^{(2)} = [b_{f+1}, \dots, b_d]$ . Hence,

$$\boldsymbol{\Theta} = (\mathbf{A}\mathbf{V}^{(1)} + \mathbf{B}^{(1)} | \mathbf{A}\mathbf{V}^{(2)} + \mathbf{B}^{(2)}).$$

Note that there is no such split for  $\mathbf{A}$ . The complete log-likelihood function becomes:

$$\begin{aligned} L^{(c)}(\mathcal{Q}, \{\mathbf{z}_k\}_{k=1}^n) &= \sum_{k=1}^n \sum_{l=1}^m z_{kl} \log \pi_l \\ &+ \sum_{k=1}^n \sum_{l=1}^m z_{kl} \log p^{(1)}(\mathbf{x}^{(1)}[k]|\boldsymbol{\theta}^{(1)}[l]) \cdot p^{(2)}(\mathbf{x}^{(2)}[k]|\boldsymbol{\theta}^{(2)}[l]). \end{aligned} \quad (8)$$

The E-step yields for  $k = 1, \dots, n$  and  $l = 1, \dots, m$ :

$$\begin{aligned} \hat{z}_{kl} &= E\{z_{kl}|\mathbf{x}[k], \pi_1, \dots, \pi_m\} \\ &= \frac{p^{(1)}(\mathbf{x}^{(1)}[k]|\boldsymbol{\theta}^{(1)}[l]) \cdot p^{(2)}(\mathbf{x}^{(2)}[k]|\boldsymbol{\theta}^{(2)}[l]) \pi_l}{\sum_{r=1}^m p^{(1)}(\mathbf{x}^{(1)}[k]|\boldsymbol{\theta}^{(1)}[r]) \cdot p^{(2)}(\mathbf{x}^{(2)}[k]|\boldsymbol{\theta}^{(2)}[r]) \pi_r}. \end{aligned}$$

For all  $l$  and all  $k$ , each data point  $\mathbf{x}[k]$  has an estimated probability  $\hat{z}_{kl}$  of belonging to the  $l$ th mixture component.

The M-step first yields the estimates for the point-mass probabilities:

$$\pi_l^{(new)} = \frac{\sum_{k=1}^n \hat{z}_{kl}}{n}.$$

The second part of the M-step, i.e., the estimation of the parameters  $\mathbf{V}$ ,  $\mathbf{b}$ , and the point-mass support points  $\mathbf{A} = [\mathbf{a}[1]^T, \dots, \mathbf{a}[m]^T]^T \in \mathbb{R}^{m,q}$ , is affected by the mixed data type assumption. It consists of maximizing the complete log-likelihood function (8) with respect to these parameters:

$$\arg \max_{\mathbf{A}, \mathbf{V}, \mathbf{b}} E \left\{ L^{(c)}(\{\boldsymbol{\theta}[l], \pi_l^{(new)}\}_{l=1}^m, \{\hat{\mathbf{z}}_k\}_{k=1}^n) \right\}.$$

Following the notation in [20], we set, for  $l = 1, \dots, m$ :

$$\tilde{\mathbf{x}}[l] = \frac{\sum_{k=1}^n \hat{z}_{kl} \mathbf{x}[k]}{\sum_{k=1}^n \hat{z}_{kl}},$$

the  $l$ th mixture component center. It can be shown, using exponential family properties, that the loss function is:

$$\begin{aligned} L(\mathbf{A}, \mathbf{V}, \mathbf{b}) &= \sum_{l=1}^m \left\{ G^{(1)}(\mathbf{a}[l]\mathbf{V}^{(1)} + \mathbf{b}^{(1)}) - (\mathbf{a}[l]\mathbf{V}^{(1)} + \mathbf{b}^{(1)})\tilde{\mathbf{x}}[l]^T \right\} \\ &+ \sum_{l=1}^m \left\{ G^{(2)}(\mathbf{a}[l]\mathbf{V}^{(2)} + \mathbf{b}^{(2)}) - (\mathbf{a}[l]\mathbf{V}^{(2)} + \mathbf{b}^{(2)})\tilde{\mathbf{x}}[l]^T \right\}, \end{aligned} \quad (9)$$

where  $G^{(1)}(\cdot)$ ,  $G^{(2)}(\cdot)$  respectively, is the cumulant generating function associated with the exponential family distribution  $p^{(1)}(\cdot)$ ,  $p^{(2)}(\cdot)$  respectively, as seen in equation (3).

Following the derivations in [12], the Newton-Raphson method is used for the iterative minimization of the loss function (9) and the resulting update equations are as follows. First at iteration  $t$ , for  $l = 1, \dots, m$ ,

$$\begin{aligned} \mathbf{a}^{(t+1)}[l]^T &= \mathbf{a}^{(t)}[l]^T - \alpha_{\mathbf{a}}^{(t+1)} \\ &\cdot \left\{ \mathbf{V}^{(1)(t)} G^{(1)'}(\mathbf{a}^{(t)}[k]\mathbf{V}^{(1)(t)} + \mathbf{b}^{(1)(t)})\mathbf{V}^{(1)(t),T} \right. \\ &+ \left. \mathbf{V}^{(2)(t)} G^{(2)'}(\mathbf{a}^{(t)}[k]\mathbf{V}^{(2)(t)} + \mathbf{b}^{(2)(t)})\mathbf{V}^{(2)(t),T} \right\}^{-1} \\ &\cdot \left\{ \mathbf{V}^{(1)(t)} (G^{(1)'}(\mathbf{a}^{(t)}[k]\mathbf{V}^{(1)(t)} + \mathbf{b}^{(1)(t)}) - \tilde{\mathbf{x}}[k]^T) \right. \\ &+ \left. \mathbf{V}^{(2)(t)} (G^{(2)'}(\mathbf{a}^{(t)}[k]\mathbf{V}^{(2)(t)} + \mathbf{b}^{(2)(t)}) - \tilde{\mathbf{x}}[k]^T) \right\}. \end{aligned} \quad (10)$$

For the second step, the two sets of row vectors  $\{\mathbf{v}_j^{(1)}\}_{j=1}^q$  and  $\{\mathbf{v}_j^{(2)}\}_{j=1}^q$  are updated separately. The update equations can then be used for  $\{\mathbf{v}_j^{(1)}\}_{j=1}^q$  and  $\{\mathbf{v}_j^{(2)}\}_{j=1}^q$  by changing  $\mathbf{v}_j$  to  $\mathbf{v}_j^{(1)}$ , respectively to  $\mathbf{v}_j^{(2)}$ ,  $\mathbf{b}$  to  $\mathbf{b}^{(1)}$ , respectively to  $\mathbf{b}^{(2)}$ ,  $G(\cdot)$ ,  $G'(\cdot)$ , and

$G''(\cdot)$  to  $G^{(1)}(\cdot)$ ,  $G^{(1)'}(\cdot)$ , and  $G^{(1)''}(\cdot)$ , respectively to  $G^{(2)}(\cdot)$ ,  $G^{(2)'}(\cdot)$ , and  $G^{(2)''}(\cdot)$ . For  $j = 1, \dots, q$ :

$$\begin{aligned} \mathbf{v}_j^{(t+1),T} &= \mathbf{v}_j^{(t),T} \\ &- \alpha_{\mathbf{v}}^{(t+1)} \left( \sum_{l=1}^m \underline{a}_j^{(t+1)} [l]^2 G''(\underline{\mathbf{a}}^{(t+1)}[l] \mathbf{V}^{(t)} + \mathbf{b}^{(t)}) \right)^{-1} \\ &\cdot \left( \sum_{k=1}^n \underline{a}_j^{(t+1)} [l] \{ G'(\underline{\mathbf{a}}^{(t+1)}[l] \mathbf{V}^{(t)} + \mathbf{b}^{(t)}) - \tilde{\mathbf{x}}[k]^T \} \right). \end{aligned} \quad (11)$$

And finally for the last step, the update equations can then be used for  $\mathbf{b}^{(1)}$  and  $\mathbf{b}^{(2)}$  by changing  $\mathbf{b}$  to  $\mathbf{b}^{(1)}$ , respectively to  $\mathbf{b}^{(2)}$ ,  $\mathbf{V}$  to  $\mathbf{V}^{(1)}$ , respectively to  $\mathbf{V}^{(2)}$ ,  $G(\cdot)$ ,  $G'(\cdot)$ , and  $G''(\cdot)$  to  $G^{(1)}(\cdot)$ ,  $G^{(1)'}(\cdot)$ , and  $G^{(1)''}(\cdot)$ , respectively to  $G^{(2)}(\cdot)$ ,  $G^{(2)'}(\cdot)$ , and  $G^{(2)''}(\cdot)$ .

$$\begin{aligned} \mathbf{b}^{(t+1),T} &= \mathbf{b}^{(t),T} \\ &= \mathbf{b}^{(t),T} - \alpha_{\mathbf{b}}^{(t+1)} \left( \sum_{l=1}^m G''(\underline{\mathbf{a}}^{(t+1)}[l] \mathbf{V}^{(t+1)} + \mathbf{b}) \right)^{-1} \\ &\cdot \left( \sum_{l=1}^m \{ G'(\underline{\mathbf{a}}^{(t+1)}[l] \mathbf{V}^{(t+1)} + \mathbf{b}) - \tilde{\mathbf{x}}[k]^T \} \right). \end{aligned} \quad (12)$$

Table 1 summarizes the SP-PCA algorithm.

## 4.2. Exponential family PCA

The work proposed in [12] is based on the generalization of Principal Component Analysis to the exponential family technique presented in [7], often referred to as exponential Principal Component Analysis.

As stated earlier, instead of the fastidious estimation of the point-mass probabilities, exponential PCA considers the special uniform case where  $\pi_l = 1/m$  for  $l = 1, \dots, m$ , for which the number of support points equals the number of data samples ( $m = n$ ). Hence, the point-mass probabilities do not need to be estimated and the EM algorithm is unnecessary. Then, to each vector  $\mathbf{x}$  corresponds a vector  $\underline{\mathbf{a}}$ , i.e., a vector  $\underline{\boldsymbol{\theta}}$ , and they can share the same index  $k = 1, \dots, n$ .

The update equations were presented in [12]. It is easily noticed that they are the same as equations (10), (11) and (12), the only difference being that the exponential PCA update equations use  $\mathbf{x}$  instead of  $\tilde{\mathbf{x}}$ , i.e., data points instead of mixture component centers. Each data point  $\mathbf{x}$  is its own mixture component center.

As noted in [7], it is possible for the atoms obtained with exponential PCA to diverge since the optimum may be at infinity. To avoid such behavior, we introduce a penalty function that defines and places a set of constraints into the

---

### Algorithm: Semi-Parametric exp. family PCA [20]

---

**Input:** a set of observations  $\{\mathbf{x}[k]\}_{k=1}^n \subseteq \mathbb{R}^d$ , two exponential family distribution  $p^{(1)}, p^{(2)}$  defined by their cumulant generating functions  $G^{(1)}, G^{(2)}$ , a number of atoms  $m, q \ll d$  the dimension of the latent variable lower dimensional subspace.

**Output:** the NPML estimator that maximizes the complete log-likelihood function  $L^{(c)}(\mathcal{Q}, \{\mathbf{z}_k\}_{k=1}^n)$ :  $\hat{\mathcal{Q}} = \{\hat{\boldsymbol{\theta}}[l], \hat{\pi}_l\}_{l=1}^m$  with  $\hat{\boldsymbol{\theta}}[l] = \hat{\mathbf{a}}[l] \hat{\mathbf{V}} + \hat{\mathbf{b}}$  for all  $l$ ,  $\{\hat{\mathbf{a}}[l]\}_{l=1}^m \in \mathbb{R}^q$ ,  $\hat{\mathbf{V}} \in \mathbb{R}^{q \times d}$  and  $\hat{\mathbf{b}} \in \mathbb{R}^d$ .

---

#### Method:

Initialize  $\mathbf{V}$ ,  $\mathbf{b}$  and  $\{\mathbf{a}[l], \pi_l\}_{l=1}^m$  with  $\pi_l \geq 0$  for all  $l$  and  $\sum_{l=1}^m \pi_l = 1$ ;  $\boldsymbol{\theta}[l] = \mathbf{a}[l] \mathbf{V} + \mathbf{b} \in \boldsymbol{\Theta}$  for all  $l$ ;  $p(\mathbf{x}[k]|\boldsymbol{\theta}[l])$  as defined in (7) for all  $k$  and  $l$ ;

#### repeat

{The Expectation Step}

for  $k = 1$  to  $n$  do

for  $l = 1$  to  $m$  do

$\hat{z}_{kl} \leftarrow p(\mathbf{x}[k]|\boldsymbol{\theta}[l])\pi_l / \sum_{r=1}^m p(\mathbf{x}[k]|\boldsymbol{\theta}[r])\pi_r$

end for

end for

**Table 2. Exponential PCA algorithm.**

### 4.3. Bregman soft clustering

The Bregman soft clustering approach presented in [4] utilizes an alternative interpretation of the EM algorithm for learning models involving mixtures of exponential family distributions. It is a simple soft clustering algorithm for all Bregman divergences, i.e., for all exponential family distributions. We choose here to present this technique without referring to the Bregman divergence as done in [4] but by using its corresponding exponential family probability distribution for the sake of comparison with SP-PCA and exponential PCA.

Given a data set of observations  $\{\mathbf{x}[k]\}_{k=1}^n$ , Bregman soft clustering aims at modeling the statistical structure of the data as a mixture of  $m$  densities of the same exponential family. The clusters correspond to the components of the mixture model and the soft membership of a data point in each cluster is proportional to the probability of the data point being generated by the corresponding density function. The Bregman soft clustering problem is based on a

---

**Algorithm:** Bregman Soft Clustering [4]

---

**Input:** a set of observations  $\{\mathbf{x}[k]\}_{k=1}^n \subseteq \mathbb{R}^d$ , two exponential family distribution  $p^{(1)}, p^{(2)}$  defined by their cumulant generating functions  $G^{(1)}, G^{(2)}$ , a number of atoms  $m$ .

**Output:** the NPML estimator that maximizes the complete log-likelihood function  $L^{(c)}(\mathcal{Q}, \{\mathbf{z}_k\}_{k=1}^n)$ :  $\hat{\mathcal{Q}} = \{\hat{\boldsymbol{\theta}}[l], \hat{\pi}_l\}_{l=1}^m$ .

**Method:**

Initialize  $\{\boldsymbol{\theta}[l], \pi_l\}_{l=1}^m$  with  $\pi_l \geq 0$  for all  $l$  and  $\sum_{l=1}^m \pi_l = 1$ ;  $p(\mathbf{x}[k]|\boldsymbol{\theta}[l])$  as defined in (7) for all  $k$  and  $l$ ;  $\boldsymbol{\theta}[l] \in \Theta$  for all  $l$ ;

**repeat**

{The Expectation Step}

**for**  $k = 1$  to  $n$  **do**

**for**  $l = 1$  to  $m$  **do**

$\hat{z}_{kl} \leftarrow p(\mathbf{x}[k]|\boldsymbol{\theta}[l])\pi_l / \sum_{r=1}^m p(\mathbf{x}[k]|\boldsymbol{\theta}[r])\pi_r$

**end for**

**end for**

{The Maximization Step}

**for**  $l = 1$  to  $m$  **do**

$\pi_l \leftarrow (1/n) \sum_{k=1}^n \hat{z}_{kl}$

$\boldsymbol{\theta}[l] \leftarrow$  solve for  $\boldsymbol{\theta}[l]$ :

$G'(\boldsymbol{\theta}[l]) = \sum_{k=1}^n \hat{z}_{kl}\mathbf{x}[k] / \sum_{k=1}^n \hat{z}_{kl}$

**end for**

**until convergence;**

return  $\hat{\mathcal{Q}} = \{\hat{\boldsymbol{\theta}}[l], \hat{\pi}_l\}_{l=1}^m$ .

---

**Table 3. Bregman soft clustering algorithm.**

maximum likelihood estimation of the cluster parameters  $\{\boldsymbol{\theta}[l], \pi_l\}_{l=1}^m$  satisfying the following mixture structure:

$$p(\mathbf{x}) = \sum_{l=1}^m p(\mathbf{x}|\boldsymbol{\theta}[l])\pi_l,$$

where  $p(\mathbf{x}|\cdot)$  is an exponential family distribution. The data likelihood function takes the following form:

$$p(\mathbf{X}) = \prod_{k=1}^n \sum_{l=1}^m p(\mathbf{x}[k]|\boldsymbol{\theta}[l])\pi_l. \quad (13)$$

The data likelihood function in (13) is similar to the data likelihood function in (6) without the linear constraint  $\boldsymbol{\theta}[l] = \mathbf{a}[l]\mathbf{V} + \mathbf{b}$  for  $l = 1, \dots, m$ . Hence, the Bregman soft clustering problem is similar to the SP-PCA problem without the lower dimensional subspace constraint and a simple EM algorithm is used to estimate the cluster parameters. We consider again the mixed data type case. The E-step and the first part of the M-step yield the same results as for SP-PCA. In the second part of the M-step, the component parameters

$\theta[l], l = 1, \dots, m$ , are estimated in the following way:

$$\begin{aligned}\theta[l]^{(new)} &= \arg \max_{\theta[l]} \sum_{k=1}^n \sum_{r=1}^m \hat{z}_{kr} \log p(\mathbf{x}[k]|\theta[r]) \\ &= \arg \max_{\theta[l]} \left\{ \sum_{k=1}^n \sum_{r=1}^m \hat{z}_{kr} \log p^{(1)}(\mathbf{x}^{(1)}[k]|\theta^{(1)}[r]) \right. \\ &\quad \left. + \sum_{k=1}^n \sum_{r=1}^m \hat{z}_{kr} \log p^{(2)}(\mathbf{x}^{(2)}[k]|\theta^{(2)}[r]) \right\},\end{aligned}$$

with  $\log p(\mathbf{x}[k]|\theta[r]) = \theta[r]\mathbf{x}[k]^T - G(\theta[r])$ . Using the convexity properties of  $G(\cdot)$ , it is easily shown that:

$$G'(\theta[l]^{(new)}) = \left( \sum_{k=1}^n \hat{z}_{kl} \mathbf{x}[k] \right) / \left( \sum_{k=1}^n \hat{z}_{kl} \right)$$

can be solved for  $\theta[l]^{(new),(1)}$  and  $\theta[l]^{(new),(2)}$  by changing  $\mathbf{x}$  to  $\mathbf{x}^{(1)}$ , respectively to  $\mathbf{x}^{(2)}$ ,  $G'(\cdot)$  to  $G^{(1)'}(\cdot)$ , respectively to  $G^{(2)'}(\cdot)$ .

Table 3 summarizes the Bregman soft clustering algorithm.

## 5. Experimental results on synthetic data

We compare the relative performances of exponential PCA, SP-PCA and Bregman soft clustering in a mixed data set clustering problem with two data types and demonstrate how exponential PCA with the addition of a nonparametric estimation of the point-mass probabilities exceeds SP-PCA in performance.

We first consider a synthetic  $d = 3$ -dimensional data set with a lower dimensional subspace of dimension  $q = 1$ . The first data feature is Poisson distributed, the second and third features are Gaussian distributed. The data has  $n = 500$  points and is composed of two mixture components with parameters  $\theta[1]$  and  $\theta[2]$  constrained to the lower dimensional subspace.

We first use exponential PCA. However, exponential PCA does not estimate point-mass probabilities. We use a nonparametric density estimation technique based on a kernel smoothing method to estimate the point-mass probabilities using the support points values  $\mathbf{a}[k]$ ,  $k = 1, \dots, n$ , obtained by exponential PCA. Figure 3 shows that the nonparametric density estimation exhibits a definite two-component shape. The dotted lines represent the correct values  $\mathbf{a}[1]$  and  $\mathbf{a}[2]$ . We can then estimate the values of  $\mathbf{a}[1]$  and  $\mathbf{a}[2]$  as well as their mixing distributions  $\pi_1$  and  $\pi_2$  using a simple kmeans algorithm, with the  $\pi_1 + \pi_2 = 1$  assumption.

Figure 4 presents the histogram of the estimated point-mass probabilities obtained with SP-PCA,  $m = 2$ .

Table 4 shows detailed results for this synthetic data setting (“modified” means the extension to mixed data sets of the algorithm): the mixing distributions or point-mass probabilities  $\pi_1$  and  $\pi_2$ , the latent variable or point of support values  $\mathbf{a}[1]$  and  $\mathbf{a}[2]$ , the parameter values  $\theta[1]$  and  $\theta[2]$  as well as the sine of the angle between the estimated lower dimensional subspace and the correct subspace. Bregman soft clustering does not have the lower dimensional subspace constraint, and hence does not exhibit a sine or the latent variables values in Table 4. The estimation quality of the  $\theta[1]$ ,  $\theta[2]$  and  $\pi_1$ ,  $\pi_2$  values defines the clustering performance. For this simple Poisson-Gaussian mixed data setting, both exponential PCA and Bregman soft clustering seem to perform better than SP-PCA: the SP-PCA obtained parameter values for  $\theta[2]$  are far from the original values, contrary to exponential PCA and Bregman soft clustering.

**Figure 3. Nonparametric estimation of the point-mass probabilities obtained with exponential PCA (dotted: correct cluster centers).**

**Figure 4. Histogram of the estimated point-mass probabilities obtained with SP-PCA (dotted: correct cluster values).**

Results for a second experiment are shown in Table 5 for a Binomial-Gaussian mixed data set created in a similar fashion as the Poisson-Gaussian mixed data set (the parameter  $N$  is set to 10 for the Binomial component). Again, exponential PCA exceeds SP-PCA in clustering performance.

## 6. Conclusion

We presented a mixed data-type hierarchical Bayes graphical model framework that adds clarity and perspective to our understanding of exponential PCA, SP-PCA and Bregman soft clustering. We demonstrated that these techniques are not separate unrelated algorithms but different manifestations of parameter choices taken within a common framework. Because of this insight, we were able to extend the algorithms to readily derive novel extensions that deal with the important mixed data type case. Our framework has the critical advantage of allowing one to go from high-dimensional mixed-type data components to low-dimensional common-type latent variables that are then used to perform clustering in a much simpler manner using well-known continuous-parameter clustering techniques.

### Abstract

*A new complete proposal to solve the problem of automatically selecting good and non redundant n-gram words as attributes for textual data is proposed. Generally, the use of n-gram words is required to improve the subjective interpretability of a text mining task, with  $n \geq 2$ . In these cases, the n-gram words are statistically generated and selected, which always implies in redundancy. The proposed method eliminates only the redundancies. This can be observed by the results of classifiers over the original and the non redundant data sets, because, there is not a decrease in the categorization effectiveness. Additionally, the method is useful for any kind of machine learning process applied to a text mining task.*

### 1. Introduction

The amount of information in the digital universe corresponded to 161 exabytes according to 2006 estimates, which was about 3 million times the information in all books already written. In the period from 2006 to 2010, an increase in the digital universe has been estimated from 161 exabytes to 988 exabytes [6]. Facing this scenario, the human capability of analyzing and understanding those data has been exceeded. Therefore, much of the information and knowledge, potentially useful, can be wasted, hidden in data bases spread throughout the world. As a consequence, the need for developing new tools and knowledge extraction techniques from storage data is becoming more and more indispensable [5].

The Text Mining (TM) process, using computational techniques of knowledge extraction, acts in this scenario as a transformer agent, extracting from this enormous quan-

tity of textual data some useful knowledge that can be used as a competitive advantage or as a support to decision making. This process can be seen as a particular case of Data Mining and it is composed by five steps: problem identification, pre-processing, pattern extraction, pos-processing and knowledge use. These steps can be instanced according to the process goals [18].

Frequently, the pre-processing is considered a step of minor importance, or less interesting than the others, due to the lack of technical glamor and the excess of manual tasks. Basically, this step aims at transforming the text collection into a useful form for the learning algorithms, involving tasks as treatment, cleaning and reduction of the data. Additionally, in this step, the most representative features in the collection must be considered, looking for the elimination of the irrelevant features. Nevertheless, the difficulties and challenges imposed by this nontrivial step result in the rich or poor quality of the analyzed data and, consequently, in the efficiency of the used learning algorithms and the confidence of the obtained results. Moreover, it is important to consider the explicit knowledge contained in the attributes in a text mining task, since the final results can be subjectively analyzed [20].

In this way, the probability of considering an attribute as a domain term in a text collection can be taken as a quality and discriminative property. Although many authors consider the dimensionality increase more harmful than beneficial, the attributes representation using single and compound words seems to be more easily interpreted and, consequently, it is more suitable to the users of the results of a text mining task ([14], [15]). When working with single and compounded words, found after a statistical analysis, there are some observed redundancies and a lot of compounded words that can be discarded. Some initiatives to discard redundancies can be found in the work of Zhang and Zhu

[21] and of Dejun and Maosong [3]. According to Dejun and Maosong there is a kind of redundancy arising from feature overlapping in Chinese character n-gram and they have proposed a model to avoid the redundancies that they believed to be language independent, in which the overlapping is estimated and then absorbed by the attribute model; besides, the model is not confined to supervised learning. In the proposal of Zhang and Zhu, a window length between words that form a n-gram is estimated in a model to set a discriminative value to the n-gram words, based on the document frequency of the found n-gram words and in the class label value; consequently, it is better applied to supervised learning, but it is an interesting solution to remove words among the goal word grams.

In this work, a new complete proposal to solve the problem of automatically selecting good and non redundant n-gram words as attributes for textual data is detailed. The model is useful to supervised and unsupervised learning and it depends only on statistical tests over the attribute candidates. In the next section the methodology to select good and non redundant n-gram words is described. In the experiments and results, section 3, we can observe that the reduction of feature space did not sacrifice the categorization results. Finally, some the conclusions and future work are discussed in section 4.

## 2. Proposed Method

The general idea is to generate attributes and apply filters that have more reliable behavior for each kind of n-gram sequentially, using statistical methods only, so the whole process can be completely automated. First of all, there are some terms that has to be defined according to their use in this paper:

- **n-gram word**: the used n-gram word model removes the stopwords from the texts, identify simple words as tokens, apply a stemming process over the words and then combine all of them in a sequential way [13]. The stemming process was based on Porter's algorithm [17] and adapted to the Portuguese and Spanish languages, as well as English. For example, a n-gram word can be "artific", "artific-intelligenc", "intelligenc-conferenc" and "artific-intelligenc-conferenc".
- **stopwords**: always the habitual list of stopwords, as articles and other grammatical classes that are very common in the texts and can be discarded from the attribute set. The set of words discarded from a filter selection is also considered stopwords, and in this paper this set of discarded words is called **collection stopwords**, referring to the specific text collection used in the example processes.

Figure 1. Steps of non-redundant n-gram word selection

- **attribute or term**: the two words refer to a selected n-gram word, that is, a n-gram word that is accepted as a valid attribute or a candidate attribute, because of its statistical discriminative potential.

The method is divided in five steps as illustrated in Fig.1. The text collection is supposed to be from a specific domain, because this method sees the text collection as a bag of n-gram words, so it is not able to treat polysemous words (or n-gram words) in different contexts; consequently this assertion decreases the probability of polisemy occurrence in the collection. For the first step, **unigram generation**, the text collection and the habitual stopwords list are considered to generate only the unigram word set of candidate attributes and their frequencies are counted; that is all possible unigram word forms is in this set, for example, "artific", "intelligenc" and "conferenc".

In the second step, a **filter selection** is applied to the generated unigram word set. The filters are based on the observed frequencies and their variance. The most common used filter attribute is the Luhn's method [11], that finds two cutoff points by ascending and plotting the attributes. So, two cutoff points are chosen close to the tendency curve inflexion points, considering the attributes which have very low or very high frequencies as irrelevant. Despite that, the elimination of low frequency terms is not a common-sense. For example, in the information retrieval area they have been favored, because of the wide use of the tf-idf indexer (tf-idf: term frequency - inverse document frequency) [19]. Some filters based on variance representativeness are also used: the Term Contribution (TC) [10] that can be defined as how much one specific term contributes to the simi-

larity among documents in a document collection; the Term Variance (TV) measure [9] uses the variance of all terms in the collection, attributing the highest scores to those terms that do not have low document frequency and have a non-uniform distribution through the collection; and, the Term Variance Quality (TVQ) [4] that is very similar to Term Variance and used to calculate the quality of a term through the total variance. Therefore, these filters provide an attribute ranking which implies in a cutoff choice. All of these filters are applicable for unsupervised attribute sets, because the most of interesting documents are unstructured and not classified. Besides, filters based on frequencies are more reliable to one gram sets, because they have a tendency on favoring terms that are not so frequent neither so rare. Experimentally it is easy to note that composed terms tend to have very low frequencies compared to simple terms (or unigram words). Moreover, the most interesting composed terms generally are the most frequent ones, although this observation does not guarantee that they can be considered domain terms or collocation candidates[12]. In this step, the filter that presents the best behavior is selected and the unigram word set selected by the filter is considered as a **valid attribute set**.

After obtaining the **filtered unigram word** set, in the third step, the **collection stopwords** are selected. They correspond to those single terms discarded from the text collection, that is, those words that do not help in the construction of the filtered unigram word set. The collection stopwords have to be discarded of the high order n-gram words because the interesting high order n-gram words are only those whose are formed by unigram words that are statistically discriminative. In this way, many of the possible n-gram words for the text collection have already been eliminated. In this work only **bigram and trigram words are being generated** in the fourth step so far.

Finally, there are three sets of attributes, where only the one gram set has already been evaluated by some statistical tests, and there are still a lot of redundant n-gram words. For example, in the text “*Textual data mining is data mining over textual data. Textual data are textual collections in several formats. Data mining has several definitions, but data are always data that are aimed at a special meaning and use.*” there are several possibilities of constructing n-gram words. Not all combinations of unigram words are interesting to discriminate the text or make any sense. In table 1 there are only the trigram, bigram and unigram words, presented in the text, that were subjectively considered to be useful and to have sense. In the **second column** there are the observed occurrence frequencies of each n-gram word in the text. As each low order n-gram word is also presented in a high order n-gram word, in the **third column** the number of occurrences was subtracted from the highest order n-gram word, in this first case from the trigram word; and,

Subjectively chosen n-grams	observed frequency	- 3gram occurrence	- 2gram occurrence
textual data mining	1		
data mining	3	3-1=2	
textual data	3	3-1=2	
textual collections	1	1-0=1	
several formats	1	1-0=1	
several definitions	1	1-0=1	
several meaning	1	1-0=1	
special meaning	1	1-0=1	
data	7	7-1=6	6-2-2-1=1
mining	3	3-1=2	2-2=0
textual	4	4-1=3	3-2-1=0
collections	1	1-0=1	1-1=0
several	2	2-0=2	2-1-1=0
formats	1	1-0=1	1-1=0
definitions	1	1-0=1	1-1=0
aimed	1	1-0=1	1-0=1
special	1	1-0=1	1-1=0
meaning	1	1-0=1	1-1=0
use	1	1-0=1	1-0=1

**Table 1. Redundant selected n-gram words**

finally, in the **fourth column** the last number of frequencies for each n-gram word is subtracted from the last obtained frequencies for each bigram word in which it also occurs. As a result of this process, the n-gram words that have null frequency in the last column are discarded from the original set of attributes candidate, because their linear combinations of frequencies have resulted in higher order n-gram words. The n-gram words that have a non zero frequency are the non redundant. The systematization of these ideas occurs in the **selection of non redundant n-gram words**, fifth step illustrated in Fig. 1, and are described as follow.

First of all, the n-gram words, with  $n = 3, 2, 1$ , must be statistically selected as candidates for domain terms, instead of the subjectively selection. This can be carried out by using a set of tests for dependence among the unigram words of the generated n-gram in the whole text collection ([12], [1]). To simplify this process, the Yule’s Q test, a robust test used in decomposed contingency tables (for details see [2]) was chosen and incorporated to the method presented here. To reach all test results, a set of frequency measures has to be taken from each n-gram word.

Let  $w_1w_2w_3$  be a trigram word and its observed frequency be  $f_{123}$ , it is also needed to obtain the observed frequency of the bigram word  $w_1w_2$  in the first and second positions of all trigram words in the collection as  $f_{12}$ , the observed frequency of  $w_2w_3$  in the second and third positions as  $f_{23}$ ; and the frequencies of  $w_1$  in the first position ( $f_{1..}$ ) and  $w_3$  in the third position ( $f_{...3}$ ), of all obtained trigram words. The frequency of all trigram words in the collection ( $f_{...}$ ) has also to be obtained.

In table 2, the frequency values for  $w_1$  in the first position ( $f_{1..}$ ) and  $w_2w_3$  in the second position ( $f_{.23}$ ) of the

trigram word  $w_1w_2w_3$  ( $f_{123}$ ) are illustrated, and, the frequency values of the n-gram words different from them in all the collection.

	$w_2w_3$	$!(w_2w_3)$	
$w_1$	$f_{123}$	$f_{1..} - f_{123}$	$f_{1..}$
$!(w_1)$	$f_{.23} - f_{123}$	$(f_{...} - f_{1..}) - (f_{.23} - f_{123})$	$f_{...} - f_{1..}$
	$f_{.23}$	$f_{...} - f_{.23}$	$f_{...}$

**Table 2.**  $w_1$  in the first and  $w_2w_3$  in the second and third positions of  $w_1w_2w_3$

To test the hypothesis of the independence between  $w_1$  in the first position and  $w_2w_3$  in the second and third positions, using the Yule's Q statistic, the following values must be obtained (for details see [2]):

$$d_1 = ((f_{...} - f_{1..}) - (f_{.23} - f_{123}))$$

$$\alpha_1 = \frac{f_{123} * d_1}{(f_{.23} - f_{123}) * (f_{1..} - f_{123})}$$

$$Q_1 = (\alpha_1 - 1) / (\alpha_1 + 1)$$

$$v_1 = \sqrt{\frac{1}{f_{123}} + \frac{1}{f_{1..} - f_{123}} + \frac{1}{f_{.23} - f_{123}} + \frac{1}{d_1}}$$

$$\sigma_{Q_1} = \frac{1}{2} * (1 - Q_1^2) * v_1$$

$$IC_{Q_1} = [Q_1 - 2 * \sigma_{Q_1}, Q_1 + 2 * \sigma_{Q_1}]$$

In table 3, the frequency values for  $w_1w_2$  in the first and second positions ( $f_{12.}$ ) and  $w_3$  in the third position ( $f_{..3}$ ) of the trigram word  $w_1w_2w_3$  ( $f_{123}$ ) are illustrated, and, the frequency values of the n-gram words different from them in all the collection.

	$w_3$	$!(w_3)$	
$w_1w_2$	$f_{123}$	$f_{12.} - f_{123}$	$f_{12.}$
$!(w_1w_2)$	$f_{..3} - f_{123}$	$(f_{...} - f_{12.}) - (f_{..3} - f_{123})$	$f_{...} - f_{12.}$
	$f_{..3}$	$f_{...} - f_{..3}$	$f_{...}$

**Table 3.**  $w_1w_2$  in the first and second and  $w_3$  in the third positions of  $w_1w_2w_3$

So, to test the hypothesis of the independence between  $w_3$  in the third position and  $w_1w_2$  in the first and second positions, using the Yule's Q statistic, the following values must be obtained (for details see [2]):

$$d_2 = ((f_{...} - f_{..3}) - (f_{12.} - f_{123}))$$

$$\alpha_2 = \frac{f_{123} * d_2}{(f_{12.} - f_{123}) * (f_{..3} - f_{123})}$$

$$Q_2 = (\alpha_2 - 1) / (\alpha_2 + 1)$$

$$v_2 = \sqrt{\frac{1}{f_{123}} + \frac{1}{f_{..3} - f_{123}} + \frac{1}{f_{12.} - f_{123}} + \frac{1}{d_2}}$$

$$\sigma_{Q_2} = \frac{1}{2} * (1 - Q_2^2) * v_2$$

$$IC_{Q_2} = [Q_2 - 2 * \sigma_{Q_2}, Q_2 + 2 * \sigma_{Q_2}]$$

If  $0 \notin IC_{Q_1}$  and  $0 \notin IC_{Q_2}$  then  $w_1w_2w_3$  is a candidate to be a domain term collocation and is also selected as a trigram word attribute candidate. All selected trigram words, as attribute candidates, are ranked by their occurrence frequency, that is, by their  $f_{123}$ . As soon as all trigram words were tested, selected and ranked, all bigram and unigram words which frequencies form the trigrams by linear combinations are eliminated with the Algorithm 1, according to their observed frequencies:  $O_{f_{ij}}$ ,  $i, j = 1, 2, 3$  for bigram words; and  $O_{f_i}$ ,  $i = 1, 2, 3$  for unigram words.

It has to be highlighted that, only the best ranked candidate trigram words can be selected as final attributes. Additionally, for each of these trigram words there are some bigram or unigram words with frequency greater or equal to their frequencies. In this way, the redundancy is a selection criteria and it is used to eliminate itself.

**Input:** *TriGramList*: list of trigram words ordered by rank value

**Output:** *FinalAttributesList*: list of final attributes with updated frequencies and selected trigram words

**for all trigram  $w_a w_b w_c$  in *TriGramList* do**  
  select next best ranked trigram word,  $w_1w_2w_3$ ;  
  search for  $w_1w_2$ , with  $O_{f_{12}} \geq O_{f_{123}}$ ;  
  search for  $w_2w_3$ , with  $O_{f_{23}} \geq O_{f_{123}}$ ;  
  search for  $w_1$ , with  $O_{f_1} \geq O_{f_{123}}$ ;  
  search for  $w_2$ , with  $O_{f_2} \geq O_{f_{123}}$ ;  
  search for  $w_3$ , with  $O_{f_3} \geq O_{f_{123}}$ ;  
  subtracted  $O_{f_{123}}$  from all above n-gram  $O_{f_{ij}}$  and  $O_{f_i}$ ;  
  add  $w_1w_2w_3$  in *FinalAttributesList*;  
**end**

**Algorithm 1:** Trigram words selection algorithm

After the trigram word selection, the same process and ideas are applied to the bigram words that were not eliminated yet. In this way, the bigram word candidates are selected using the Yule's Q test and they are ranked by their occurrence frequencies.

Let  $w_1w_2$  be a bigram word and its observed frequency be  $f_{11}$ , it is also needed to obtain the observed frequency of the unigram word  $w_1$  in the first position in all bigram words in the text collection as  $f_{1.}$  and the observed frequency of  $w_2$  in the second position as  $f_{.1}$ . The frequency of all bigram words in the collection,  $f_{..}$ , has also to be obtained; and all these values are illustrated in table 4.

To test the hypothesis of the independence between  $w_1$  in the first position and  $w_2$  in the second position, using

	$w_2$	$!(w_2)$	
$w_1$	$f_{11}$	$f_{1.} - f_{11}$	$f_{1.}$
$!(w_1)$	$f_{.1} - f_{11}$	$(f_{..} - f_{1.}) - (f_{.1} - f_{11})$	$f_{..} - f_{1.}$
	$f_{.1}$	$f_{..} - f_{.3}$	$f_{..}$

**Table 4.**  $w_1$  in the first and  $w_2$  in the second positions of  $w_1w_2$

the Yule's Q statistic, the following values must be obtained (for details see [2]):

$$\begin{aligned}
d &= ((f_{..} - f_{1.}) - (f_{.1} - f_{11})) \\
\alpha &= \frac{f_{11} * d}{(f_{1.} - f_{11}) * (f_{.1} - f_{11})} \\
Q &= (\alpha - 1) / (\alpha + 1) \\
v &= \sqrt{\frac{1}{f_{11}} + \frac{1}{f_{1.} - f_{11}} + \frac{1}{f_{.1} - f_{11}} + \frac{1}{d}} \\
\sigma_Q &= \frac{1}{2} * (1 - Q^2) * v \\
IC_Q &= [Q - 2 * \sigma_Q, Q + 2 * \sigma_Q]
\end{aligned}$$

So, if  $0 \notin IC_Q$  then  $w_1w_2$  is candidate of a domain term collocation and the bigram word is also selected as an attribute candidate. All selected bigram words, or attribute candidates, are ranked by their occurrence frequency,  $f_{11}$ . As soon as all the remaining bigram words were tested, selected and ranked, all remaining unigram word which frequencies form the bigrams by linear combinations are eliminated, according to their observed frequencies:  $O_{f_i}$ ,  $i = 1, 2$ ; and following the Algorithm 2.

**Input:** *BiGramList*: list of the remaining bigram words ordered by rank value

**Output:** *FinalAttributesList*: list of final attributes with updated frequencies and selected bigram words

```

for all bigram $w_a w_b$ in BiGramList do
 select next best ranked bigram, $w_1 w_2$ with
 remaining frequency $O_{f_{11}}$;
 search for w_1 , with $O_{f_1} \geq O_{f_{11}}$;
 search for w_2 , with $O_{f_2} \geq O_{f_{11}}$;
 subtracted $O_{f_{11}}$ from all above unigram O_{f_1} and
 O_{f_2} ;
 add $w_1 w_2$ in FinalAttributesList;
end

```

**Algorithm 2:** Bigram words selection algorithm

It has to be highlighted that, only the best ranked bigram word candidates, for which there are some unigram words with frequency greater or equal their frequency, can be selected as final attributes. Note that, the redundancy is a selection criteria and it is used to eliminate itself.

Again, it has to be highlighted that, only the best ranked candidate bigram words can be selected as final attributes. Additionally, for each of these bigrams words there are some unigram words with frequency greater or equal to their frequencies. In this way, the redundancy is a selection criteria and it is used to eliminate itself.

Moreover, it is easy to see that the two algorithms are almost the same indicating that the process can be expanded to any number n of n-gram words, if desired.

Besides, the evaluation of the method is available through an implementation of some prototypes (developed in C) to test, rank and select the candidate attribute sets and the final attribute set. In this way it is possible to obtain the candidate ranked attribute lists and the final selected attribute sets, in order to compare them. Although the best comparison should be a subjective evaluation carried out with information specialists or domain specialists, because of the data and the attribute nature, it is not an easy task over big text collections. Even a small text collection frequently results in a huge attribute set for human judgment.

To perform a non subjective evaluation of the pre-processing results and obtain a validation of the generated attribute set, some labeled document collections are used within a supervised learning process and evaluation. In this way, all the described steps are applied to a labeled text collection, but considering it as non labeled. Two attribute sets are constructed to each text collection:

1. **ranked attributes:** these are the attributes selected only by ranking the generated bigram and trigram words, using first the independence test explained and then the filter to the generated unigram words.
2. **non redundant selected attributes:** applying all the steps explained before to all generated attribute candidates.

The independence test applied to rank and select the n-gram words is the same in the two attribute sets, because the goal is to compare the attribute sets only at the presence or absence of redundancy, avoiding any other possible effect.

Then an attribute-value matrix is constructed for each attribute set, where, each row vector represents a document and each column an attribute; the cells correspond to the occurrence frequency of the attribute in the document; and finally the last column corresponds to the codified label. So, to validate the results, for each obtained attribute set, two classification models are constructed using two largely known classification algorithms: C4.5 decision trees and Support Vector Machines (SVM). Both of them were chosen due to the fact that they can face well sparse attribute matrices, besides SVM is able to generalize even in the presence of many redundant features [8]. Additionally, to estimate the classifiers accuracy rate, the 10-fold cross validation process is used. Finally, the accuracy of the ob-

tained classifiers at each attribute set are compared using the t-student test.

### 3. Some Experimental Results

Three data sets from different domains and languages were selected. The first is a collection of complete articles from the Instituto Fábrica do Milênio (IFM) [7]; that is a Brazilian organization whose actions are focused on the search for manufacturing solutions for the needs of industry. This data set is composed of 614 documents in the Portuguese language, divided into 4 classes, with 291 documents in the majority class. The second document collection is the Case Based Reasoning- Inductive Logic Programming - Information Retrieval - Sonification (CBR-ILP-IR-SON) data set<sup>1</sup> composed of 681 document abstracts in the English language, classified according to 4 classes with 276 documents in the majority class; it is a scientific production collection; and, in this paper that base is referred as **CIIS**. The third text collection is a set of complete articles, in English, divided in five sub topics of Artificial Intelligence: Agents & Multiagents, Fuzzy Logic, Machine Learning, Planning & Scheduling e Robotics<sup>2</sup>; in this paper that data base is referred as **IA**.

A random selection process was used to choose balanced samples for the three text collections, obtaining approximately fifty documents per class in each collection. In this way, effects due to the unbalanced classes are eliminated. In table 5 there are the number of documents, number of generated unigram words for each collection, the number of filtered unigram words for each collection. The chosen filter was the term contribution, TC [10], taking only 10% of the ranked unigram word attributes due to some previous experiments. In these experiments it was observed that filters based on the term contribution to the explained variance select the best attribute sets with smaller sets than the other techniques [10] and some other experiments suggested that only 10% of the ranked attributes produces results as reliable as the bigger sets [16]. In the same table, the last two columns refer to the number of generated bigram and trigram words after the unigram word filtering and the collection stopwords selection.

Taking the attribute candidates corresponding to the three last columns of table 5, the fifth step of the selection of non redundant n-gram word attributes is applied. The implemented prototypes were adapted to produce the non redundant attribute sets and the only ranked attribute sets. In this way, two attribute sets were generated for each text collection; the number of non redundant (NR) selected attributes, generated in the fifth process step, is in Table 6 and

Text Collection	#docs	#gen. 1gram	#filt. 1gram	#gen. 2gram	#gen. 3gram
IA	250	42753	4276	87297	30326
CIIS	200	10810	1081	17940	17944
IFM	193	20795	2080	82325	84200

**Table 5. Results from first,second, third and fourth process steps**

the number of ranked (R) attributes, that is with the redundancies, are in Table 7.

Text collection	#NR 1gram	#NR 2gram	#NR 3gram
IA	4264	26270	24303
CIIS	1065	1379	1831
IFM	1984	7043	42741

**Table 6. Non redundant n-gram words**

Text collection	#R 1gram	#R 2gram	#R 3gram
IA	4276	53595	30060
CIIS	1081	4284	2811
IFM	2080	48775	82354

**Table 7. Ranked n-gram words**

To each of the attribute subsets of each text collection, the two classifiers, C4.5 and SVM, were applied and their accuracy rate was estimated using 10-fold cross validation. It is important to highlight that the classifiers are not being compared; the focus is on comparing how the different attribute sets react under a same evaluation process.

Text collection	Ranked $acc \pm se$	NonRed $acc \pm se$	t-test $p - value$
IA	$90 \pm 5.42$	$89.6 \pm 7.11$	0.3838
CIIS	$87 \pm 9.19$	$87 \pm 9.19$	0.3880
IFM	$70.45 \pm 8.28$	$75.63 \pm 7.88$	0.1385

**Table 8. Classifier C4.5 -  $H_0 : \overline{acc_r} = \overline{acc_{nr}}$**

Text collection	Ranked $acc \pm se$	NonRed $acc \pm se$	t-test $p - value$
IA	$79.6 \pm 8,1$	$82 \pm 7.12$	0.2968
CIIS	$90 \pm 8.82$	$90.5 \pm 6.85$	0.3837
IFM	$59.97 \pm 10.24$	$68.84 \pm 11.74$	0.0835

**Table 9. Classifier SVM -  $H_0 : \overline{acc_r} = \overline{acc_{nr}}$**

In tables 8 and table 9, it is possible to see the evaluation results along with the estimated accuracies and their standard deviation for each classifier and for each attribute set. The attribute sets are ranked (Ranked) and non redundant (NonRed). At the last columns there are the results for the

<sup>1</sup><http://infoserver.lcad.icmc.usp.br/infosvis2/PEX>

<sup>2</sup><http://labic.icmc.usp.br/projects>

t-student test for the hypothesis of the equality of the accuracy means ( $H_0 : \overline{acc_r} = \overline{acc_{nr}}$ ), where:  $\overline{acc_r}$  and  $(se)_r$ , the accuracy mean and the standard deviation for the ranked attribute set, and  $\overline{acc_{nr}}$  and  $(se)_{nr}$  the accuracy mean and standard deviation for non redundant attribute set. It was calculated using equation 1 to obtain a  $t_{value}$  and then calculating the cumulative probability of this value, under a t-student distribution. If the cumulative probability value is the interval of  $[0.025, 0.975]$ , the hypothesis of the statistical equality of the accuracies is accepted. This interval corresponds to the values of the t-student table for nine degrees of freedom, because the accuracies have been calculated from a 10-fold cross experiment.

$$t_{value} = \frac{\overline{acc_r} - \overline{acc_{nr}}}{\sqrt{\frac{(se)_r^2}{10} + \frac{(se)_{nr}^2}{10}}} \quad (1)$$

At a first glance, focusing only on the performance, for each classifier we have the feeling that the feature redundancy removal was better, especially because of the range of the standard deviations. But after applying the t-test, the equality hypothesis was accepted for all data sets and classifiers. In this way, we can observe that the redundancy removal did not sacrifice the categorization effectiveness. Besides, as the accuracy estimates were good, we believe the attribute selection was also good.

## 4. Conclusions

A new complete proposal to solve the problem of automatically selecting good and non redundant n-gram words as attributes for textual data is proposed. The method is based on the assumption that attribute redundancy is always present when using n-gram words, for  $n \geq 2$ , due to the stochastic nature of them.

The proposed method was shown to reach the main goals: selecting good n-gram words and eliminating only the redundancies. Firstly, the accuracy estimates of the classifiers were good, what is an indication of a good attribute selection. Moreover, the categorization effectiveness has been not decreased after the redundancy removing, which indicates that only redundant attributes had been eliminated.

Since the method does not depend on class labels, it can be used in unsupervised or supervised learning. We believe that for supervised learning it is better to change the filtering process used in the second step, because an appropriated filter could produce a better unigram word selection.

The proposed method is completely dependent only on statistical tests over a bag of n-gram words instead of contiguous character n-grams, as on the method of Dejun and Maosong. Besides, Dejun and Maosong believed their method would be language independent; and the proposed method is language independent after the stemming process, as we could observe in the experiments with text

collections in two different languages (Portuguese and English).

Moreover, this method uses the collection stopwords, as defined here, to remove undesirable words among the goal n-gram words; in this way, there is no need of estimating a window length between the words, as Zhang and Zhu had proposed. The proposed method can be classified closer to the method of Zhang and Zhu, because we believe that the removal of the collection stopwords also causes a semantic information improvement similar to the window length estimation.

As future work, we intend to realize subjective analysis over the generated set of attributes, along with domain specialists, to evaluate the semantic improvement. Besides, it is necessary to expand the algorithms, and the implemented prototype, to deal with any number of n in the n-gram word model.

# gSVMT: Aggregating SVMs over a Dynamic Grid Learned from Data

Shaoning Pang, Tao Ban, Youki Kadobayashi, and Nik Kasabov

**Abstract**—Addressing the problem of adaptively modelling a classifier as a modular system, a new type of SVM aggregating method termed gridding SVM Tree (gSVMT) is proposed in this paper. The proposed gSVMT achieves to discover data subregions with principal discriminant knowledge through a recursive SVM-supervised data partitioning procedure. For each subregion, an individual SVM is allocated to extract the subregion knowledge. A set of such SVMs are aggregated in a specific order, resulting in a globally reliable decision rule to predict new coming samples. Experiments on a synthetic Gaussian data set and 13 benchmark machine learning data sets, have highlighted the usability of the gSVMT on its competitive classification capability. In particular, the proposed gSVMT is found to have better generalization performance than SVM classifiers for data sets with high sparseness and/or class-imbalance. Its performance has been further demonstrated with the successful real application on a face membership authentication system.

## I. INTRODUCTION

When faced with a new classification problem, one often considers, for the first instance, to employ one of the available discriminative classifiers such as the well known  $k$ -nearest neighbor classifier, feed-forward neural networks, or support vector machines (SVMs) to solve the problem swiftly in a single-stage mode. But more often, when complex applications are confronted, just as in most real-world applications, the problem could come into a scale too large and a nature too complicated for a single-stage model to be solved efficiently in terms of the convergence time in the training phase and the response time in the testing phase. In such a case, one may fall back on data preprocessing techniques, e.g. feature extraction and feature selection, to reducing the difficulty of the problem, or alternatively turn to multi-stage approaches. The idea to observe, measure, and break the learning problem into a collection of simpler subproblems and then summarize solutions of the subproblems to yield a global decision, is generally known as the ‘divide-and-conquer’ methodology. In this paper, to make difference between a single-step classifier, we call a classification method which makes use of the divide-and-conquer strategy as a multi-stage algorithm. Representative multi-stage algorithms include decision tree classifiers [19] and modular classifiers [20], e.g. SVM ensemble [10], and SVM classification tree (SVMT) [15].

Shaoning Pang and Nikola Kasabov are with the Knowledge Engineering & Discovery Research Institute, Auckland University of Technology, Private Bag 92006, Auckland 1020, New Zealand (email: {spang, nkasabov}@aut.ac.nz). Tao Ban and Youki Kadobayashi are with Information Security Research Center, National Institute of Information and Communications Technology, Tokyo, 184-8795 Japan (email: bantao@nict.go.jp, youki-k@is.aist-nara.ac.jp)

Profiting from the divide-and-conquer strategy, the advantages of a multi-stage classifier over a single-stage classifier include quick convergence, parallel training, and better generalization. In the literature, multi-stage classifiers have been successfully applied in a diversity of areas including character recognition, remote sensing, medical diagnosis, expert systems, and speech recognition [4], [6]. However, given a new data set, there is no existing guideline on how to choose an appropriate multi-stage classifier that can well suit the specific problem with a preferable performance guaranteed. Thus, one often confronts the embarrassment to implement and evaluate multiple methods on the data set. This procedure is usually frustrating because it is not only time and labor demanding, but sometimes could be resultless as well, considering the case of a dataset with a large scale that rendering some of the methods noneffective.

In this paper, we focus our discussion on the usability and construction of a novel multi-stage classifier. The contribution of the paper is twofold. First, we introduce two measurements characterizing the distribution of the data set, namely the sparseness and the class-imbalance. They help to identify whether the dataset can be fitted well by a multi-stage approach so that a generalization performance better than a state-of-the-art single-stage classifier can be expected. Hence, via a preceding exploratory analysis step, we can learn whether experiments on multi-stage classifiers are necessary. Second, we present an SVM based modular classifier termed gridding SVM Tree (gSVMT). The name of gSVMT comes from the fact that the component SVM classifiers are aggregated over a grid learned from data. gSVMT implements a ‘divide-and-conquer’ strategy by first performing data partitioning at the sparse region of the data distribution, and then conducting decision-making through aggregation of the collection of component SVM classifiers. Since each component SVM classifier not only explores the discriminant knowledge but imposes a balancing requirement in the subregion as well, gSVMT demonstrates a strong capability on sparse and/or class-imbalanced data sets.

The organization of the paper is as follows. Section II gives a brief review on related researches on multi-stage classifiers. Section III presents our pattern observation measurements: sparseness and class-imbalance. Section IV describes the detail of the proposed gSVMT methodology and its training and testing algorithms. In Section V, experimental results on 13 UCI data sets and an application of the proposed method to a face membership authentication problem are reported. Section VI concludes the paper.

## II. RELATED RESEARCHES

In this section, we first review some properties of the multi-stage approaches for classification and then discuss a certain group of modular classifiers which has enlightened our idea.

### A. Problem of Classifiers

A multi-stage classifier is generally defined as a learning model where the computation performed by the classifier is decomposed into more than one module that operates on inputs with/without communicating with each other [20], [6], [9]. Different from a single-stage classifier where input data are directly fed to the learning model, a multi-stage classifier normally performs a first step of data observation and analysis. Further steps of data partitioning and decision making are conducted only when a certain criterion is satisfied. This criterion reflects the design philosophy of the employed multi-stage approach.

Despite the mentioned successful applications in various areas, multi-stage classifiers also have confronted some failures: Huang and Ling [7] reported that decision trees performs obviously no better than single-stage method Naive Bayes and SVM on nonuniform data classification in terms of the Receiver Operating Characteristics (ROC). Drucker et. al [3] had reported that an empowered decision tree, called boosting decision tree, is not as successful as a single SVM for email spam categorization. Also, Andrew Senior [21] had found that a standard decision tree can not achieve a satisfied performance on fingerprint classification, unless the decision tree is combined properly with a hidden Markov model (HMM). This raises a problem that how a multi-stage system can be better constructed over different case studies from real world applications.

Given the learning task presented in a set of objects associated with their labels, there are three possible sources of generalization errors for a multi-stage method: 1° selection of learning models based on domain knowledge or a preceding analysis of the input data; 2° the decomposition of the problem and the aggregation of the solutions of the subproblems; 3° decision rules obtained by individual component classifiers. For errors from 2°, most multi-stage classifiers impose cost functions to guide the decomposition procedure and use statistical analysis to reduce the aggregation error as much as possible. For errors from 3°, one may employ a powerful classifier, such as an SVM or a Neural Network, as the component classifier to build the local learners. However, errors from 1° have been overlooked by researchers in most previous works. In fact, analysis of input data and selection of learning models are the basis of all subsequent data processing, especially for multi-stage classifiers which are sensitive to data distribution.

To address the errors from 1°, this paper focuses on two data characteristics that are common to see in real applications, namely the sparseness and class-imbalance. The sparseness of a data set indicates the capability of the data to be decomposed, without losing too much discriminant information presented in the data. The class-imbalance measures the property of a data

set that the samples are not evenly distributed into the two classes.

In practice, the class-imbalance problem has led to degenerated classification performance for many single-stage approaches including SVM. This is because that most classifiers have taken the assumption of a balanced prior probability, which is not true for real applications. This also gives us a very challenging difficulty to model a robust multi-stage learner in the case of imbalanced class distribution. To solve this problem, during module aggregating, we take a straightforward method to allocate more individual modules on the skewed class.

### B. Related Works

Our work can be viewed as a new attempt under the framework of SVM aggregating [14]. As an SVM based modular approach, SVM aggregating aims to create SVM-based multi-core cooperative computing techniques towards optimized problem-solving for computational intelligence. SVM ensemble learning [10] is a type of SVM aggregation in the principle of deriving a mixture of SVM experts to improve the generalization ability of single SVM decision making. SVM ensemble learning assumes that the number of SVMs in aggregation should be known in advance as prior knowledge. In fact, this number is often difficult to determine in real applications. The SVM classification tree (SVMT) was first proposed in [15], in the context of face membership authentication application [16]. SVMT overcomes the difficulty of SVM ensemble learning by determining the number of SVMs automatically during the learning.

## III. CHARACTERIZING THE DATA

In this section, we introduce two measurements to characterize the distribution of a data set. The data are assumed to be presented in a vectorial form.

### A. Sparseness

We often conduct a divide-and-conquer on a data set without caring about whether the data is dividable, i.e. be divided without losing information for classification. What if an improper data partition is performed? Due to this concern, it is interesting to see if we can define a measurement on the feasibility of a data set to be partitioned.

The sparseness is defined to describe the uniformity of a data distribution. From the view point of divide-and-conquer, it also identifies the position where the data could be partitioned, without much loss of discriminant information. Given a data set  $X = \{\mathbf{x}_i\}, i = 1, \dots, N$ , with the attribute set  $\{a_1, \dots, a_M\}$ , we analyze the data distribution of  $X$  along each attribute  $a_i$ . By partitioning the range  $[\max(a_i), \min(a_i)]$  equally into  $K$  unit intervals, a histogram  $s_l (l = 1, \dots, K)$  is calculated by counting the number of points dropping into each interval. Further, the sparseness can be calculated as the ratio of the geometric mean to the arithmetic mean of the list

Fig. 1. The illustration of data sparseness definition. Sparsenesses of the two data sets are: (a)  $\mathcal{S}_a = 0.2045$ , and (b)  $\mathcal{S}_b = 0.8923$ .

Fig. 2. Comparison of sparseness over two data sets for binary classification. (a)  $\mathcal{S}_a = 0.6545$ , and (b)  $\mathcal{S}_b = 0.6923$ .

associated with the histogram:

$$\mathcal{S}(X) = 1 - \frac{1}{\log 2} \left( \prod_{i=1}^M \frac{1}{K} \sum_{l=1}^K \log(|s_{il}| + 1) \right)^{\frac{1}{M}}. \quad (1)$$

Note that the above sparseness measures an averaged uniformity of the global data distribution, but it does not recognize any sparseness caused by data clusters. Fig. 2 gives a comparison on the sparseness of two synthetic data sets with multiple gaussian distribution. Although Fig. 2 (a) and (b) have a comparable sparseness value, obviously the capability of the two data sets for data partitioning is different. With respect to labelled data sets for classification, it is suggested that the proposed sparseness be applied to each of the classes. The obtained class-sparseness reflects the suitability of this data set for the divide-and-conquer based modelling.

### B. Class Imbalance

Class-imbalance is another problem which leads to degeneration of the generalization performance for single-stage classifiers including SVM. When class-imbalance occurs in a data set, the number of samples from one class is much larger than those of the other classes. In the case of binary classification, the class with the smaller number of samples

is called ‘skewed’ class and the other class is called ‘over-weighted’ class). In this paper, we measure the class-imbalance of a data set by computing the following class-imbalance ratio (CIR),

$$\mathcal{C}(\omega_1, \omega_2) = 1 - \frac{\min(|\omega_1|, |\omega_2|)}{\max(|\omega_1|, |\omega_2|)}. \quad (2)$$

where  $|\omega_i|$  is the cardinal number of class  $\omega_i$ . Obviously, a larger  $\mathcal{C}$  value shows a more imbalanced class distribution.

Single-stage classifiers including SVM often fail to classify the skewed class correctly [24], [23], [12], [22], since most classification algorithms assume a balanced prior probability [18]. To solve the problem caused by class-imbalance, data sampling method is a straightforward solution. Popular approaches include undersampling, which reduces the number of samples in the over-weighted class closer to the smaller class; oversampling, which repeatedly takes equal numbers of random subsamples from the two classes [1]; and resampling, which is a mixture of undersampling and oversampling [5], [25]. Algorithmic methods, e.g. adjusting decision class probability, imposing different penalty for different classes, [12], [22] modifying learning function to adjust the class boundary [24], [23], are also commonly used alternatives. Since class imbalance often occurs along with class-overlapping in many applications, the above approaches still have the following problem: improvement on the recognition rate of the skewed-class will generally leads to too much degeneration of the recognition rate on over-weighted class, especially when serious class-overlapping is involved.

Instead of a single-stage SVM with a complicated classification hyperplane, in this paper, the problem is modelled as an aggregation of a set of component SVM classifiers, e.g. linear SVMs or RBF kernel SVMs. Hence the class-imbalance problem can be treated easily by allocating more computing power, i.e. individual SVMs, for the classification of the skewed-class.

## IV. THE PROPOSED GSVMT AGGREGATION METHOD

Towards a modular SVM aggregation classifier with high generalization ability, we address three aspects of problem-solving: 1<sup>o</sup> the convergence of an SVM classification tree (SVMT), 2<sup>o</sup> problem decomposition with the minimum discriminant knowledge loss, and 3<sup>o</sup> the creation of inter-module communication amongst individual SVMs for aggregation.

### A. The Convergence of SVMT

Mathematically, a modular SVM can be formulated as a composite structural model as follows: Given a 2-class data set  $X$  for classification, and a predefined data partitioning model  $\mathcal{P}$  on  $X$ , the data set  $X$  can be partitioned via an optimized  $\mathcal{P}^*$  into  $L$  partitions  $\{g_1, g_2, \dots, g_L\}$ .

Then, an SVMT for binary classification is modelled as,

$$\mathcal{T}_{\text{SVMT}}(\mathcal{P}, f_{\text{SVM}_i^{<2>}}), i = 1, \dots, L, \quad (3)$$

where  $f_{\text{SVM}_i^{<2>}}$  is a regional 2-class decision maker modelled as a standard alone SVM classifier. Parameter  $L$  is determined

during the SVMT modelling process. Then we can have the decision function of SVMT  $\hat{f}$  as,

$$\hat{f}(\mathbf{x}) = f_{\text{SVM}_i^{<2>}} \text{ if } \mathcal{P}(\{\mathbf{x}\}) \in g_i. \quad (4)$$

Obviously, errors may occur when  $\hat{f}$  is used to predict the class label of new coming samples, because of the difference between  $\hat{f}$  and the true classification function,  $f$ . We use a real-valued loss function  $\mathcal{L} = \mathcal{L}(\hat{f}, f)$  to capture the extent of this error. The expectation of  $\mathcal{L}$  is therefore data dependent:

$$\hat{\mathcal{L}} = \int |\hat{f}(\mathbf{x}) - f(\mathbf{x})| p(\mathbf{x}) d\mathbf{x} = \int |\hat{f}(\mathbf{x}) - y| p(\mathbf{x}) d\mathbf{x}, \quad (5)$$

where  $y$  is the true class labels offered by the training set, and  $p(\mathbf{x})$  is the density function.

Given a data partitioning  $\mathcal{P}(\{X\}) = \{g_1, \dots, g_L\}$ , the minimal  $\hat{\mathcal{L}}$  can be obtained by training individual SVMs over all data partitions  $X_i$  (see proof in Appendix).

### B. Data Partitioning

Partitioning methods, such as K-means clustering, partition data normally on the basis of similarity. Yet in the spirit of searching for better individual partitions, we are aiming at partition data, which is to decompose data into partitions of different sizes, taking both input similarities and discriminant ability into consideration.

Assume the data are presented as vectors of attributes,  $X = \{\mathbf{x}_1, \dots, \mathbf{x}_N\}$ . Let  $A = \{a_1, \dots, a_M\}$  be the attributes set, and  $Y = \{y_1, \dots, y_N\}$  the class labels. The recursive data partitioning function  $\mathcal{P}$  over  $G_0 = \{X\}$  is noted as

$$\mathcal{P}(G_0) = \mathcal{P}^J(G_{J-1}, A_J, E_J) = \{g_1^J, \dots, g_{L_J}^J\}, \quad (6)$$

where  $G_j$  is the partition learned at iteration  $j$  and  $A_j$  the selected set of attributes on which the partitioning is performed. The number of partitions,  $L_J$ , and the number of iterations,  $J$ , are determined during the learning.  $E_J$  is the cost function ensuring an optimal data partitioning, which will be made clear later.

The iteration process is formulated as follows.

**Step 1.** For each partition  $g_i^j$ , an optimal attribute  $a_i^j$  can be picked from attribute set  $A$ , embodying a data partitioning with the minimal discriminant information loss for current subset  $g_i^j$ . In our implementation, we select  $a_i^j$  as

$$a_i^j = \arg \min_{a_i \in A} \frac{|u_{i1} - u_{i2}|}{\sqrt{\frac{s_{i1}}{n_{i1}} + \frac{s_{i2}}{n_{i2}}}}, \quad (7)$$

where  $u_{ik}$  and  $s_{ik}$  are the mean vector and variance of the samples in class  $k$ , respectively.

Along the selected attribute  $a_i^j$ , the data partitioning described in Eq.(6), noted as a data separation  $T(a_i^j)$ , is implemented by a crisp median-point split, or more properly by fuzzy histogram thresholding [2].

**Step 2.** For each subset  $g_i^j$  obtained from the above grid data partitioning, a cost function  $E_i^j$  is defined as

$$E(g_i^j) = \sum_{\mathbf{x}_r \in g_i^j} (y_r - \sum_s (y_s \alpha_s^* K(\mathbf{x}_r, \mathbf{x}_s) + b^*)), \quad (8)$$

where  $\sum_s y_s \lambda_s^* K(\mathbf{x}, \mathbf{x}_s) + b^*$  is the decision function of SVM and  $K(\cdot, \cdot)$  is a user defined kernel function. Equation (8) is applied to estimate the applicability of a given data partition  $g_i^j$  to act as a component classifier in SVMT. As discussed in Section II.A, this guarantees that the loss function of SVMT converges in the end.

**Step 3.** A threshold parameter  $\xi$  is put on  $E_i^j$  to see whether  $g_i^j$  bears a class discriminability large enough to be treated as a component classifier. Hence, every data partition obtained with its  $E_i^j$  less than  $\xi$  are extracted out, and the remaining data are forwarded to the next iteration of data partitioning.

### C. SVMs Aggregating over Grid

From Eq. (6), we can obtain a collection of subsets via  $J$  iterations of recursive partitioning. For regional decision making, a stand alone SVM is trained over each subset to build a 2-class classifier  $f_{\text{SVM}_i^{<2>}}$ . Towards final global decision making, these local SVM classifiers are aggregated onto a grid, whose columns and rows correspond to the iteration of data partitioning and selected attributes by Eq. (7), respectively.

Specifically, given that  $q_j$  attributes are selected by Eq. (7) at iteration  $j$ , and totally  $Q(Q \leq M)$  attributes are selected for  $J$  iterations. Then all data partitions extracted by Eq.(6), together with the corresponding partitioning functions or regional SVM classifiers, composes a composite model  $\Omega$  as

$$c = \begin{pmatrix} \{\mathcal{V}_{11}\} \\ \{\mathcal{V}_{21}\}, \{\mathcal{V}_{22}\} \\ \{\mathcal{V}_{31}\} \dots \{\mathcal{V}_{3q_3}\} \\ \vdots \\ \{\mathcal{V}_{ji}\} \dots \dots \dots \{\mathcal{V}_{jq_j}\} \\ \vdots \\ \{\mathcal{V}_{J1}\} \dots \dots \dots \{\mathcal{V}_{Jq_J}\} \end{pmatrix} \quad (9)$$

where  $\{\mathcal{V}_{ji}\}$  denotes a group of functions that use attribute  $a_i$  for data partitioning at the  $j$ th iteration. The functions could be either regional SVM classifiers  $f_{\text{SVM}_{ji}^{<2>}}$  or regional data partitioning functions  $T(a_i^j)$ .  $\Omega$  models a  $Q$ -dimensional grid which partitions the data into  $L_J$  grids, with the discriminant information in the dataset well preserved in the subsets.

Thus, over the grid learned from data, an SVM tree is constructed by building connections between every two lines of composite model  $\Omega$ .

### D. Coping with Class-Imbalance

During the aggregation, the class-imbalance is addressed in the following two parallel ways.

The first approach implements a recursive data zooming-in schema. Data size with comparatively large sample sizes, especially for the subsets from the over-weighted class, are extracted out in the first few rounds. As a result, the class-imbalance is alleviated for the remaining data. Data with class-overlapping/class-mixture are left for the next step partitioning. Hence, as we drilled down in SVMT, decisions are made only at an appropriate scale where the decision is reachable.

In the second approach, the skewed-class is protected by SVMT via turning SVM loss function  $E$  in Eq. (8) to the skewed class as,

$$L_{\text{SVM}} = \frac{1}{n} \sum_{r=1}^n (y_r - \sum_i (y_s \alpha_s^* K(\mathbf{x}, \mathbf{x}_s) + b^*)). \quad (10)$$

where  $n$  is the sample size of the *regional skewed class*, and  $\mathbf{x}$  a sample from the class.

Note that the *regional skewed class* represents the skewed-class within a data partition. In other words, a *regional skewed class* also could be a globally over-weighted class, if its class distributes are skewed regionally. Hence, Eq. (10) does no overbalanced adjustment as most data resampling methods do to favor the skewed class by using the skewed-class data repeatedly. In fact, the *regional skewed class* loss function Eq. (10) protects equally both the skewed class and the over-weighted class from being underestimated in the regional decision functions and thus helps to overcome the class-imbalance. In practice, Eq. (10) eventually favors the skewed class, because the probability for the globally skewed class to be regionally skewed is often much higher than that of the globally over-weighted class.

#### E. The Proposed gSVMT Algorithm

To build a gSVMT, Eq. (6) is implemented recursively in two steps. First, the grid partitioning is employed to split the data recursively. During this procedure, data partitions with a cost function  $E_i^j$  smaller than threshold  $\xi$  are extracted out. For each of these partitions, an SVM classifier is built and associated with a leaf node of the gSVMT structure.

To test a constructed gSVMT, an input sample  $\mathbf{x}$  is first judged by the test function  $\mathcal{T}(\mathbf{x})$  at the root node of the gSVMT. Depending on the decision made by the root node,  $\mathbf{x}$  will be redirected to one of the children of the root node. This procedure is repeated until a leaf node is reached. The final prediction  $\hat{f}(\mathbf{x})$  is made by the SVM classifier associated with the leaf node. Algorithm 2 presents the testing procedure of a gSVMT.

In the above algorithms,  $\mathbf{K}$  specifies the type of SVM used in gSVMT construction.  $\xi$  is the permitted minimal loss function value, which gives a criterion to select partitions which can be well modelled by a stand alone SVM classifier. The default value for  $\xi$  is zero. However, in practice, a small positive value near zero should be given. Obviously, the smaller  $\xi$ , the more time cost to train the gSVMT. Fig. 3 gives an example of gSVMT. As can be seen, gSVMT is a binary tree with ‘P0’ as the root node. Every ellipse here represents an SVM node, and every internal node is a testing function for data partitioning. The size of an ellipse identifies the size of training data set associated with the node.

## V. EXPERIMENTS AND DISCUSSION

In this section, the experimental results on UCI Machine Learning benchmark data sets and a facial membership authentication application are reported.

Algorithm 1. gSVMT Training

#### A. UCI Data sets

We test the proposed gSVMT algorithm on 13 UCI data sets. Table 1 reports the error rates obtained by the proposed gSVMT method with a comparison against previously reported results on SVM classifiers [13]. We divide the 13 data sets into two categories according to the sparseness value. Six data sets with the sparseness greater than 0.3 are taken as sparse data sets, and the remaining 7 data sets are counted as non-sparse data sets.

As shown in the table, the proposed gSVMT matches SVMs on 5 out of 6 sparse data sets when proper RBF kernels are employed. It is surprising that gSVMTs wins SVM over 15% on the classification accuracy of 2 non-sparse data sets, Flare-solar and Titanic. As we exploring the distribution characteristics of these two data sets in their feature space, it is found that both of them have some discrete attributes. In other words, both two data sets are a type of discrete data set, which is a special case of sparseness covered by our sparseness definition. The extraordinary performance on these two data sets suggests that the proposed gSVMT is very efficient on the classification of discrete data sets. The proposed gSVMT performs not as well as single SVMs on those non-sparse data set, this possibly because the grid partitioning of gSVMT has destroyed too much information useful for classification.

**Function:** gSVMTtesting

### B. Face Membership Authentication Application

To test gSVMTs on problems where dynamic class-imbalance and class-overlapping are prevalent, we have also applied the algorithm to the face membership authentication (FMA) problem [17], [16], [15]. The objective of an FMA system is to distinguish the membership class from the non-membership class based on their facial features presented as images.

FMA is counted as a problem involving sparse data, because the within-class similarity is rather low: Facial appearance of one person may look very different from another, despite the fact that they both belong to the same membership group. In other words, face samples for one person can be far away

Fig. 3. An example of gSVMT

Fig. 4. The illustration of FMA of 5 members against 100 non-members

from samples for another person in the feature space. Another challenging property of a FMA problem is severe class-imbalance: The size of membership group is generally much smaller than that of non-membership, and the class-imbalance may vary dynamically over time in real applications.

In the experiment, we work on a database composed of facial images from 271 individuals, with 5 different images for each. Facial features are extracted using principle component analysis (PCA), and the eigenvector associated with top 100 eigenvalues are used in our experiment. The sparseness of the data set is 0.6605. Although this value does not really reflect the sparseness of the data set, the capability of the data set for data partitioning is obvious. Fig. 4 presents an FMA problem of 5 members against 100 non-members in the feature space defined by the first two eigenvectors. As we can imagine, to distinguish these 5 members from the 100 non-members, a complicated decision function is required. However, such classification difficulty can be reduced greatly, as shown in Fig. 4, if 5 members can be individually authenticated by separated simpler decision rules. This indicates that the FMA problem

Fig. 5. The sparseness for the membership class data, with membership group size increasing from 10 to 135.

can be well fitted by a divide-and-conquer model.

To test the robustness of gSVMT to class imbalance, we formulate a sequence of FMA problems with the membership group size increasing from 10 ( $C_1 = 0.962$ ) to 120 ( $C_1 = 0.205$ ), with a step size of 10 persons. Here, as an extreme case of class-imbalance, results for the member group size of 135 ( $C_1 = 0.007$ ) are also reported. Note that the sparseness for the whole data set does not change over time, however, that of the membership class data is decreasing as shown in Fig. 5.

In particular, when the size of the membership group is 10, it indicates that 10 members scatter randomly in the feature space among the remaining 261 non-members. In this case, although the sparseness for the whole data set is the same as before, the sparseness within membership group reaches the maximum because the within-class similarity of the 10 members is less than cases with more than 10 members. Hence, membership group data distribution shows a large sparseness value.

Figure 6 gives a comparison of the member authentication rate (the classification rate of the skewed class) versus class-imbalance. Four curves have recorded how the four classifiers perform under the variation of class-imbalance. As shown in the figure, SVMs get large variations on the classification of the skewed class (the membership group), while the membership group size is growing from a small size, 10, to the maximum, 135. On the other hand, the proposed gSVMT shows obvious robustness to the class-imbalance variation, keeping the member authentication rate around 80% under all class-imbalance situations.

Especially for cases where the sparseness is large, it is difficult for ordinary SVMs to find a complicated but continuous decision rule to distinguish a small number of members accurately from a large number of non-members. On the contrary, the proposed gSVMT has shown a very good performance on these cases. The sparsity of the data set can be seen as rather an advantage for gSVMT, than a disadvantage for ordinary SVMs.

Fig. 6. The proposed gSVMT is compared with 3 single SVMs on FMA

## VI. CONCLUSION AND FUTURES WORK

Addressing the problem caused by the sparsity and class-imbalance of data distribution, this paper proposes a new type of SVM based modular methods. The advantages of the proposed gSVMT are as follows. First, gSVMT keeps every iteration of data partitioning to be performed only at the sparse region of the data, minimizing the loss of discriminant information during the SVMT construction. Second, gSVMT addresses the class-imbalance problem by adjusting the partitioning cost function on the skewed-class, so that the skewed-class is emphasized by every SVM node in gSVMT. The proposed gSVMT is experimented on 13 UCI data sets and a real Facial Membership Authentication application which is characterized by the dynamic class-imbalance and class-sparseness property. The experimental results demonstrated that, compared with stand alone SVMs, the proposed gSVMT is able to treat with the sparseness and class-imbalance of the input data and delivers competitive classification performance.

From the viewpoint of SVM aggregating intelligence [14], the proposed gSVMT follows the same route of recursive data partitioning plus aggregating as the previous SVM tree methods. The gSVMT is different from all previous SVMT aggregating methods [15] because 1<sup>o</sup> grid partitioning is used for problem decomposition; 2<sup>o</sup> every internal node of the gSVMT is a data partitioning function, and every leaf node is an SVM node. Note that gSVMT has no one-class node, and decisions are made by the leaf SVM node.

The proposed gSVMT is merely sustainable for 2-class problems. It can be simply extended to  $m$ -class problems by learning  $m$  binary classifiers for each class versus the others, or by learning  $m(m-1)$  binary classifiers for each class versus another class. This topic is generally discussed under the framework of SVM decision forests [8]. Alternatively, in the principle of SVM aggregating, a multi-class gSVMT (m-gSVMT) can be constructed by decomposing a  $m$ -class task into a certain number of 2 to  $m$  classes subtasks as

$$\mathcal{T}_{m\text{-gSVMT}}(\mathcal{P}^n, f_{\text{SVM}^{<2>}}, \dots, f_{\text{SVM}^{<m>}}, \mathbf{x}), \quad (11)$$

where  $\mathcal{P}^n$  represents a partitioning function which is able to split a set into multiple subsets. Similar to 2-gSVMT,  $f_{\text{SVM}^{<i>}}$  is an  $i$ -class ( $2 \leq i \leq m$ ) local SVM classifier. Accordingly, the classification function of a  $m$ -gSVMT can be written as,

$$\hat{f}(\mathbf{x}) = f_{\text{SVM}^{<i>}} \text{ if } \mathcal{P}^n(\mathbf{x}) \in g_j. \quad (12)$$

As a measurement of the sparsity of a data set, sparseness is an important concept for divide-and-conquer data modelling. However, it is also a concept difficult to give an accurate and consistent evaluation, just as has been reflected in our work. Still, sparsity does exist for most life data, thus for better generalization ability of gSVMT, it will be an interesting future work to derive a new sparseness measurement consistent for most data sets.

### **Abstract**

*Grid computing is becoming a requirement for the processing of large amount of data now-a-days. The Gridbus broker schedules jobs depending on data and compute resources. Current scheduling process does not reassign a job from lower compute resource to higher compute resource if higher compute resource is available. In this paper, we have proposed a technique to reassign a thread to higher grade executor by preempting the thread in lower grade executor by using the data restoration technique which track the information of the thread so far ran on a lower rate compute resource. It is done only if there is an idle higher computer resource is available. The performance as well as the reliability of the Grid has been improved by this approach in a considerable extent.*

### **1. Introduction**

Grid computing is very useful in the large scientific projects. A grate number of researcher organization and communities using grid computing to carry out their sheared data resource out come. However the using of the power of Grid Computing remains to be a challenging problem for the users due to the complexity involved in the creation of the application and deployment on distributed computational resources [1]. The Gridbus broker is an advanced service-oriented meta-scheduler for data Grids which deals with computation on very large amount of data where data host may geographically distributed. It supports different Grid middleware and services. It takes care of many functions that Grid applications require such as resource selection, job scheduling and management, data access to any distributed Grid

resources and handling faults that may occur during execution, collecting result and presenting them. The Gridbus Broker schedules the job depending on some criteria like data and computes resources, job completion history etc. Here we present a modified scheduling algorithm, where we can use any idle higher power compute resource extensively and thus can improve the performance.

This paper is organized as follows: section 2 discusses the related works and section 3 shortly discusses Gridbus broker architecture, section 4 describes the problem scope of Gridbus broker architecture and scheduling, section 5 elaborates our proposed algorithm to counteract the problems of Gridbus broker scheduling, section 6 illustrates the experimental evaluation and performance analysis of algorithm with some examples. We conclude in section 7.

### **2. Related works**

As the scheduling of independent jobs on distributed heterogeneous resources [2] is a well-studied problem, so here we discussing only a few major work which deal with Grid. In the context of Data Grid, the Storage Resource Broker (SRB) [3] from San Diego Supercomputing Centre (SDSC) provides middleware for storing datasets over a network and accessing them; although it does not deal with applications executing directly.

The Gridbus broker extends the Nimrod-G [4] computational Grid resource broker model to distributed data-oriented grids. Nimrod-G specializes in parameter-sweep computation. However, the scheduling approach within Nimrod-G aims at optimizing user-supplied parameters such as deadline and budget [5] for computational jobs only. Like

Nimrod-G, the AppLeS PST [6] supports deployment of parameter-sweep applications on computational grids, but its adaptive scheduling algorithm emphasizes on data-reuse.

Harold, Shazia, Liao, Krishna, Buyya developed a Grid Thread Programming Environment (GTPE) [7] for the Gridbus broker, a software grid resource broker that provide transparent access to grid services. However, it does not provide any way to save the output of thread at any point of its runtime.

Venugopal, Buyya, Winton [1] focuses on a resource scheduling strategy within a Data Grid but concentrated on adaptive scheduling algorithms and brokering for heterogeneous resources that are shared by multiple user jobs.

Similar to [1], our work focuses on a resource scheduling strategy within a Data Grid but we concentrate on runtime thread scheduling algorithms and brokering for heterogeneous resources that are shared by multiple user jobs. However our work focuses on using the higher rate compute resources more extensively. In addition, the scheduling strategy is based on our 'File based Grid Thread Implementation' that provides a way for saving the output of a thread and creating restoration files.

### 3. Gridbus broker overview

The architecture of the Gridbus broker is shown in Figure 1[1]. The Gridbus broker inputs are considered as task and the parameter values associated with the task. The parameters can be static or dynamic. Among the other component the Grid Index Information service (GIIS), gathers information from remote information services i.e. availability and the properties of compute resources. The Data Service Catalogue organizes the data files as Logical File Names (LFNs). Network weather service (NWS) obtains the information about the current available bandwidth between the data sources and the compute resources. Global Access to Secondary Storage (GASS) obtains the inputs or parameter file from the secondary storage if required. Logical and Physical File Names (LFNs), each LFN maps to one or many Physical File Names (PFNs) somewhere on the Grid and the Job Monitor keeps track of job status, whether the jobs are queued, executing, finished successfully or failed.

A task is further considered as sequence of commands that focuses user requirements. The task along with its associated parameters decomposed in to jobs. A job is unit of work that is send to a Grid node. The set of jobs along with the set of service nodes are

an input to the scheduler. For jobs requiring remote data, it interacts with a NWS to obtain the information about current available bandwidth between the data sources and the compute resources. It then uses this information to schedule jobs by optimizing on the amount of data transfer involved.

In the current implementation, the jobs are dispatched to the remote node through the Actuator component. The Actuator submits the job to the remote node using the functionality provided by the middleware running on it. The Actuator has been designed to operate with different Grid middleware frameworks and toolkits such as Globus 2.4 that primarily runs on Unix-class machines and Alchemi [8], which is a .NET based grid computing platform for Microsoft Windows-enabled computers.

**Figure 1: Gridbus broker architecture and its interaction with other Grid entities**

The Gridbus broker scheduling algorithm schedules a job depending compute resources and data host associated with a job that is to be deployed to an executor. Firstly it gathers the information about the compute resources and data hosts using GIIS and Data Service Catalogue and determines the job completion rate for every compute resources for its history. For a job to be deployed, identifies the data hosts associated with that job and for every pair of data and compute resources, it finds the pair with earliest job completion rate and if such a pair exist the scheduler assigns the job to that pair. After the job has successfully finished at the remote node (i.e. executor), its returns any results to the Broker. If any job becomes failed, it is marked as failed and reset for rescheduling.

#### 4. Problem scope of Gridbus Broker architecture and scheduling

In the present scheduling algorithm, the Gridbus Broker schedules the jobs depending on data and compute resources available at the time of the deployment of jobs. An executor (i.e. remote node) with a higher history of job completion gets the higher priority for executing new job i.e. if there is one thread and two executors, one with relatively rich job completion history but lower compute resource and other with poor job completion history but higher compute resource then the first one will get the job. Then the scheduler takes decision depending on the compute resource. Also in the case when a compute resource with a higher job completion rate comes after the scheduling and deployment all jobs, the present scheduling algorithm does not take advantage of that compute resource. Also if there are two executors working for an application one with much higher computing power than the other and the slower one executes the last thread then the completion time of the application depends on the completion of the last thread while the faster one remains idle after completing its last job long before the slower one. In these contexts, the completion time of a job as well as for an application gets much higher as a result of threads running on lower grade compute resource. But in this case if we can use the idle time of the higher compute resource then it can reduce the computation time by a considerable factor.

#### 5. Proposed solution

For the solution of the problem stated in the previous section, if any job running on lower grade compute resource and there is a much higher grade compute resource (let it can finish the job in half of the time than current one) available after the task assignment or gets connected to grid after the first deployment of the job. Then we can preempt the job from the current executor with lower resources and assign the job to the newly available compute resource depending on the data resource for the job. Though this approach gives better performance than existing one however as the new executor starts the job from the beginning the margin of performance improvement is low depending on the time of preemption. The closer the preemption happens to the closer to the start time of the thread the higher the degree of performance improvement. However, there are cases can be found where this approach gives much

worse result if the preemption time is very closer to the finished time of the job.

So, we further move to an approach where we can save the output of a thread in any point of runtime. As we can make restoration point of a thread then we can save the computation time of the job has been executed before preemption. By this approach, whenever a compute resource with higher computation power gets idle or available in the Grid, we can preempt the job running on a lower grade computation resource and reschedule the job to execute on that new executor. At the time of reassigning the job to the new compute resource we can make the restoration file of the job available to the new executor so that it can start executing from the saved point of the job. Suppose the previous node compute 40% of the job before preemption, when the job is reassigned to new node with generated output file. This node will restart the job from the saved point (i.e. from the 40%, not from the beginning). As in this approach the new executor does not need to start from the beginning of the job, as a result the degree of performance improvement gets much higher.

In our application (File Based GRID Thread Implementation), we created a random access file associated with each thread and writing the results to that file and thus creating restoration point. The file only contains the last two computed output of a thread. The file size depends on the type of application but in our application we managed it to be quite small. This generated file is stored in the Manager Node. The file of a thread is deleted automatically after the successful completion of the thread. Threads received from the User are placed in a pool and scheduled to be executed on the various available Executors by the Manager. Manager can reassign that thread to any executor node with the same thread ID from the thread pool. When the Manager distributes the thread to any Executor node, the node first checks if there is any file available with its own thread ID. If any file is available for that thread, the node then recovers the resultant value of that thread from the file created and starts execution from the recovered value. If no file is found for that thread then the thread will start execution from the beginning and also create a file in the Manager Node using Thread ID (i.e. filename) as Thread ID remains same throughout the lifetime of an application.

In the global grid environment, these generated restoration files can be stored in the remote data host assigned with that for that Grid node or can be stored in some different host depending on the bandwidth

and cost of data transfer etc. For the jobs requiring remote data, the scheduler interacts with the Network Weather Service (NWS) [9] to get the current bandwidth condition. We can create a new instance for the restoration file in the Logical File Names (LFNs) which maps to Physical File Name of the restoration file stored in the appropriate location or data host. This instance can be updated and can use for the selection of the restoration file host. The Gridbus broker can resolve the restoration files by querying the Data Service Catalogue. When the scheduler reschedules that job for execution the restoration file can be assigned with that job so that the new executor can retrieve the file from the data host before execution and start execution from that successful executed point.

Depending on this approach, we modified the existing scheduling algorithm of the Grid bus broker. The modified Gridbus broker scheduling algorithm is stated in *Figure 2*. We added a new module (module 6) in the existing algorithm for rescheduling the jobs running on lower grade compute resource while there available any idle higher grade compute resource and no job in unassigned-job-list.

The scheduler schedules the job considering the earliest job completion time between two compute resources depending on the data host associated with that job. If the higher grade compute resource has the earliest job completion time then the scheduler preempt the job and reassign it to the new executor with the restoration files. The new executor collect the restoration files and start the job from the last saved point.

#### **Initialization**

1. Identify characteristics, configuration, capability, and suitability of compute resources using the Grid information services (GIS).

2. From the task definition, obtain the data query parameters (if present), such as the logical file name.

a. Resolve the data query parameter to obtain the list of Logical Data Files (LDFs) from the Data Catalog.

b. For each LDF, get the data sources or Data Hosts that store that file by querying the Data Catalog.

#### **Scheduling loop**

Repeat while there exists unprocessed jobs. [This step is triggered for each scheduling event. The event period is a function of job processing time, rescheduling overhead, resource share variation, etc.]:

3. For each compute resource, predict and establish the job consumption rate or the available

resource share through the measure and extrapolation strategy taking into account the time taken to process previous jobs. Use this estimate along with its current commitment to determine expected job completion time.

4. If any of the compute resource has jobs that are yet to be dispatched for execution and there is variation in resource availability in the Grid, then move such jobs to the unassigned-Jobs-List.

5. Repeat until all unassigned jobs are scheduled or all compute resources have reached their maximum job limit.

a. Select the next job from the Unassigned-Jobs-List.

b. Identify all Data Hosts that contain the LDF associated with the job.

c. Create a Data-ComputeResource-List for the selected job:

- For each data host, identify a compute resource that can complete the job earliest given its current commitment, job completion rate, and data transfer time using current available bandwidth estimates.

d. Select a data host and compute resource pair with the earliest job completion time from the Data-ComputeResource-List.

e. If there exists such a resource pair, then assign the job to the compute resource and remove it from the Unassigned-Jobs List.

6. Repeat while there is no unassigned job and there exists any idle higher grade compute resource then any node in the Grid [This step is triggered for each scheduling event. The event period is a function of rescheduling overhead, restoration file recovering over head, etc.]:

a. Select the lowest grade compute resource executing any job.

b. Select a data host and compute resource with the earliest job completion time between the two compute resources depending Data-ComputeResource-List.

c. If the idle compute resource can complete the job in earliest time then preempt the job and

i. Select the restoration file host (data host) that contain LDF associated with that job.

ii. Reassign the job to the higher grade compute resource.

7. End of scheduling loop.

**Figure 2: Modified adaptive scheduling algorithm for Data Grid**

## **6. Experimental result and performance analysis**

We setup the experiment environment with heterogeneous executors, one with lower grade computation power and the other with much higher

grade computation power. This higher grade compute resource can perform almost twice as faster than the other lower grade compute resource. The configuration of the two executors is given in *Figure 3* and *Figure 4*.

 OS: Microsoft Windows XP Professional V2002 Service Pack 2

**Figure 3: Executor 1 (lower grade compute resource)**

Processor: Inter Core2Duo 1.86 GHz  
 Ram: 1024 MB  
 OS: Microsoft Windows XP Professional V2002 Service Pack 2

**Figure 4: Executor 2 (higher grade compute resource)**

Two different application programs have been used to evaluate the performance comparison. In our Implementation, both applications take an integer as input and give the number of factors as output. In case of first application program, we developed with existing algorithm that does not use any technique to save the output of any thread. As there is a non-zero probability of thread failure so, if any thread became failed, we can not get the partial result so far computed by that thread. In contrast, in our ‘File based Grid Thread implementation’, we created a random access file associated with each thread and writing the results to that file and thus creating restoration point. The file only contains the last two computed output of a thread. Two status characters for two results are also stored to indicate which of the results are stored successfully or not. The size of each result is 10 byte. Since the file contains two results, the total size of the file is 20 byte.

In both applications, same input is used to compare between them, both give the same results as well. Both application give the total number of factors of a given

input value (e.g.  $10^{10}$ ). We will show the performance comparisons in the context of a single thread and also in the context of an application comprises by a number of thread. These cases will give us an overview of how these approaches effect in case of a thread and in the application context. Here we have shown different performance comparisons where our modified approach gives better performance than the existing approach in almost every case. The performance of modified approach depends on how long a thread is executed before it is being preempted. The much shorter a thread executed before it is being preempted the much better performance is obtained by our modified file based implementation.

### 6.1. In the context of a single thread

This case gives an overview how the modified run thread scheduling using preemption approach improves performance in case of a single thread. Here we give the comparisons between the performance of thread scheduling technique using the existing implementation (where preempted thread starts form the beginning at the reassigned executor) and the modified file based implementation (where preempted thread starts form the last saved point at the reassigned executor).

**6.1.1. Test case 1 (without preemption):** In this test module we showed how much time a single thread takes to finish by *Executor 1* and by the *Executor 2* separately. In all the test cases here threads are executed without any preemption (i.e. finished successfully). This table also shows the comparisons between the times taken by the existing implementation verses our modified file based implementation.

**6.1.2. Test case 2 (with preemption):** In this test module we show the comparison between the performance of the existing implementation and the modified implementation by preempting a thread at several times in its life time. We took the thread same as the thread describe in *Test Module 1*. The thread using existing implementation, first executed in the *Executor 1*, which takes an average of 1:21.9 min to execute normally. So we preempt the thread for  $10^{\text{th}}$  to  $70^{\text{th}}$  second with 10 sec interval after starting execution at the *Executor 1*. Then we make the higher compute resource (*Executor 2*) available to the grid and the thread starts execution form the saved point using restoration point. This technique finishes the job

in much lesser time in almost every case though the second executor starts the job from the beginning.

**Table 1: Comparisons between the execution time of Executor 1 and Executor 2 with a single thread**

Test case	# of thread	Existing implementation		Modified file based implementation	
		Executor 1	Executor 2	Executor 1	Executor 2
1	1	0:1:21.87500	0:0:36.390625	0:1:21.828125	0:0:37.687500
2	1	0:1:21.78125	0:0:36.437500	0:1:21.109375	0:0:36.421875
3	1	0:1:22.12500	0:0:37.390625	0:1:21.890625	0:0:36.390625

**Table 2: Comparison between two implementation with job preemption**

Test Case	Preempt time (n <sup>th</sup> sec)	Finish time with preemption (min : sec)	
		Existing Implementation	Modified Implementation
1	10	0:57.265625	0:39.421875
2	20	1:06.171875	0:57.984375
3	30	1:17.546875	0:59.015625
4	40	1:26.859375	1:09.359375
5	50	1:37.187500	1:32.078125
6	60	1:48.515625	1:38.953125
7	70	1:58.156250	1:48.609375

**Figure 5: Comparison between two implementation with job pre-emption**

By using the modified file based implementation we use the same technique but the second executor does not need to start the job from the beginning. As the *Executor 2* starts the job from last saved point it

has executed in the first executor thus we can save more time. Thus this approach gives a greater degree of performance improvement, which can be clearly seen from the *Figure 5* and *Table 2*.

## 6.2. In the context of an application (multiple threads)

In this case we show how the run time thread scheduling with preemption effect on completion time of an application comprises of several number of threads. We take an application with five threads. For this test case last thread is executed on the lower grade compute resource. Here we preempt the last thread in several point of its life time.

**6.2.1. Test case 1 (without preemption):** This test module gives an overview of how much time the executors takes (separately or both executors together) to finish an application with five threads. This table also compares between the existing and modified implementation.

**6.2.2. Test case 2 (with preemption):** In this test module we show the comparison between the performance of the existing implementation and the modified implementation by preempting the last thread of an application which runs at the lower grade compute resource (*Executor 1*) by the existing Gridbus Broker scheduling algorithm. Firstly, we run the application with existing implementation and preempt the last thread at *Executor 1*. We took the similar approach described in the *Test Module 2* to do this section experiment. We preempted the job with 10

**Table 3: Comparison of execution time of an application with five threads between existing and modified implementation**

Modified implementation (min : sec)			Existing implementation (min : sec)		
Executor 1	Executor 2	Together	Executor 1	Executor 2	Together
6:45.7344	3:01.4063	3:00.1094	6:47.2031	3:01.8069	2:43.2812
6:44.9817	3:00.4063	2:54.8594	6:48.1709	3:01.4687	2:43.0570
6:44.1986	3:00.1563	2:54.8906	6:47.5803	3:00.8390	2:44.0196

seconds interval and let the *Executor 2* to execute the job which can do the job much faster than the

*Executor 1*. This technique finishes the application in much lesser time in almost every case as we remove the bottleneck created by the lower grade executor though the second executor starts the job from the beginning. By using the modified file based implementation we use the same technique but as the second executor does not need to start the job from the beginning. Since the *Executor 2* starts the job from last saved point it has executed by the first executor, it reduces the execution time greatly. Thus this approach gives a greater degree of performance improvement, which we can clearly see in the *Figure 6* and *Table 4*.

**Table 4: Performance comparison between two implementations with job preemption**

Test Case	Preempt time (n <sup>th</sup> sec)	Application finish time (min : sec)	
		Existing Implementation	Modified Implementation
1	2	2:25.406250	2:16.578125
2	10	2:25.312500	2:07.171875
3	20	2:27.921875	2:16.250000
4	30	2:32.500000	2:28.812500
5	40	2:41.937500	2:35.843750
6	50	2:51.859375	2:44.875000
7	60	3:01.156250	2:51.468750
8	70	3:10.734375	2:54.281250

**Figure 6: Performance comparison between two implementations with job preemption**

## 7. Conclusion

In this paper, a modified algorithm has been presented for the scheduling of the Gridbus broker. By using this modified file based implementation and the described approach to reschedule the threads at run time; it is clear that algorithm gives better time improvement with compare to the existing thread

implementation. It is known that, Grid thread is the last unit of the job that is executed in the executor node. As we get better performance by using discussed approach so we can propose that if this mechanism can be added to the Gridbus Broker it can push the Grid computing one step further.

### Abstract

*In some medical applications where a tissue of interest covers a large fraction of the image or a prior knowledge on the region of interest is available, extracting features by fixed blocs in the image is sufficient. However in the general case, one would like to identify features for each tissue in the image. This would require prior image segmentation. Medical image segmentation is one of the most challenging problems in medical image analysis and a very active research topic. Therefore, there is no algorithm available in the general case for isolating medical image regions [1].*

*This paper presents an accurate method for extracting texture features from medical image for classification. It is based on bloc wise clustering of medical images. The proposed technique extracts accurate and general set of textural features. Experimental result showed the high accuracy of the extracted textural features. Experiments held on Mammographic Image Analysis Society (MIAS) dataset.*

### 1. Introduction

Image analysis techniques have played an important role in several medical applications. In general, the applications involve the automatic extraction of features from the image which is then used for a variety of classification tasks, such as distinguishing normal tissue from abnormal tissue. Chabat [2] used 13 texture parameters, derived from the histogram, co-occurrence matrix and run-length matrix categories, to differentiate between a variety of obstructive lung diseases in thin-section CT images. Kovalev [3] used texture parameters derived from gradient vectors and from generalized co-occurrence matrices for the characterization of texture of some MR-T2 brain images. Herlidou [4] used texture parameters based on the histogram, co-occurrence matrix, gradient and run-length matrix for the characterization of healthy and pathological human brain tissues (white matter, grey matter, cerebrospinal fluid, tumours and oedema). Mahmoud [5] used the texture analysis approach based on a three-dimensional co-occurrence matrix in order to improve brain tumour characterization. Du-Yih Tsai [6] used four texture features derived from the co-occurrence matrix was used for classification of the heart disease. H.S. Sheshadri [7] used Six textural features for mammogram images derived from the histogram categories was used as a part of developing a computer aided decision system for early detection of breast cancer. Maria-Luiza [8] used texture parameters based on the histogram for tumour classification in mammograms.

Feature extraction [9] is a vital component of the Computer Aided Diagnosis (CAD) System that can discriminate between medical tissues to serve as a second reader to aid radiologists. The feature extraction unit is used to prepare

data in a form that is easy for a decision support system or a classification unit to use. Compared to the input, the output data from the feature extraction unit is usually of a much lower dimension as well as in a much easier form to classify. Medical images possess a vast amount of texture information relevant to clinical practice [10]. Hence texture is the most promising feature to work on. Texture analysis gives information about the arrangement and spatial properties of fundamental image elements [11]. Coggins [12] has compiled a catalogue of texture definitions.

One of the most commonly used texture parameters come from Co-occurrence matrix as a statistical approach [10] which represents texture in an image using properties governing the distribution and relationships of grey-level values in the image methods normally achieve higher discrimination indexes than the structural or transform methods.

This paper introduces a bloc wise clustering as a region of interest selection (ROI) approach which provides a more accurate extraction of textural features. We use four texture features measured from a gray-level co-occurrence matrix generated from the breast images for classification of the images. A statistical discrimination method (fisherfaces algorithm) [13, 14] for feature selection algorithm is also used for extracting discriminative information from extracted feature of medical images to be used as inputs to our classification system.

### 2. Data collection

The data collection which has been used in our experiments was taken from the MIAS [15]. The same collection has been used in other studies of automatic mammography classification. Its corpus consists of 322 images, which belong to three big categories: normal, benign and malign. There are 208 normal images, 63 benign and 51 malign, which are considered abnormal. In addition, the abnormal cases are further divided in six categories: microcalcification, circumscribed masses, speculated masses, ill-defined masses, architectural distortion and asymmetry.

### 3. Pre-processing phase

Mammograms are images difficult to interpret, and a preprocessing phase of the images is necessary to improve the quality of the images and make the feature extraction phase more reliable. We applied to the images two

techniques: a cropping operation and an image enhancement one. The first one was employed in order to cut the black parts of the image as well as the existing. Image enhancement helps in qualitative improvement of the image with respect to a specific application. In order to diminish the effect of over brightness or over darkness in the images and accentuate the image features, we applied a widely used technique in image enhancement to improve visual appearance of images known as Histogram Equalization. This process equalizes the illumination of the image and accentuates the features to be extracted [8].

## 4. Feature extraction

A major component in analyzing images involves data reduction which is accomplished by intelligently modifying the image from the lowest level of pixel data into higher level representations. From these higher level representations we can gather useful information; a process called feature extraction [9]. Extracting features by fixed blocs in the image has been considered to be sufficient as an ROI selection method in some medical applications where a large fraction of the image is covered by tissue of interest.

### 4.1. Measurements of texture features

The gray-level co-occurrence matrix (GLCM) is a matrix used to express the correlation of spatial location and gray-level distribution of an image [16]. From it, the local variation of gray levels on an image or sub-image can be statistically investigated and in turn, enable us to know the manner of change in gray level as a whole. In the current application, we used the following conditions to generate gray-level co-occurrence matrices.

- Direction: In general the gray-level co-occurrence matrices from 0, 45, 90, and 135 directions are used. Only the direction of 0 was used in the study.
- Distance: The length of 1-pixel was used.

Of the 14 original statistics developed by Haralick et al. (1973) for generating texture features based on co-occurrence probabilities, we chose the four most commonly used features for our evaluation.

Dissimilarity, uniformity, entropy, and contrast are often used in practice. The following four statistics will be used exclusively in this paper:

1. Dissimilarity =  $\sum_{i,j=1}^G C_{ij} |i-j|$ .
2. Uniformity =  $\sum_{i,j=1}^G C_{ij}^2$ .
3. Entropy =  $-\sum_{i,j=1}^G C_{ij} \lg C_{ij}$ .

$$4. \text{ Contrast} = \sum_{i,j=1}^G C_{ij} (i-j)^2.$$

Where,  $C_{ij}$  represents co-occurring probabilities stored inside GLCM.  $G$  represents number of grey level available.

Now, we introduce and study two ROI selection methods that give us better texture feature extraction when co-occurrence matrix method is used and hence a more accurate texture feature (see section 7).

#### 4.1.1. Extraction based on pixel wise segmentation approach.

For a more accurate feature extraction, apply extraction based pixel wise partitioning method as follows (see Figure.1):

**Step1:** divide the entire image into SN non-overlapping sub-images  $SI = \{I_1, I_2, \dots, I_{SN}\}$ .

**Step2:** use the k-means algorithm [17] to cluster the sub-images ( $SI$ ) into several classes based on pixel intensity for each  $I_i$ ,  $i=1,2,\dots,SN$  independently.

**Step3:** for each cluster in  $I_i$ ,  $i=1,2,\dots,SN$ , construct a sub-image representing set of texture feature vectors  $F_K = \{f_1, f_2, \dots, f_X\}$ ,  $k=1,2,\dots,L$ ; where  $L$  is the number of classes each of which contains  $X$  texture features.

**Step4:** build the final set of texture features representing the overall image in the form of a single transaction of the final dataset (set of images),  $T = \{t_1, t_2, \dots, t_c\}$ , where  $c$  is the number of images,  $t_i$  is a vector of the size  $(SN \times L \times X)$ ,  $i=1, 2, \dots, c$ .

**Step 5:** for each  $t_i$ ,  $i=1,2,\dots,c$  add the class label of its image.

**Figure.1** Illustrate simple example describes feature extraction phase: where  $SN=6$  and  $L=3$ .

#### 4.1.2. Extraction method based on proposed ROI selection approach.

For a more accurate feature extraction and a further investigation of the localization, apply extraction based bloc wise partitioning method as follows (see Figure.2):

**Step1:** divide the entire image into SN non-overlapping sub-images  $SI = \{I_1, I_2, \dots, I_{SN}\}$ .

**Step2:** split each of these SN sub-image into other M blocs  $I_j = \{B_1, B_2, \dots, B_M\}$ ,  $j=1,2,\dots,SN$ .

**Step3:** for each bloc  $B_i$ ,  $i=1,2,\dots,M$ , construct a bloc representing set of texture feature vectors.

**Step4:** use the k-means algorithm to cluster the feature vectors into several classes for each sub-image  $I$  independently.

**Step5:** for each cluster in  $I_i, i=1,2,\dots,SN$ , construct a sub-image representing set of texture feature vectors  $F_K = \{f_1, f_2, \dots, f_X\}, k=1,2,\dots,L$ ; where  $L$  is the number of classes each of which contains  $X$  texture features.

**Step6:** build the final set of texture features representing the overall image in the form of a single transaction of the final dataset (set of images),  $T=\{t_1, t_2, \dots, t_c\}$ , where  $c$  is the number of images,  $t_i$  is a vector of the size  $(SN \times L \times X), i=1, 2, \dots, c$ .

**Step7:** for each  $t_i, i=1,2,\dots,c$  add the class label of its image.

**Figure.2** Illustrate simple example for describe feature extraction phase: where  $SN=6, M=6$  and  $L=3$ .

## 5. Feature selection

The statistical discrimination methods are suitable not only for classification but also for characterization of differences between a reference group of patterns and the population under investigation.

For the image classification case, without class labels, Principle Component Analysis (PCA) can be applied, when some class labels are available, linear discriminant analysis (LDA) is applied to transform the features into the most discriminating Feature space [18-21].

Let us consider a set of  $N$  sample images  $\{x_1, x_2, \dots, x_N\}$  taking values in an  $n$ -dimensional image space, and assume that each image belongs to one of  $c$  classes. Let us also consider a linear transformation mapping the original  $n$ -dimensional image space into an  $m$ -dimensional feature space, where  $m < n$ . The new feature vectors  $Y$  are defined by the following linear transformation:

$$Y_k = W^T x_k, \quad k=1, N. \quad (1)$$

### 5.1. Fisher's Linear Discriminant Analysis (FLD)

In this method,  $W$  in (1) can be selected in such a way that the ratio of the between-class scatter and the within-class scatter is maximized. Let the between-class scatter matrix be defined as

$$S_b = \sum_{i=1}^c N_i (\mu_i - \mu)(\mu_i - \mu)^T,$$

and the within-class scatter matrix be defined as

$$S_w = \sum_{i=1}^c \sum_{x_k \in X_i} (x_k - \mu_i)(x_k - \mu_i)^T,$$

where  $\mu_i$  is the mean image of class  $X_i$ , and  $N_i$  is the number of samples in class  $X_i$ . If  $S_w$  is nonsingular, the optimal projection  $W_{opt}$  is chosen as the matrix with orthonormal columns which maximizes the ratio of the determinant of the between-class scatter matrix of the projected samples to the determinant of the within-class scatter matrix of the projected samples, i.e.,

$$W_{opt} = \arg \max_W \frac{|W^T S_b W|}{|W^T S_w W|}. \quad (2)$$

In this paper, we can not apply (FLD) directly to solve the recognition problem since the dimension of the sample space is typically larger than the number of samples in the training set. As a consequence,  $S_w$  is singular in this case.

**5.1.1. Fisherfaces.** Swets and Weng [22] proposed a two stage PCA+LDA method, also known as the Fisherfaces method, in which PCA is first used for dimension reduction so as to make  $S_w$  nonsingular before the application of LDA.

In this method an alternative to the criterion in (2) is applied. This method avoids this problem by projecting the image data set to a lower dimensional space so that the resulting within-class scatter matrix  $S_w$  is nonsingular. This is achieved by using PCA to reduce the dimension of the feature space to  $N-c$ , and then applying the standard FLD defined by (2) to reduce the dimension to  $(c-1)$  [20]. More formally,  $W_{opt}$  is given by

$$W_{opt}^T = W_{fld}^T W_{pca}^T,$$

where

$$W_{pca} = \arg \max_W |W^T S_T W|,$$

$$W_{fld} = \arg \max_W \frac{|W^T W_{pca}^T S_b W_{pca} W|}{|W^T W_{pca}^T S_w W_{pca} W|},$$

$$S_T = \sum_{k=1}^N (x_k - \mu)(x_k - \mu)^T.$$

Note that the optimization for  $W_{opt}$  is performed over  $n \times (N-c)$  matrices with orthonormal columns, while the optimization for  $W_{fld}$  is performed over  $(N-c) \times m$  matrices

with orthonormal columns. In computing  $W_{opt}$ , we have thrown away only the smallest (c-1) principal components.

## 6. Measures for performance evaluation

We evaluated the performance of the proposed methods in terms of sensitivity, specificity and overall accuracy [6], Such that k-fold cross validation process is used.

K-fold cross validation is used for model testing and evaluation to determine how accurately a learning algorithm will be able to predict data that it was not trained on. In this method it is not important how the data is divided. Every data point appears in a test set exactly once, and appears in a training set k - 1 times. We can independently choose the size of the each test and the number of trials (Kohavi & Provost, 1998).

## 7. Experimental results

In our experiment a sample of 22% from the MIAS data set is selected randomly for model testing and evaluation. The sample is distributed among classes as follows:

Normal class (n=30), Microcalcification class (n=10), Circumscribed Masses class (n=7), Spiculated Masses class (=8), Ill-Defined Masses class (n=5), Architectural Distortion class (n=7) and Asymmetry class (n=4).

We evaluated the performance of the proposed methods described in sections 4.1.1 and 4.1.2 with standard classifiers. Using weka experimenter [23], Such that 10-fold cross-validation process is used.

Table.1 present the overall accuracy of textural feature set extracted by the extraction method based on bloc wise segmentation as a ROI selection approach (see section 4.1.2) for SN=6 and L=3. Several values of M were checked for the possibility of improving the results and increasing features localization. See table. 1.

**Table.1** Overall accuracy for the proposed method with M=4, 6 and 8.

Classifier	Overall accuracy		
	4-blocs	6-blocs	8-blocs
NNGe	93.10%	100%	100%
RBF net	95.77%	98.59%	100%
Bayes net	92.95%	95.77%	100%
J48	88.73%	84.5%	94.37%
Kstar	95.77%	97.18%	98.59%
NB tree	95.77%	95.77%	98.59%

From results in the above table, we can notice that, using a certain feature selection algorithm (Fisherfaces), classifiers accuracy is dependent on number of blocs regardless of classification algorithms used. The overall accuracy with different bloc size is presented in Figure.3.

**Figure.3** Success rates of classifiers with decreasing of bloc size.

Table.2 illustrates comparison between the following textural feature sets based on different ROI selection methods:

1. Textural feature sets based on fixed bloc segmentation (simply divide the whole image into 6 non-overlapping sub-images then split each of these 6 sub-images into other 8 non-overlapping blocs).
2. Textural feature sets based on pixel intensity segmentation described in section 4.1.1 with SN=6 and L=3.
3. Textural feature sets based on our bloc wise segmentation described in section 4.1.2 with SN=6, M=8 and L=3.

**Table.2** The classification rate comparison.

Classifier	ROI	Sensitivity	Specificity	Overall accuracy
NNGe	Fixed bloc	100%	100%	100%
RBF net		100%	100%	100%
Bayes net		96.77%	100%	98.59%
J48		85.71%	95.35%	90.14%
Kstar		96.77%	100%	98.59%
NB tree		93.75%	100%	97.18%
NNGe	Pixel wise	100%	100%	100%
RBF net		100%	100%	100%
Bayes net		96.77%	100%	98.59%
J48		88.24%	97.62%	92.96%
Kstar		100%	100%	100%
NB tree		96.77%	100%	98.59%
NNGe	Bloc wise	100%	100%	100%
RBF net		100%	100%	100%
Bayes net		100%	100%	100%
J48		90.9%	97.62%	94.37%
Kstar		96.77%	100%	98.59%
NB tree		96.77%	100%	98.59%

From results shown in the table.2, we can notice that, using Fisherfaces feature selection algorithm, our proposed extraction methods gave better accuracy than extraction method based on fixed bloc partitioning as a ROI selection method, which means a more accurate extraction of textural feature and hence a more efficient image representation. The classifier NNGe and RBF-Network gave the highest performance when compared to the others which implies that NNGe and RBF-Network are much more suitable for such application. Figure.4. presents a comparison between classification results.

**Figure.4** Success rates of classifiers with our proposed methods.

## 8. Conclusions

In this work, four texture features derived from the co-occurrence matrix was used as a part of developing CAD system for early detection of breast cancer.

This paper present textural extraction method based on three different ROI selection methods for obtaining efficient image representation. We proposed an ROI selection method based on bloc wise segmentation designed to obtain more accurate extraction of textural feature from medical images. It was shown that this approach improves the localization of texture features and produce general texture features. A fisherfaces feature selection algorithm is used for extracting discriminative information from extracted feature of medical images to be used as inputs to our classification system.

Our experiments confirm the importance of our proposed ROI selection approaches as a primary step of feature extraction in the final decision of the CAD.

### Abstract

*In this article a new ant clustering algorithm based on case based reasoning (CBR) is presented. Every ant has a case base which is updated iteratively by the process of CBR. The ant which is successful in dropping an item becomes an expert and can use its knowledge for future picked up items. Also expert ants are capable of cooperating to share their knowledge for even better clustering. Our simulation results demonstrated better performance than previous approaches.*

**Keywords:** ant based clustering, ant colony optimization

### 1. Introduction

Machine learning is divided into two primary sub-fields: supervised learning and unsupervised learning. Within the category of unsupervised learning, one of the primary tools is clustering [1]. Clustering means the act of partitioning an unlabeled dataset into groups of similar objects. Each group, called a 'cluster', consists of objects that are similar between themselves and dissimilar to objects of other groups [2]. Swarm Intelligence emerged out of social insect collective behavior shows many interesting properties such as flexibility, robustness, decentralization and self organization [3]. The swarm intelligence clustering models and algorithms have advantages in many aspects, such as no need of priori information, self-organization, flexibility, robustness and decentralization [4]. Ant-based clustering is a heuristic clustering method that draws its inspiration from the behavior of ants in nature [5]. Some of the proposed ant based clustering algorithm can be found in [6-11].

In the present article, we have introduced a clustering algorithm based on expert ants. After each successful dropping, the value and the coordination of

the object being dropped is saved in the ant's case base. In the beginning, the case bases of all ants are empty. We have introduced two types of ants: normal ants, which have empty case base and have not dropped an object yet, and expert ants, who were able to drop at least one object. Whenever an expert ant picks up a new load, it searches its case base for the best match and if such a case is found, it will be retrieved and then the ant immediately drops down its load in the nearest neighborhood of the grid coordination of the stored case. Otherwise it uses the drop down function. The case base of all expert ants updates each time they drop down an object. Also expert ants are able to cooperate with each other to find the best place for dropping their load. The results of our approach demonstrated that it can speed up the process of clustering and prevents from producing too many small clusters which is one of the main drawbacks of ant based clustering.

### 2. The general principle of ant clustering

Ant based clustering is a distributed process. The pioneers of this work are Deneubourg *et al.* [12]. Their model is known as basic model (BM) in which ants are simulated by simple agents that randomly move in an environment which is a square grid. Initially, each data object that represents a multi-dimensional pattern is randomly distributed over the 2-D space. Data items that are scattered within this environment can be picked up, transported and dropped by the agents in a probabilistic way. The picking and dropping operations are influenced by the similarity and density of the data items within the ant's local neighborhood. Deneubourg *et al.* proposed a computational model for spatial sorting. Their model is based on the following probability of picking and dropping functions:

$$Pp = \left(\frac{Kp}{Kp + f}\right)^2. \quad (1)$$

$$Pd = \left(\frac{f}{Kd + f}\right)^2. \quad (2)$$

Where  $Pp$  is the probability of picking,  $Pd$  is the probability of dropping, and  $Kp$  and  $Kd$  are constants.  $f$  is the perceived fraction of items in the neighborhood of the ant. The probability of picking ( $Pp$ ) is increased if a data object is surrounded by dissimilar data, or when there's no data in its neighborhood. Also, ants tend to drop data in the vicinity of similar ones, so the probability of dropping ( $Pd$ ) is increased if ants are surrounded with similar data. Deneubourg *et al.*'s model was later extended by Lumer *et al.* [13] to allow its application to exploratory data analysis. They modified the dropping probability functions as the following:

$$Pd(i) = \begin{cases} 2f(i) & \text{if } f(i) < Kd \\ 1 & \text{if } f(i) \geq Kd. \end{cases} \quad (3)$$

Where  $Pd$  is the same as before, i.e., the probability of dropping and picking. In addition, they introduced the density function as the following:

$$f(i) = \max(0, \frac{1}{\sigma^2} \sum_{j \in L} (1 - \frac{\delta(i, j)}{\alpha})). \quad (4)$$

Where  $\delta(i, j) \in [0, 1]$  is the dissimilarity function between two data object  $i$  and  $j$ .  $\alpha \in [0, 1]$  is the scaling parameter that permits further adjustments of resulting values.  $\sigma^2$  is the size of local neighborhood  $L$  around the ant's current position. The basic ant clustering algorithm is like the one summarized as bellow [14]:

Let  $R \in [0, 1]$  be a random number drawn for each use, the basic algorithm is then given by:

Randomly scatter data items on a square grid.

For a number of steps or until a criterion is met, repeat for each ant:

- If the ant is unladen and placed on location  $l$  occupied by object  $o$ , the object is picked up if

$$P_{pick\_up}(o) \geq R.$$

- If the ant is carrying object  $o$  and placed on an empty location  $l$ , the object is dropped if

$$P_{drop\_down}(o) \geq R.$$

- Move the ant to a new randomly selected (neighboring) location.

### 3. Case Based Reasoning (CBR)

CBR is a familiar process that is a normal, intuitive method of decision-making for humans in everyday life. It is a process of considering past cases and arriving at decisions on comparison between the current situation and the old cases [15].

In CBR terminology, a case usually denotes a problem situation. A previously experienced situation, which has been captured and learned in a way that it can be reused in the solving of future problems, is referred to as a past case, previous case, stored case, or retained case. Correspondingly, a new case or unsolved case is the description of a new problem to be solved [16].

CBR is done by considering the similarity between the current situation and old seen situations. The basic idea of CBR for solving a new problem is as follows:

- Remembering a previous similar situation.
- Comparing the new problem to the old solved problems
- Reusing information and knowledge of that situation.

At the highest level of generality, a general CBR cycle may be described by the following four processes [16]:

1. RETRIEVE the most similar case or cases.

The goal of this step is to retrieve old cases stored in the case library [17]. Retrieving is the selection of the most similar cases (source cases) to the new problem specifications (target case) from the library of cases.

2. REUSE the information and knowledge in that case to solve the problem.

3. REVISE the proposed solution.

Because a new case may not exactly match the old one, the old knowledge may often need to be fixed to fit the new one [17].

4. RETAIN the parts of this experience likely to be useful for future problem solving.

In "Fig. 1", this cycle is illustrated [16].

### 4. The Framework of the Algorithm

Our ant clustering algorithm uses the same probability and density function as the one proposed by Lumer *et al.* [13], but instead of consuming a long time for finding an item to pick, we have kept the location of all available items on the grid in an array. After an ant drops its load, it immediately picks up one item from the list of available items on the grid [18] and the ant jumps to the location of the picked up item.

We have considered a grid with  $s \times s$  cells. The number of cells must be greater than the number of all objects. All ants move with different speeds on the grid. We have considered a maximum speed for all ants which is set as  $\text{max\_speed} = s/3$ . The step of movement of each ant is generated randomly between 1 and  $\text{max\_speed}$  before each movement. We decrease the  $\text{max\_speed}$  by one every 200 iterations. The details of our proposed method are discussed in the following subsections.

**Figure 1.** The CBR cycle [16].

#### 4.1 Expert Ants

In the beginning of clustering, all ants are identical, but only with different loads. The memory of all is empty and no one has any kind of information about the search space and the location of items in the grid. We call these ants as normal ants. They move randomly in grid and try to pick up loads using equation (3) and drop their load according to equation (4). An ant becomes an expert by memorizing the location of at least one dropped data. The method of reasoning of these expert ants is based on case based reasoning. Each normal laden ant when for the first time wants to drop an item, needs to use the probability of dropping. It obtains a new experience with each dropping and it keeps the value and location of that data in a repository called case base. After dropping at least one data, it is called an expert ant. When an expert ant is laden, it first refers to its case base, looking for a similar case. If it found such a case, it decides to put its load somewhere next to the location of most similar data it has dropped before. In this way

there is no need to compute the probability of dropping and it causes the gathering of similar data in a single area.

#### 4.2 Case and Case Base of Expert Ants

Each ant has a private case base for keeping the different cases it has seen. A case consists of value of attributes and the place they have been dropped. The place of dropping, is a two dimensional matrix (because the search space is a grid). The value of attributes of a data is a multidimensional matrix, in which the number of dimensions depends on the dimensions of data. There is also a variable for each ant which specifies the number of the existing cases in the case base.

#### 4.3 Retrieve and Revise

Whenever an expert ant wants to put its load, it searches for a case in its case base, and compares the value of all cases with its current load to find the most similar case. For this, each ant first collects all the cases having a distance less than a threshold from its load in an array, then it sorts the array ascendingly, and finally selects the first element of the array which has the lowest distance value. But, before retrieving this case, it first checks whether the case is a valid one, or not. Because ants pick up and drop down the data iteratively, it is so probable that the value of case bases become invalid during clustering process. A case is valid for an ant, only if its current location on the grid is the same as the one recorded in the case base of that ant. If the first element of the array was invalid, the second element is checked. This process repeats until a case is retrieved or no other case remains in case base. If a case was retrieved it can be used. It is possible that whenever an ant is looking for a case, it faces a case with identical attribute values with its current load. Under this condition, the case must be revised and then updated. For this purpose, the dropping probability must be computed. When a suitable location for dropping that item is found, the old stored location in case base is replaced with a new one.

#### 4.4 Cooperation between Ants

According to the number of successful droppings, each ant gains some kind of expertise so that the expertise of each ant is different from that of others. In this way we have a multi expert- multi agent system. Whenever a laden ant fails in dropping its load, and an

unladen ant fails for picking up an item, they can sense their neighborhood for getting help from other ants. So, a laden ant can put its load on an unladen ant, and an unladen ant can get load from a laden ant. If both ants were laden, they only exchange their loads. Nothing will happen if both were unladen. If there were more than one neighbor ant, one is chosen randomly. All the process of getting load from other ants and exchanging of loads happen with probability of 0.5. This kind of cooperation can prevent ants from moving aimlessly and it can also increase the speed of convergence.

#### 4.5 The algorithm of clustering by expert ants

The details of our algorithm are as follows:

//Initialization part

1. Spread the data and ants randomly on the grid and give all ants a random load.

//main part

1. **While** iter < max\_iter
2. **For** i=1 to #ants
3. a = Choose a random ant without replacement
4. step = Generate a random speed from interval (1,max\_speed)
5. new\_location=Move (a, step)
6. **if** ant a is unladen and there is an object o in location l then pick\_done=try\_pick(o)
7. **if** pick\_done=0 then try to find a laden expert ant in the neighborhood of ant a and take the load of it with probability of .5
8. **end if**
9. **end if**
10. **if** ant a is laden then search its case base for a case which has the similarity of more than .9 with the current load,
11. **if** such a case was found then
12. // retrieve  
Drop the load in a neighborhood of 2 from the place of that case
13. **end if**
14. **if** a case was found with the same value with the current load then
15. // revise  
Find a place for dropping it and change the place part of the case with the new found location
16. **end if**
17. **if** no similar case was found and the current location of it is empty then
18. drop\_done=try\_drop(l)
19. **end if**

20. **if** drop\_done=1
21. // retain  
Make a new case and save it in case base
22. **end if**
23. **if** drop\_done=0
24. find an unladen expert ant in the neighborhood of 2 and give the load of ant a to it with probability of .5
25. **if** no unladen expert ant was found, find a laden expert ant in the neighborhood of 2 and exchange the load of ant a with the load of the neighboring ant
26. **end if**
27. **End For**
28. **End while**

**try\_pick(o)**

1. r= a random number from interval (0,1)
2. p=compute probability function (1)
3. **if** p>r then
4. pick up the object o
5. pick\_done=1
6. **else**
7. pick\_done=0
8. **end if**

**try\_drop(l)**

1. r= a random number from interval (0,1)
2. d=compute probability function (3)
3. **if** d>r then
4. drop down load l
5. drop\_done=1
6. **else**
7. drop\_done=0
8. **end if**

#### 5. Experimental Results and Comparison

The algorithm is applied to six datasets. The datasets are summarized in Table 1 and all except for Iris and Wine datasets are shown visually in “Fig. 2”. Iris and Wine datasets are not illustrated because their dimensionality is more than 3.

We have compared our algorithm with k-means algorithm, which works as follows: Starting from a partitioning of the data into k randomly generated clusters, the k-means algorithm repeatedly (i) computes the current cluster centers (i.e., the average vector of each cluster in data-space) and (ii) reassigns each data item to the cluster whose center is closest to it. It terminates when no more reassignments take place. As k-means can sometimes generate empty clusters, these are identified in each iteration and are randomly

reinitialized. This enforcement of the correct number of clusters can prevent convergence, and we therefore set the maximum number of iterations to 100. To reduce suboptimal solutions k-means is run repeatedly (20 times) using random initialization, and only the best result in terms of intra-cluster variance is returned. [7].

**Table 1.** Summary of the used data sets. k gives the number of clusters, size shows the number of members of a cluster, and dim is the dimensionality,.

Name-k-size	dim	Source

The results of applying k-means algorithm and ant clustering by normal ants are compared to the results of our algorithm in Table 2 and the best result out of a few runs is selected and is illustrated in “Fig. 3”.

**Figure 3.** Best visual results of benchmark data. a) Square6, b) Square5, c) Iris, d) Wine, e) D2C4, f) D2C2

A crucial matter in ant based clustering is the requirement for spatial separation between clusters. Fig.3 shows that there is a good boundary between clusters that are generated by our algorithm, which makes the cluster retrieval process to be done with less ambiguity. The results of Table 2 shows the number of clusters that our algorithm can find is nearer to the true number of clusters than normal ants, the average error of clustering which is computed based on the number of objects that were assigned to incorrect clusters is decreased in our approach and the number of iteration needed for our proposed method is much less than that of normal ants.

## 6. Conclusion

In this article we presented a novel method for ant clustering which uses case based reasoning. We have introduced “expert ants” who are able to decide about the best place for dropping their load using their case bases. The case base of each expert ant contains different information about promising places for dropping loads. We have added a mechanism for taking advantage of the knowledge of other ants. Those ants that were unsuccessful in dropping their loads can give their loads to other unladen expert ants in their neighborhood, and those that were unsuccessful in picking up an object can take the loads of other laden ants in their neighborhood. If two neighboring ants both were laden they can exchange their loads. Our proposed method has shown better results in terms of speed, correctness and compactness of clusters.

### Abstract

*The manufacturing process is complex due to the large number of processes, diverse equipment set and nonlinear process flows. Manufacturers constantly face yield and quality problems as they constantly redesign their processes for the rapid introduction of new products and adoption of new process technologies. Solving product yield and quality problems in a manufacturing process is becoming increasingly difficult. There are various types of failures and their causes have complex multi-factor interrelationships. High innovation speed forced today's manufacturers to find failure causes quickly by examining the historical manufacturing data. Data mining offers tools for quick discovery of relationships, patterns, and knowledge in large databases. This has been applied to many fields such as biological technology, financial analysis, medical information, etc. Application of data mining to manufacturing is relatively limited mainly because of complexity of manufacturing data. Growing self-organizing map (GSOM) algorithm has been proven to be an efficient algorithm to analyze unsupervised DNA data. However, it produced unsatisfactory clustering when used on some manufacturing data. Moreover, there was no benchmark to monitor improvement in clustering. In this study a method has been proposed to evaluate quality of the clusters produced by GSOM and to remove insignificant variables from the dataset. With the proposed modifications, significant improvement in unsupervised clustering was achieved with complex manufacturing data. Results show that*

*the proposed method is able to effectively differentiate good and faulty products.*

### 1. Introduction

Manufacturing databases usually comprise of process control, process step, and quality control data. In many applications data are automatically generated by sensors and therefore the number of inputs can be very large. This large volume of data coupled with quicker time to market expectations is making finding and resolving problems quickly an overwhelming task. The analysis of such a large volume of data, interpreting results, and implementing design improvements is computationally intensive and time-consuming. A high priority goal for today's manufacturing is finding the most probable causative factor(s) that discriminate between low yield and high yield products by quickly examining the historical manufacturing data.

Engineers often perform a series of experiments to identify and resolve potential problems with the design. Traditional techniques of dealing with quality problems are the use of statistical process control (SPC) and design of experiments (DOE). However, these techniques fail to extract underlying features from complex data [1]. Moreover, these methods are highly time-consuming. In order to decrease design cycles and the time-to-market new products, it is important to have a method for analyzing manufacturing data quickly and efficiently, predicting the effects of design changes and determining the best design parameters. Effective product data management has a significant influence on product quality improvement [2, 3]. However, traditional techniques

---

\* Corresponding Author: (617) 3138 1516 , Email: [azharul.karim@qut.edu.au](mailto:azharul.karim@qut.edu.au)

are incapable of dealing with large volumes of manufacturing data [4].

Advances in the data mining techniques enhanced automatic knowledge discovery as well as extraction of useful information from large volumes of data. Literature shows that the dynamic GSOM is a powerful tool for unsupervised data analysis [5]. In this study, a modified GSOM is used to detect faulty products from manufacturing data. Several modifications are proposed in order to reduce noisy data and to improve clustering quality.

## 2. Unsupervised Clustering Method

Cluster analysis is an unsupervised data mining technique that processes data that do not have known class labels, or where the analyst opts not to use them. Data within a cluster are highly similar to one another, but are very dissimilar to data in other clusters. Each cluster can be treated as a class of data, on which class or concept characterisation and discrimination can be performed.

The neural network approach to data mining has gained popularity due to the facts that most real world data have complex decision boundaries and contain a substantial amount of noise and the neural networks are robust against noise. A popular and well-accepted self-organising method of neural network analysis is self-organising maps (SOMs) [6]. A SOM with two-dimensional constraints can provide a visualisation of high-dimensional data by projecting it into a two dimensional network. However, the two-dimensional SOMs are rectangular grids of neurons that have predefined sizes and are specified by widths and heights. This can potentially hinder the real representation of input space topology [7].

Consequently, several modifications to SOM have been proposed to overcome the problem of predefined grids. One of the most recent variants, called the growing self-organising map (GSOM) was proposed to let the algorithm determine the size of the feature map [7-9]. A significant difference between these two algorithms is that SOM is not able to grow but GSOM grows according to its own growing criterion. Hsu et al. [9], proposed a hierarchical clustering algorithm using multiple layers of GSOM that automatically suggests an appropriate number of clusters that are present in the data.

### 2.1. GSOM algorithm

GSOM is an unsupervised learning algorithm and the basic idea is to:

1. Represent high-dimensional data in a low-dimensional form without losing any of the important features of the data.
2. Organise data on the basis of similarity by grouping objects that are geometrically close to each other.

This makes GSOM popular for visualizing high-dimensional data. Though computationally more expensive than other unsupervised methods, it has proved to be extremely useful with high-dimensional and complex input data.

A GSOM consists of neurons that are usually arranged in a two-dimensional grid with rectangular or hexagonal topology. Each neuron is represented by an n-dimensional weight vector  $m_i = [m_{i1}, m_{i2}, \dots, m_{in}]$ , where, n is equal to the respective dimension of the input vectors. The neurons are connected to adjacent neurons by means of neighbourhood relations.

The GSOM utilizes a competitive learning method [9]. When a training sample is given to the network, its distance to all weight vectors is computed. The best-matching unit (BMU) or winning neuron is the unit whose weight vector possesses greatest similarity with respect to the input sample  $\mathbf{x}$ . The distance measure used to define the similarity is typically Euclidean distance. Thus for each input vector  $\mathbf{x}$ , there exists a winning neuron  $m_b$  with minimum Euclidean distance to input  $\mathbf{x}$ , such that

$$\|\mathbf{x} - m_b\| = \min_i \|\mathbf{x} - m_i\| \quad (1)$$

This is referred to as the competitive learning part of the learning process, since all neurons compete to be the winner. Having found the BMU, the weight vectors of the GSOM are updated. The weight vectors of the BMU and its topological neighbours are moved closer to the input vector from the input space. This phenomenon is illustrated in Figure 1. The magnitude of the change decreases with time and is smaller for neurons physically far away from the BMU.

The update rule for changing the respective weight vectors of unit  $i$  is:

$$m_i(t+1) = m_i(t) + \alpha(t)h_{bi}(t)[x(t) - m_i(t)] \quad (2)$$

where,  $t$  denotes the time step,  $x(t)$  is the input vector chosen from the input data set at time  $t$ ,  $\alpha(t)$  is a monotonically decreasing learning rate, and  $h_{bi}(t)$  the

neighbourhood kernel around the winner unit at time  $t$ . The neighbourhood kernel defines the region of influence that the input sample has on the GSOM. This is called cooperative learning.

Figure 1: Updating the BMU and its neighbors towards the input sample [10]

There are many possible types of neighbourhood functions, the simplest and most commonly used are the following [10]:

- Bubble: In this simplest form it is one for all neurons close enough to BMU and zero for others

- Gaussian:  $e^{-\frac{\|r_b - r_i\|^2}{2\sigma^2(t)}}$

where,  $r_b$  and  $r_i$  are positions of the winning neuron  $b$  and  $i$  respectively, and  $\sigma(t)$  is the neighborhood radius. The learning rule makes the weights of the winning neuron and its neighbours more similar to the input  $x$ . Regardless of the functional form, the neighbourhood function shrinks with time. For each input vector this process is repeated for large number of cycles. The final network associates the output nodes with groups or patterns in the input data set. During the training process a map is built and the neural network organises itself using a competitive process. As the weights of the whole neighborhood are moved in the same direction during the training phase, similar items tend to excite adjacent neurons. Therefore, GSOM forms a semantic map where similar samples are mapped close together and dissimilar apart. An analyst can then evaluate the map with the knowledge of input dataset.

The characteristic feature distinguishing neural maps from other neural network paradigms and regular vector quantisers is the preservation of neighbourhoods. This desirable feature obviously depends on the choice of the output topology. The proper dimensionality of the output space is usually not known a priori, but has to be specified prior to learning in the GSOM algorithm.

GSOM starts with a minimal number of nodes (usually four) and grows new nodes on the boundary based on a heuristic. By using the value called the spread factor (SF), the data analyst has the ability to control the growth of the GSOM. A parameter of growth known as, the growth threshold (GT) is defined as [9]:

$$GT = -D \times \ln(SF) \quad (3)$$

where,  $D$  is the dimensionality of data and SF is the user defined spread factor that takes values between 0 and 1. An SF value close to 0 represents minimum growth and close to 1 represents maximum growth. Note that the outer boundaries of the spread factor (0 and 1) cannot be included since  $\ln(0) = \text{undefined}$ , and  $\ln(1) = 0$  renders the growth threshold meaningless.

The algorithm first identifies the winning node. Then an accumulated error  $E$  (difference between input vector and weight) of the winning node is updated by the following rule:

$$E(t+1) = E(t) + |x - m_b| \quad (4)$$

where,  $x$  is the input vector and  $m_b$  is the weight vector of the winning node. If the winning node is the boundary node and  $E$  exceeds GT, growing is initiated on that node to fill the surrounding unoccupied spaces of the lattice. If  $E$  of the winning node exceeds GT but the winning node is not a boundary node, then  $E$  is propagated outwards to other neighboring nodes. Weights of the new nodes will be initialized according to the following equation [3]:

$$m_{new} = 2m_{winner} - m_{opposite} \quad (5)$$

where  $m_{opposite}$  represents the weight of the node topologically opposite to the new node. If there are no topologically opposite nodes, weights of the new nodes will be calculated according to the following equation:

$$m_{new} = m_{winner} + m_{other1} - m_{other2} \quad (6)$$

where,  $m_{other1}$  and  $m_{other2}$  are weights of the nodes nearest to the new node. For hexagonal topology,

equation (6) is applicable as there will always be a neighbor of the winning node that is topologically on the opposite side of the new node. Growing phenomenon in GSOM is illustrated in Figure 2. New nodes are inserted around the high ‘error node’ (node ‘Error’ in Figure 2), with accumulated error exceeding the predefined growth threshold.

Figure 2: Growth in GSOM: (a) initial state (b) two new nodes and (c) three new nodes

## 2.2. Clustering quality improvement

Main objective of GSOM is to transform high-dimensional data in a low-dimensional cluster maps. However, with complex datasets, it may not be straightforward to obtain a good clustering. It is more applicable for manufacturing datasets, which are considered as complex due to the large number of processes, diverse equipment set, and nonlinear process flows. Manufacturing datasets often comprise of hundreds of process control, process step and quality control data. It might be necessary to change different variables and monitor the change of ‘quality’ of the cluster. This study proposes a clustering quality (CQ) measure, as a benchmark to evaluate the changes in clustering quality with different parameter changes. Mathematically, clustering quality can be expressed as:

$$CQ = \sum_i \max \left\{ \frac{\frac{g_i - G}{n_i - N} * \frac{n_i}{N}, 0 \right\} + \sum_i \max \left\{ \frac{\frac{b_i - B}{n_i - N} * \frac{n_i}{N}, 0 \right\} \quad (7)$$

where,  $B$  is total number of faulty products,  $G$  is total number of good products,  $N$  is total number products ( $B+G$ ),  $b_i$  is number of faulty products in neuron  $i$ ,  $g_i$  is number of good products in neuron  $i$ , and  $n_i =$  number of products in neuron  $i$  ( $b_i + g_i$ ).

A CQ of 1 would mean a perfect separation of good and faulty products and a 0 would mean no separation

at all. This proposed CQ takes the complete cluster map into account and can be generated automatically as an objective quantifier of the programme to separate good and faulty products from the data provided

Many datasets (manufacturing databases for example) are large and complex and may have substantial amounts of noise. Noise reduction from the data is one of the primary conditions for obtaining good clustering. Some datasets may contain many categorical variables, which are comprised of letters or a combination of numbers and letters. These categorical data should be transformed into numerical data to allow their use in data mining programmes. One of the ways to transform categorical data to numerical data is to use the binary convention.

Investigation of sample manufacturing datasets has revealed that there are many categorical variables that do not have any affect on separating good and faulty products. For example, a categorical variable may have an equal distribution among good and faulty products. These variables, when expanded, only add noise to the dataset. To filter out these unnecessary categorical variables, a method is proposed to remove them from the dataset. Mathematically the constraint can be expressed as:

$$FI = \left( \frac{X_{ig}}{N_g} - \frac{X_{if}}{N_f} \right) \leq \alpha \quad (8)$$

where,  $FI$  = Filtration index,  $X_{ig}$  = number of good products having a particular categorical variable,  $X_{if}$  = number of faulty products having a particular categorical variable,  $N_g$  = number of good products in the sample,  $N_f$  = number of faulty products in the sample,  $\alpha$  = user defined constraint limit.

If the Filtration Index for a variable is close to zero, it can be considered that the variable is equally distributed among good and faulty products and hence, should not be considered for analysis. For example, if a dataset has 50 good products and 25 faulty products and among them 10 good products and 5 faulty products have the same variable, then  $FI$  will be  $[(10/50)-(5/25)] = 0$ . As the variable is similarly distributed among the good and faulty products, it will have no effect on clustering. However, it is not expected that a variable would have  $FI$  value exactly zero. In practice, the user has to define the value (or range of values) for  $\alpha$  depending on the characteristics of the dataset. Although the  $FI$  has been proposed for categorical variables, it can similarly be used for numerical variables.

An improved GSOM process taking clustering quality and  $FI$  into consideration is described below:

1. Initialize the weight vectors of the starting nodes (usually four) with random numbers between 0 and 1.
2. Calculate the growth threshold (*GT*) using equation (3)
3. Determine the winning neuron using equation (1).
4. Update the weight vectors of the neighbourhood using equation (2).
5. Calculate error values and if the error of node *i* is greater than *GT*, grow nodes if *i* is a boundary node. Distribute weights to neighbors if *i* is a non-boundary node.
6. Initialize the new node weight vectors to match the neighboring node weights.
7. Repeat steps 3 – 6 until all inputs have been presented and node growth is reduced to a minimum level.
8. Reduce learning rate and fix a small starting neighborhood.
9. Find winner and adapt the weights of the winner and neighbors in the same way as in growing phase.

The GSOM process with clustering quality improvement described above can be summarized as follows. Primary or basic data is first pre-processed. Then the dataset is filtered to remove insensitive variables. If there are some categorical data in the dataset, these are converted to numerical values. Data are then normalized to feed into the GSOM. The quality of the cluster maps are then evaluated using equation (7). If the clustering quality is not acceptable, the dataset is further refined by removing insensitive data. Finally the cluster maps are analyzed and interpreted with the knowledge of the dataset used.

### 3. Results and Discussions

The method proposed has been applied to a complex manufacturing datasets. The results demonstrate the effectiveness of the methodology. Details of the simulation results are described in the following sections.

Recorded manufacturing process data can be used to analyze the performance of a process. However, it is difficult to find the causes of any abnormal output or the factors resulting in lower yield rates [11]. To determine whether GSOM could deal with a complex manufacturing dataset, a simulation has been run with a large dataset obtained from Motorola USA. The

quality problem of the Motorola wafer fabrication process is described in reference [1].

In the context of analysis of manufacturing quality problems, the focus involves two main aspects - separation of good and faulty products and identifying the reason for yield failure. The present study focuses on the first aspect. The challenge is not solely in clustering, but also to obtain a meaningful and adequate number of clusters. With meaningful clusters, grouped in appropriate numbers, identification of the reasons that contribute significantly to the differentiation of clusters should become a simpler task.

The dataset is the historical wafer data collected for 2500 wafers over a 2-month period. The input database measured 133 parameters by 16,381 entries organized into an Excel file. The data consisted of wafer probe data of 39 wafer probe functional tests, process control data (59 numerical electrical PC measurements probed at 8 sites per wafer) and process step data such as material vendor/lot, wafer boat position, etc. A sample of the dataset is shown in Table 1. The second column in the table is the product ID, the 3<sup>rd</sup> column is the product reference number, and columns C1 to X133 are measured parameters. In the original dataset, there are 59 'C' columns (C1-C59), 38 'K' columns (K60-K98), and 34 'X' columns (X99-X133). The reference number in the 3<sup>rd</sup> column identifies which product is good and which product is faulty. Reference numbers above 8750 indicate good products and below 8750 indicate faulty product.

As shown in Table 1, there are many categorical variables especially in the X-columns. This dataset must be converted into a suitable format to use in GSOM. Pre-processing of data includes removal of outliers, transformation of categorical data into numerical values, and normalization. It was found that there are some excessively large values in the dataset and if these are not removed, most of the values will become zero after normalization. After removing the outliers, the categorical data are transformed into binary. Considering the complexity of the dataset, about one quarter of the entries (4000) was considered for simulation purposes.

**Table 1.** Motorola Wafer Manufacturing Data showing dimensionality and layout)

SF(IF $\leq$ 0)	<b>0.1</b>	0.5	0.7	0.8	0.9	<b>0.95</b>
CQ	<b>0.25</b>	0.40	0.45	0.49	0.51	<b>0.52</b>
IF (SF=0.95)	$\leq$ <b>0.05</b>	$\leq$ 0.10	$\leq$ 0.12	$\leq$ 0.13	$\leq$ 0.14	$\leq$ <b>0.15</b>
CQ	<b>0.71</b>	0.76	0.78	0.79	0.80	<b>0.81</b>

**Table 2.** Improvement of Clustering Quality Changing SF and IF

Simulation was run at SF 0.1 first but a very poor (0.25) CQ was obtained. Clustering quality was improved with higher SF but the maximum CQ was only 0.52, obtained at an SF of 0.95. It is thought that the large number of attributes imposed unnecessary noise in the dataset. It may be necessary and of great insight to study the effect of removing several attributes from the input dataset and to check the impact on the generated maps.

The categorical data from the dataset were reduced using equation (8). First using the constraint  $IF \leq 0.05$ , 163 categorical variables were deleted and the simulation was rerun. A significantly higher CQ of 0.71 was achieved. To test further, more categorical variables were deleted. Using  $IF \leq 0.15$  a CQ of 0.81 was achieved. As further deletion of variables did not produce any more significant improvement, no further deletion was done. Moreover, if many variables are deleted, some important features may be lost. A summary of the results is presented in

Table 2 and a cluster map of SF=0.95 and  $IF \leq 0.15$  is presented in Figure 3.

Although higher clustering quality is desired, it may not be possible to obtain high CQ with complex manufacturing data as 100% separation of all good and faulty products is not possible. For example, consider that the desired dimension of a product is 10mm. If the dimension of the finished product is 11mm it will be considered a failure and if the dimension of final product is 15mm it is also a failure but certainly different to the previous failure. It cannot be expected that all products with a dimension 10mm (plus

tolerance) be clustered in one group and the rest will be grouped in another cluster. There will certainly be some mixing. In practice, some clusters with 100% good and faulty products and the rest of the clusters with majority either good or faulty products are expected. In this study some clusters with 100% good and faulty products were obtained and other clusters either contained majority of good products or faulty products.

#### 4. Conclusions

The proposed methodology is a significant contribution

to the data mining techniques available, especially in dealing with complex manufacturing datasets. The GSOM algorithm has been proven to be an efficient algorithm to analyze unsupervised DNA data. However, it produced unsatisfactory clustering when used on manufacturing data. Moreover, there was no benchmark to monitor improvement in clustering. The present study has proposed methods to evaluate quality of the clusters produced by GSOM and to remove insignificant variables from the dataset. With the proposed modifications, significant improvement in unsupervised clustering was achieved with simple as well as complex manufacturing data. Possible further improvement in cluster analysis may be achieved by applying evolutionary optimization algorithms.

For manufacturing data, the objective is not limited to finding the separation of good and faulty

products. The main objective is to find the underlying reason for poor yield. To discover this, it is necessary

to create clusters of good and faulty products, as has been done in this study. The technique is being extended to model the failure causes of the lower yielding products.

### Abstract

*Cancer is the top most death threat for human life all over the world. Current research in the cancer area is still struggling to provide better support to a cancer patient. In this research our aim is to identify the significant risk factors for particular types of cancer. First, we constructed a risk factor data set through an extensive literature review of bladder, breast, cervical, lung, prostate and skin cancer. We further employed three association rule mining algorithms, Apriori, Predictive apriori and Tertius algorithm in order to discover most significant risk factors for particular types of cancer. Discovery risk factor has been identified to shows highest confidence values. We concluded that apriori indicates to be the best association rule-mining algorithm for significant risk factor discovery.*

### 1. Introduction

Cancer is the one of the most common cause of death all over the world. Furthermore, in Australia, United States and the United Kingdom, breast cancer is the second leading cause of death [1]. Research shows that most of the cancers are not detected in the early stage-resulting in high death rates. Medical practitioner diagnostic systems (mammography, biopsies, ultrasound, etc) can takes a long time to inform the patient about the cancer status, thus early cancer prevention could save human life. The aim of this research is to find out the different cancer risk factors using modern machine learning techniques. We consider bladder, breast, cervical, lung, prostrate and skin cancer in this research. Association Rule Mining (ARM), a particular method of machine learning technique could prove to have great potential within the medical domain identifying responsible factors

for a specific disease. The ARM technique has been considered as a tool for our research.

The use of association rules on medical data records with heart perfusion measurements is explored for the first time in [2]. Discovering association rules on segmented images is studied in [3]. Another study use association rule mining algorithm to study associations of different female hormones with the occurrence of breast cancer and also bench mark the performance of artificial neural networks (ANN) and data envelopment analysis (DEA) against the standard parametric Fisher's linear discriminant analysis (FLDA) technique [4]. Ho et al presented an induction data mining approach in order to predict cervical cancer by using a combination of demographic, environmental and genetic factors. They examined the risk factors for cervical cancer using a combination of logistic regression and a decision tree algorithm, and reported the relationship among demographic, environmental and genetic factors for cervical cancer using induction technique. In addition, to the induction technique, they compared logistic regression and the decision tree algorithm, and present the practical use of rule induction for the management of cervical cancer [5]. Their emphasis was on a specific cancer with several limitations to their research. One being the limited access to data, relying on one single source subjecting themselves to bias in an otherwise potentially data rich subject group its. Sufficient validation for the generalization of their findings to other geographic areas or groups was not performed. The other limitation was the lack of input variables for patient characteristics, such as exercise behaviour, nutrition, stress, and depression. Further study limitations also included a low sensitivity for the logistic regression and Chi-squared Automatic Interaction Detection (CHAID) algorithm. An association rule mining algorithm was applied to

extract associations between the selected socioeconomic variables and the colorectal, lung, breast, and prostate cancers mortality from 1988 to 1992 cancer mortality rates in United States [6]. Geographic information system technology is used for data integration which is defined at different spatial resolutions, and to visualize and analyze the results from the association rule mining process. This study provided the emphasis on mortality rates. We failed to find a single study which was able to demonstrate on the significant risk factor for a specific cancer. We therefore, decided to contribute towards cancer risk factor issue through this research.

To the best of our knowledge, this is the first risk factor extraction research using association rule mining algorithms. Our paper is organized as follows: section two will explain the problem description. Data collection evidence is described in section three. The association rule mining algorithm is summarized in section four. In section five, we publish our experimental finding concluding in section six

## 2.0 Problem Descriptions

We initially we considered bladder, breast, cervical, lung, prostate and skin cancer oriented risk factors. This section will summarize each problem definition and its significance.

### 2.1 Bladder Cancer

Bladder cancer is a cancer where abnormal cells multiply without control in the bladder. In most of the cases bladder cancer begins in cells lining of the bladder and is called urothelial cell or transitional cell carcinoma (UCC or TCC). If the bladder cancer that is only in the lining is called *superficial bladder cancer*, and if the cancer spreads into the muscle wall of the bladder, it is called *invasive bladder cancer* [7]. The American Cancer Society estimates that in the United States there will be about 68,810 new cases of bladder cancer diagnosed in 2008 (about 51,230 men and 17,580 women). The chance of a man developing this at any time during his life is about 1 in 27 and for a woman, 1 in 85. In 2008, there will also be about 14,100 deaths from bladder cancer in the United States (about 9,950 men and 4,150 women) [8]. The cancer affected bladder is presented in Figure 1.

Figure 1. Affected cancer bladder shows by circle. (Source: [http://www.ecureme.com/emyhealth/data/Bladder\\_Cancer.asp](http://www.ecureme.com/emyhealth/data/Bladder_Cancer.asp).)

### 2.2 Breast cancer

Breast cancer is the combination of more than 100 different diseases. Breast cancer develops while some of the cells in the breast begin to grow out of control. Cancerous growth begins to appear anywhere inside the breast. Most breast cancers starts in the lining of the ducts though a small number can start in the milk sacs. In time if not treated properly, cancer cells from the breast can spread to other parts of the body [8]. One in eight Australian women will develop breast cancer before the age of 85. In Australia, about 12,000 women and 84 men were diagnosed with breast cancer in 2002. In 2005, breast cancer caused 502,000 deaths worldwide (7% of cancer deaths; almost 1% of all deaths). It is predicted that by 2011, the number of new diagnoses will increase to about 14,800 women and 122 men [7]. The cancer affected breast is presented in Figure 2.

Figure 2. Normal breast with lobular carcinoma in situ (LCIS) in an enlarged cross-section of the lobule. **Breast profile:** A ducts, B lobules, C dilated section of duct to hold milk, D nipple, E fat, F pectoralis major muscle, G chest wall/rib cage. **Enlargement:** A normal duct cells, B

ductal cancer cells, **C** basement membrane, **D** lumen (center of duct). ([http://www.cancer.org/docroot/CRI/content/CRI\\_2\\_2\\_1X\\_What\\_is\\_breast\\_cancer\\_5.asp?sitearea=](http://www.cancer.org/docroot/CRI/content/CRI_2_2_1X_What_is_breast_cancer_5.asp?sitearea=))

### 2.3 Cervical

Cervical cancer is a type of cancer that starts in the cervix (part of the female reproductive systems), the lower part of the uterus (womb) that opens at the top of the vagina. Most of the time, early cervical cancer has no symptoms. Cervical cancer is divided into two stages; early or pre-invasive stage, and the late or invasive stage. Cervical cancer is a major worldwide health problem with incidence and mortality rates second only to breast cancer. It is the number one killer of young women in under developed countries. In Korean women for example, cervical cancer is the third most common form of cancer, after stomach and breast cancer [9]. The affected cervical cancer is presented in Figure 3.

Figure 3. Cervical cancer, ( Source: [http://www.righthealth.com/Health/Cervical\\_Cancer\\_Pictures/-od-definition\\_adam\\_2%25252F9163-s](http://www.righthealth.com/Health/Cervical_Cancer_Pictures/-od-definition_adam_2%25252F9163-s))

### 2.4 Lung cancer

There are different types of lung cancer, depending on which cells are affected. The lungs are made up with three right lobes and two left lobes. As soon as we breathe, air goes through the nose, down the windpipe (trachea), and into the lungs where it spreads through tubes called bronchi. The majority of lung cancer begins in the cells that line these tubes [7]. Statistics shows that for both men and women people die from lung cancer more often than any other type of cancer. In 2004 lung cancer accounted for more deaths than breast cancer, prostate cancer, and colon cancer combined. In that year, 108,355 men and 87,897 women were diagnosed with

lung cancer, and 9,575 men and 68,431 women died from lung cancer. During 2008, there will be about 215,020 new cases of lung cancer (114,690 among men and 100,330 among women) [8]. The cancer affected lung is shown in Figure 4.

Figure 4. Lung cancer. (Source: <http://search.live.com/images/>)

### 2.5 Prostate cancer

The cancer which originates in the prostate with an uncontrolled (malignant) growth of cells in the prostate gland which is located at the base of the urinary bladder and is responsible for helping control urination as well as forming part of the semen. It is a common malignancy in men older than 50 years of old and it may cause no symptoms in the early stage. Prostate cancer may remain in the prostate gland or may spread to nearby lymph nodes to other parts of the body. It is a second leading cause of death of males in the U.S.A. In Australia one in nine males affects for prostate cancer at the age of 75 years and one on five by the age 85 years. The death rate of prostate cancer is lower which is one in 84 men under the age of 75 years and one in 22 by the age of 85 years [10]. The prostate cancer is shown in Figure 5.

Figure 5. Prostate cancer. (Source, <http://health.allrefer.com/pictures-images/prostate-cancer.html>)

## 2.6 Skin cancer

Skin cancer is the most common form of cancer which estimated that over 1 million new cases occur annually. Skin cancer occurs in the outer layers of your skin. Each year the annual rates of all forms of skin cancer are increasing, representing a growing public concern. Research estimated that nearly half of all Americans who live to age 65 will develop skin cancer at least once ([www.cpaaindia.org](http://www.cpaaindia.org)). The affected skin cancer is shown in Figure 6.

Figure 6. Skin cancer. (Source: <http://www.taconichills.k12.ny.us/webquests/noncomdisease/skin%20cancerpic.jpg>)

## 3.0 Data Collection

We constructed a risk factor data set containing  $n$  from patient records  $M = \{m_1, m_2, \dots, m_n\}$  with categorical attributes. All attributes are uniformly treated as categorical to simplify the problem. Due to lack of space the sources of data are not available here. All the data are available upon request.

## 4.0 Association Rule Mining

In this section we introduce the standard definition of association learning [11,12]. An association rule is a simple rule, such as:

Smoking  $\cap$  family\_history\_positive  $\Rightarrow$  lung\_cancer

Where ‘Smoking  $\cap$  family\_history\_positive’ is called the body rule and lung\_cancer the head of the rule. It associates the rule body with its head.

In context of medical data, our example expresses the fact that people who are smoking and past family history have lung cancer are likely to have risk of lung cancer. This association rule makes no assertion about people who are not getting skin or breast cancer.

Let  $D$  be a database consisting of one table over  $n$  attributes  $\{a_1, a_2, \dots, a_n\}$  and the table contain  $k$  instances. In the following an attribute-value-pair will be called an item. An item set is a set of distinct attribute-value-pairs. For instance, smoking, family\_history\_positive, lung\_cancer and so on.

Let  $d$  be a database record and it satisfies an item set  $X \subseteq \{a_1, a_2, \dots, a_n\}$  if  $X \subseteq d$ . An association rule is an implication  $X \rightarrow Y$  where  $X, Y \subseteq \{a_1, a_2, \dots, a_n\}$ ,  $Y \neq \emptyset$ ; and  $X \cap Y = \emptyset$ .

The *support* ( $s$ ) and *confidence* ( $c$ ) are two measures of rule interestingness that reflect usefulness and certainty of a rule respectively. The association rules that satisfy user specified minimum support threshold (*minSup*) and minimum confidence threshold (*minCon*) are called strong association rules. The formulations of support and confidence measure are as follows:

Support ( $X \rightarrow Y$ ) =  $P(X \cap Y)$

Confidence ( $X \rightarrow Y$ ) =  $P(Y|X) = \frac{P(X \cap Y)}{P(X)}$

where  $P$  is used for probability measure in support and conditional probability in confidence. A probabilistic interpretation of support and confidence is discussed in [13]. Another rule measure metric called lift, defined as

$$\text{Lift}(X \rightarrow Y) = \frac{P(X \cap Y)}{P(X)P(Y)}$$

Lift quantifies the relationship between  $X$  and  $Y$ . Basically, a lift value greater than 1 provides strong evidence that  $X$  and  $Y$  depend on each other. A lift value below 1 state  $X$  depends on the absence of  $Y$  or vice versa.

The task for association rule mining can be divided into two folds:

- Find all combinations of the risk factors for a specific cancer whose supports are greater than a user-specified minimum support (threshold).
- Use the risk factors from frequent risk factors to generate the desired rules. Generally the confidence of each rule is computed, and if it is above the confidence threshold, the retrieve the rule in the system.

Among the long list of association learning algorithms Apriori [11], Predictive Apriori [14], Tertius [15] are most popular algorithms in the machine learning community. The Apriori algorithm is a state of the art algorithm most of the association rule algorithms are somewhat variations of this algorithm [11].

## 5.0 Experimental Results

We considered three association rule mining algorithms: Apriori, Predictive Apriori and Tertius for our experiment. We found among these three algorithms Apriori to be the number one choice to extract useful rules for our cancer data set. The reputed rules were selected based on confidence and lift measure. All the reported rules obtained confidence 1. However, in the lift measure all types of cancer discussed in this paper show a stable performance except prostate cancer as shown in Figure 7. The breast data-set shows the highest lift values, while on the other hand skin cancer showed the worst lift values.

**Figure 7.** Lift performances measures with Apriori association rule mining algorithm for six types of cancer problems.

Moreover we verified Apriori performance with leverage measures as shown in Figure 8. Similar to lift measures we found all other types of cancers suggested similar steady performance, except prostate cancer. The most reliable performance was shown with the skin type cancer data-set while breast cancer data demonstrated the worst performance in the leverage measure.

**Figure 8.** Leverage performances measures with Apriori association rule mining algorithm for six types of cancer problems.

Finally we compared the apriori performance with conviction measures as shown in Figure 9. We found similar steady performances for all the cancer data set except prostate cancer, showing the highest performance. On the other hand again the breast cancer data set showed the worst performance.

**Figure 9.** Conviction performances measures with Apriori association rule mining algorithm for six cancer types' problems.

We therefore concluded a rule for each cancer dataset and summarized as below. All the rules were shown highest confidence. We found the breast and prostate cancer rules are very simple. Whereas rest of the rules contained several significant risk factors to predict an appropriate cancer.

**Relation: bladder**

**Rule:** (work\_exposure  $\cap$  work\_leather\_industry  $\cap$  work\_rubber\_industry  $\cap$  work\_cable\_industry  $\cap$  work\_printing\_industry)  $\Rightarrow$  bladder\_cancer

**Relation: breast**

**Rule:** (gender (female)  $\cap$  age(>40)  $\cap$  family\_history)  $\Rightarrow$  breast\_cancer

**Relation: cervical**

**Rule:** (poor\_hygienic\_practices  $\cap$  low\_socioeconomic\_status  $\cap$  low\_vegetables  $\cap$  sexually\_transmitted\_infections,smoking)  $\Rightarrow$  cervical\_cancer

**Relation: lung**

**Rule:** (chemical\_exposure  $\cap$  smoking  $\cap$  previous\_lung\_disease  $\cap$  urban\_residence  $\cap$  family\_history)  $\Rightarrow$  cervical\_cancer

**Relation: prostate**

**Rule:** (family\_history  $\cap$  age (>50))  $\Rightarrow$  prostate\_cancer

**Relation: skin**

**Rule:** (weak\_immune\_system  $\cap$  fragile\_skin  $\cap$  exposure\_to\_environmental\_hazards  $\cap$  previous\_skin\_cancer)  $\Rightarrow$  skin\_cancer

All the generated rules demonstrated high confidence. Thus, we conclude that these rules are highly acceptable. Comparatively breast and prostate cancer showed shorter rules comparing other cancer. This research argues to consider more risk factors to be considered in the experimental dataset for both breast and prostate cancer to extract most significant risk factors.

## 6.0 Conclusions

This study has demonstrated the use of association rule mining to identify some specific risk factors for a particular cancer problem. In this research we employed three types of association rule mining algorithms to extract significant risk factor for a specific cancer. Finally we suggested in our research to use Apriori algorithm for such type of task. All the generated rules were showing highest confidence level in our experiment.

We aim to extend this research by considering more risk factors in the raw data-set for each cancer problem, in order for association rule mining algorithm to extract more useful and significant risk factors for a particular type of cancer.

## **Secure Multi-party Computation: Problems, Techniques and Applications for Privacy-Preserving Data Mining**

Dr. Durgesh Kumar Mishra

Professor (CSE) and Dean (R&D), Secretary IEEE MP-Subsection,  
Acropolis Institute of Technology and Research, Indore, MP, India,  
[durgeshmishra@ieee.org](mailto:durgeshmishra@ieee.org), [dkmishra@acropolis.in](mailto:dkmishra@acropolis.in)

### **ABSTRACT**

Consider a set of parties who do not have trust in each other, nor in the channel by which they communicate. Even then the parties wish to correctly compute some common function of their local inputs, while keeping their local data secure from others. This, in a nutshell, is the problem of secure multi-party computation (SMC). This problem is fundamentally in cryptography and in the study of distributed computations. It takes many different forms depending on the underlying network, on the function to be computed, and on the amount of distrust the parties have in each others and in the network.

In this tutorial, we present several aspects of secure multi-party computation. We first present the definition of this problem in various situations. Our definition is drawn from the previous idea and formulations, and incorporate aspects that were previously overlooked. We also present several problems associated with SMC.

Next we show the problem of hiding the data from trusted third party (TTP) which computes the result. We present the existing solutions of SMC along with the protocols developed by us. First, we have introduced an anonymizer between the parties and the TTP to hide the data. In this case each party is having its own anonymizer and the entire data of a party goes through a single anonymizer. Keeping in mind the anonymizer may become malicious so we have chosen a particular anonymizer randomly to transfer the data. Apart from the randomly selection of anonymizer, the party will divide the data into number of packets and then send to different anonymizer so that the entire data will not reach to a single anonymizer and the privacy of individual will be maintained.

Next we present another problem, which enables the SMC to perform the correct computation of the result as well as the authentication of computational body. We have introduced multiple TTPs instead of a single one. If there is only one TTP then its behavior can be suspicious. Using this multiple TTP concepts we have the option to choose a TTP from domain of TTPs for computation. In this method we divide the data in several packets and these packets are sent to multiple TTPs and a randomly selected master TTP will perform the computation after accumulating data from other TTPs. In effect no body knows where computation will be performed till the last moment and thus problem of security is solved. For the authentication of TTP, we have introduced the concepts of equivalence classes. With the help of this concept we remove the malicious TTP from the system for further computation.

Finally, we present the problem of dealing with adversaries in SMC and minimizing their effects. We investigate the power of adversaries in several situations. In particular, we show how to construct a secure protocol for computing any function, where the communication channels can be tapped by the adversary, and secure communication is achieved by cryptographic primitives based on the computational limitations of the adversary.
